To the memory of
Abraham S. Aminoff,
my father and friend,

and

to my wife, Jan,
and our three children,
Alexandra, Jonathan, and Anthony
for the happiness they have brought me

Michael J. Aminoff

To my loving and supportive family,
who always provides
such happiness and joy

Preface to the Sixth Edition

More than 30 years have elapsed since the first edition of this book was published in 1989. Over this time, clinical medicine has evolved dramatically, prompted by advances in technology and molecular biology. Many diseases have come to be understood at a more fundamental level than previously. Based on genomics and other factors, disease prediction and treatment are becoming tailored more precisely to the individual patient—so-called "personalized medicine"—as is already apparent in the management of certain cancers. It has been suggested that a simple genetic test or a cheap imaging technique may eventually make clinical consultation redundant. In the face of such complexity, however, the role of the consultant is, in some ways, more important than before. Clinical medicine is not the exact science that some imagine it to be, and doctor–patient interactions remain as important as ever.

Recent advances and a daunting expansion of the published literature have led to increasing specialization and subspecialization in every branch of medicine, and it is more difficult than ever for physicians to keep abreast of developments in more than their own field. Nevertheless, specialists need to know when to collaborate and communicate with other specialists, and thus require a good fund of general medical knowledge and the ability to recognize what they do not know.

Earlier editions of this book received a wide and generous acceptance, but the changes that have occurred in the field in the last few years have emphasized the need for a new edition. The aim of the book, however, remains the same as previously—to define both the neurologic aspects of general medical disorders and the general medical and other implications of various neurologic diseases. The book therefore provides an account of clinical neurology from a different perspective than many other textbooks and serves as an interface between neurology and the other medical specialties. This interface is important. Many patients with neurologic disorders are elderly and inevitably have other co-existing disorders. Furthermore, many medical disorders have neurologic complications or manifestations. Thus, gluten sensitivity, for example, may have both neurologic and gastrointestinal consequences, and a stroke may occur as a complication of cardiac, infective, inflammatory, or hematologic disorders. Moreover, the treatment of a general medical disorder may have neurologic consequences, as exemplified by the peripheral neuropathy that may follow the use of certain drugs. General medical disorders, in turn, are influenced by neurologic disease, as when the inability to wean a critically ill patient from a ventilator reflects an underlying critical illness neuropathy, and respiratory tract infections may affect the management of diverse neurologic diseases such as myasthenia gravis, multiple sclerosis, and epilepsy.

We hope that the contents of the book will be helpful to all clinicians, but the volume is aimed especially at neurologists, internists, hospitalists, and primary healthcare providers. We believe that it will help neurologists to appreciate the implications of the general medical issues facing their patients and how these might best be managed, and that it will aid internists, family practitioners, and other physicians to gain further understanding of their patients' neurologic disorders and thereby improve patient care. It should appeal to both junior and senior physicians, serving as a guide to the former as they complete their training and hone their clinical skills, and as a reference work summarizing clinical developments and advances for more experienced physicians, who must engage in lifelong learning in order to maintain the highest standards of clinical care.

We are grateful to our contributors, acknowledged experts in their respective fields, for taking the time to update and—in some cases—extensively rewrite their chapters or provide a completely new offering. Some have contributed to the book from its very inception or for several editions, while others are more recent or new contributors. All of them have been most gracious and patient with us as we reminded them of deadlines and made various requests of them. Inevitably time has taken its toll and some of our previous authors have had to be replaced because of retirement or ill-health. We appreciate all their past support in making this book a valued contribution to the medical literature, thank them for their contributions, and wish them well.

In preparing the present edition, one of the most difficult decisions that we made was to limit the size of the bibliography of individual chapters in order to keep the book to a manageable size. Beliefs or observations once challenged but now incorporated into the general body of knowledge do not need referencing. For those of our readers requiring more detailed bibliographic information, however, references to the older literature are provided in earlier editions of this book and new work is readily found on the Internet. In addition to appearing in print form, the book is also published electronically, which should make it more easily and widely accessible and facilitate searches for specific information.

As in the past, our families provided constant support and encouragement as we saw the book through to publication, and we are indebted to them. As mentioned in the prefaces to earlier editions, this book has particular family significance to one of us (MJA). My wife, Jan, shouldered many extra burdens to ensure that I had time to work uninterrupted on this new edition, and I cannot thank her enough for her love, help, and support. When the first edition was published in 1989, our children were in school or preschool. They have grown up with the book. Alexandra, our eldest, is now a pediatric rheumatologist at the Kaiser Permanente Oakland Medical Center. I have gained much in discussing clinical cases with her, and she has been wonderful in helping my wife and I as we sheltered in place during the COVID-19 pandemic that began while this volume was in production. Our two sons are lawyers—Jonathan is a federal defense attorney in Los Angeles, while Anthony is a trial attorney in the criminal division at the Department of Justice in Washington, DC. I have enjoyed debating issues with them and delight in their enthusiasm and intellectual prowess. Throughout the pandemic, our family has held regular zoom meetings that are the highlight of our week and through which the progress of the book has been followed.

We are grateful to a number of people at Elsevier, our publisher, for their help and especially to Ms. Melanie Tucker and Ms. Tracy Tufaga for unfailing assistance in the development of this book, and to Ms. Kiruthika Govindaraju, project manager, for seeing the volume through the production process. Some of the illustrations in the book are taken from previously published sources, as is acknowledged in the figure legends, and we are grateful for permission to reproduce them here.

Michael J. Aminoff MD, DSc, FRCP
S. Andrew Josephson MD

Preface to the First Edition

The increasing sophistication and complexity of modern medicine have led to greater specialization among practitioners and to more restricted communication between physicians in different disciplines. Perhaps, inevitably, this trend has created certain major problems. These difficulties are particularly well exemplified by the relationship between neurology and general medicine.

For non-neurologists, evaluation of patients with neurologic symptoms and signs has always been difficult because of the complexity of the anatomy and physiology of the nervous system and frustrating because the therapeutic options have seemed somewhat limited. Nevertheless, a number of neurologic diseases are exacerbated by, or occur as specific complications of, general medical disorders. Appropriate management of these neurologic disturbances requires their early recognition and an appreciation of their prognosis. It is equally important to recognize the manner in which such neurologic disorders may influence the management of the primary or co-existing medical condition, as well as the manner in which systemic complications of neurologic disorders may require somewhat different management than when these complications occur in other settings.

For neurologists, who are being asked increasingly to evaluate neurologic disturbances presenting in the context of other medical disorders, the difficulty is equally apparent. The general background of cases is frequently confusing, the relationship of the neurologic to the other medical problems is commonly not appreciated, and the manner in which treatment needs to be “tailored” to the specific clinical context is often not clear. Furthermore, neurologic disturbances may themselves be the presenting feature of general medical disorders or lead to general medical complications requiring speedy recognition and effective management.

I hope that the present volume will appeal to both neurologists and physicians in other specialties by providing a guide to the neurologic aspects of general medical disorders and to some of the medical complications of certain neurologic diseases. It is not intended to be a textbook of neurology, but rather a “bridge” between neurology and the other medical specialties.

It is a pleasure to acknowledge the help that I received from various people in developing this book. I am grateful to the various contributors, who devoted a great deal of time and energy to reviewing developments in their own fields of interest and showed considerable tolerance of the many demands that I made upon them. I am grateful also to Mr. Robert Hurley and Ms. Margot Otway at Churchill Livingstone for their help and advice during the preparation of this book. Finally, the support and encouragement of my wife, Jan, and of our children, Alexandra, Jonathan, and Anthony, did much to ease the burden involved in seeing this volume to its conclusion.

Michael J. Aminoff MD, DSc, FRCP

CONCLUDING COMMENTS

Respiration involves pulmonary ventilation, gaseous exchange between lung alveoli and blood, and transport of oxygen and carbon dioxide between the blood, tissues, and interstitial fluids. The nervous system plays a pivotal role in controlling pulmonary ventilation as it exerts both automatic and

voluntary control over breathing. The anatomic pathways involve the cerebral hemispheres, pons, medulla, spinal cord, anterior horn cells, nerves, and neuromuscular junctions, as well as peripheral chemoreceptors and lung mechanoreceptors and the respiratory muscles themselves. Several central and peripheral neurologic disorders can affect respiration adversely, and hypoxia and hypercapnia resulting from respiratory dysfunction may affect the nervous system and produce neurologic complications.

PHYSIOLOGY OF BREATHING

Breathing is a predominantly involuntary, rhythmic phenomenon that can be overridden by voluntary control. Although the pathways for automatic and voluntary breathing are anatomically separate, they demonstrate significant functional integration (Fig. 1-1).

Respiratory Rhythm Pattern Generators

The respiratory rhythm originates in the medulla and neuronal activity in the brainstem can be divided into inspiratory, postinspiratory, and preinspiratory (or late expiratory) neural activities. Two main groups of neurons in the medulla are implicated in the regulation of respiration, namely the dorsal respiratory group (DRG) and the ventral respiratory group (VRG). The DRG is thought to be activated prior to inspiration, and the VRG is considered to modulate expiration. *N*-methyl-D-aspartate (NMDA) receptors are the major mediators of VRG ventilatory drive, with modulation by non-NMDA glutamate systems. In addition, recent studies have identified several other respiratory pattern generators (RPGs) in the medulla.[1] Among these, the pre-Bötzinger complex is considered to be the primary RPG that provides the inspiratory rhythm, and the retrotrapezoid nucleus and parafacial respiratory group, which contain chemosensitive neurons, are thought to provide rhythmic expiratory drive by producing tonic excitation to the pre-Bötzinger and Bötzinger complexes. In addition, located rostrally in the pons, the pneumotaxic center, comprised of the Kölliker-Fuse and parabrachial nuclei, are suggested to be the relay nuclei for reflex and higher-order control of breathing. The Kölliker-Fuse nuclei are also crucial for transition from inspiration to expiration and for modulation of airway patency during breathing. Overall, respiratory rhythm generation is controlled by multiple factors including noradrenergic, serotonergic, peptidergic, and cholinergic neurons.

Control of Breathing

The control of breathing occurs at multiple levels of the respiratory system through a negative feedback system that ensures precise control of arterial PO_2, PCO_2, and pH.[1] This homeostasis is maintained by an integration of chemical, metabolic, and mechanical inputs and adjusting the ventilatory output to meet the metabolic demands (Fig. 1-1).

CHEMICAL CONTROL OF BREATHING

Peripheral and central chemoreceptors monitor afferent inputs (arterial PO_2 and PCO_2). The central chemoreceptors modulate respiration based on changes in CO_2/pH detected in the brain, whereas the peripheral chemoreceptors, which act faster, sense changes in the periphery.

Central chemoreceptor sites are responsible for approximately two-thirds of the ventilatory response to CO_2/pH. Eight major central chemoreceptor sites have been reported and these are distributed throughout the lower brainstem.[1] Peripheral chemoreceptors are located in the carotid body, bifurcation of the carotid artery, and the arch of the aorta. The carotid bodies are the major chemoreceptor sites for hypoxia and are very sensitive to changes in partial pressure of arterial oxygen (PaO_2), arterial carbon dioxide ($PaCO_2$), and H^+. Peripheral and central chemoreceptors are anatomically linked, and this interdependence determines the normal respiratory drive in eupneic and hypoxic conditions. Carotid bodies have been shown to exert a tonic drive on the output of central chemoreceptors, and the magnitude of sensory input from the carotid chemoreceptor is known to influence the central chemoreceptor response.

MECHANICAL INPUTS FROM AIRWAYS, LUNGS, AND CHEST WALL

Inputs from the chest wall and respiratory muscles predominantly affect the pattern of breathing and are most evident when there is an increased

ventilatory demand. Respiratory muscles play a significant role in respiration by aiding in the expansion and contraction of the thoracic cavity. The main inspiratory muscles include the diaphragm, external intercostal and scalene muscles, with accessory inspiratory muscles being the sternocleidomastoid, pectoralis major and minor, serratus anterior, latissimus dorsi, and serratus posterior superior. The expiratory muscles are the internal intercostals, external oblique, internal oblique, rectus abdominis, transverse abdominis, and serratus posterior inferior. Muscles of the upper airway do not have a direct action on the chest cage or intrathoracic volume, but are crucial to keep the airway open during inspiration, regulate airway resistance, and partition airflow through nasal and oral pathways. These are muscles of the soft palate, pharynx, larynx, trachea, nose, and mouth, and are innervated by cranial nerves V, VII, IX, X, and XII. At the level of airways, the Hering–Breuer reflex, which is elicited by inflation of slow-adapting pulmonary stretch receptors, causes inhibition of inspiratory effort following stretching of the airway. In addition, the laryngeal chemoreflex, which produces reflexive central apnea, bradycardia, and glottis closure on exposure of the laryngeal mucosa to acidic or organic stimuli, plays a protective role. However, this reflex has been considered to play a role in the pathogenesis of sudden infant death syndrome.[1]

VOLUNTARY CONTROL OF BREATHING

Voluntary control of breathing is mediated by the descending corticospinal tract and its influence on the motor neurons innervating the diaphragm and intercostal muscles. The rate and rhythm of breathing are influenced by the forebrain, as observed during voluntary hyperventilation or breath-holding, as well as during the semivoluntary or involuntary rhythmic alterations in ventilatory pattern that are required during speech, singing, laughing, and crying.

Electrophysiologic and imaging studies have shown that specific areas of cortex are involved in different phases of voluntary breathing. The diaphragm can be activated by stimulation of the contralateral motor cortex using transcranial magnetic stimulation. The diaphragm lacks significant bilateral cortical representation, consistent with the finding of attenuation of diaphragmatic excursion only on the hemiplegic side in patients with hemispheric stroke, and intercostal muscles are similarly affected by hemispheric lesions. Positron emission tomographic studies have shown an increase in cerebral blood flow in the primary motor cortex bilaterally, the right supplementary motor cortex, and the ventrolateral thalamus during inspiration; and the same structures, along with the cerebellum, are involved in expiration.

The involvement of the forebrain in the regulation of breathing is further substantiated by the induction of apnea that follows stimulation of the anterior portion of the hippocampal gyrus, the ventral and medial surfaces of the temporal lobe, and the anterior portion of the insula.

Factors Influencing the Control of Breathing

Several factors including but not limited to sleep, cerebrovascular responsiveness, age, sex, and genetic factors influence the control of breathing.[1]

Sleep

During sleep, owing to the loss of wakefulness stimuli, breathing is entirely dependent on stimuli from chemoreceptors and mechanoreceptors. Transient central apnea and breathing instability can frequently occur during the transition from wakefulness to sleep. During nonrapid eye movement (NREM) sleep, loss of the wakefulness drive to breathe renders respiration highly dependent on metabolic and chemical influences, particularly $PaCO_2$. During REM sleep, respiratory control is insensitive to changes in $PaCO_2$, and is predominantly under behavioral control. Owing to this, central sleep apnea (CSA) is relatively uncommon in REM compared to NREM sleep. Due to the increased ventilatory motor output and reduced chemosensitivity, the hypercapnic and hypoxic ventilatory drive are blunted in REM sleep.

Cerebrovascular Responsiveness

Cerebrovascular responsiveness to CO_2 is a crucial determinant of hypercapnic ventilatory response and eupneic ventilation. A reduction in cerebral blood flow results in accumulation of CO_2 which stimulates the medulla, whereas an increase in blood flow depresses ventilation owing to a rapid removal of CO_2. Hence, alteration in blood flow lead to variations in cerebrovascular responsiveness to CO_2 which may contribute to respiratory abnormalities.

Age

Older adults are more prone to sleep apnea because cerebral blood flow regulation and cerebrovascular responsiveness are reduced in them, and sleep state oscillations may precipitate apnea. Transient instability in breathing and central apnea may often occur during transitions from wakefulness to NREM sleep. As sleep oscillates between the above-mentioned states, $PaCO_2$ is at or below the apneic threshold, that is, the level required to maintain rhythmic ventilation during sleep, and this results in central apnea. Recovery from this is associated with transient hyperventilation and wakefulness.

Sex

Experimental evidence has suggested a role of sex hormones in alteration of the hypocapnic apneic threshold during sleep, and women have been reported to be less susceptible than men to develop hypocapnic central apnea during NREM sleep.

Genetic Factors

A significant number of transcription factors are known to play a role in the control of breathing. The most clinically relevant is the *PHOX2B*, which is involved in the development of the retrotrapezoid nucleus, and mutations of this gene have been documented to produce congenital central hypoventilation syndrome.[1]

EVALUATION OF PULMONARY FUNCTION

A detailed discussion of the evaluation of pulmonary function is beyond the scope of this chapter.

The following is a summary of an approach to evaluating patients with impaired breathing in the setting of neurologic illness. The onset, distribution, character, and accompaniments of weakness may suggest the underlying cause. History obtained from a bed-partner or caregiver is important in determining the presence of sleep-disordered breathing.

Clinical Assessment

A detailed clinical history should be obtained and importance paid to any history of breathing or cardiac problems. The time of onset and temporal relationship to neurologic symptoms should be ascertained. Furthermore, the presence of any illness (such as infections) that may have preceded the onset of muscle weakness (e.g., in Guillain–Barré syndrome) should be recorded.

The respiratory and cardiac systems are examined to determine the respiratory rate and volume, pattern of breathing, heart rate, blood pressure, temperature, and presence of cyanosis. Bedside assessments should also include a single-breath counting exercise, observation of chest expansion, and testing of cough strength. Diaphragmatic weakness may give rise to paradoxical inward movement of the abdomen during inspiration. The presence of hypophonia, nasal intonation, dysarthria, dysphagia, and pooling of secretions suggest bulbar dysfunction. Auscultation of the chest may reveal features of bronchoconstriction, pulmonary congestion, or consolidation.

Tests of Pulmonary Function

Pulmonary Function Tests

Pulmonary function tests can be used to provide quantitative information about pulmonary function. Bedside spirometry is useful to assess pulmonary function, especially in neuromuscular disorders. Forced vital capacity (FVC), forced expiratory volume in 1 second (FEV1), and maximal inspiratory force (MIF) should be measured.[2] In neuromuscular disorders, a “restrictive” pattern of respiratory dysfunction is seen, evidenced by a normal or sometimes higher ratio of FEV1 to FVC. MIF is an indicator of the strength of the respiratory muscles.

Arterial Blood Gas Studies

Arterial blood gas analysis (pH, $PaCO_2$, PaO_2) is required for patients with impending respiratory failure to determine the need for ventilatory support. Overnight pulse oximetry is useful in patients with sleep-related breathing problems.

Imaging

Imaging plays a major role in the assessment of pulmonary function and diseases. Although a wide range of imaging techniques are available, computed tomography (CT) is still the mainstay of imaging as it allows high-resolution and quick assessment of the lung parenchyma and its surrounding structures. A CT scan of the thorax may sometimes be useful to detect small pleural effusions as well as mediastinal masses and lymphadenopathy. Functional imaging of the diaphragm using fluoroscopy or ultrasound is undertaken to evaluate diaphragmatic dysfunction, specifically diaphragmatic weakness secondary to phrenic nerve palsy.

Polysomnography

Polysomnography is useful to study abnormalities of breathing during different stages of sleep. Breathing is monitored by recording the airflow at the nose and mouth using thermal sensors and a nasal pressure transducer, effort is recorded using inductance plethysmography, and oxygen saturation is also measured. The breathing pattern is analyzed for the presence of apneas and hypopneas.

PATTERNS OF RESPIRATORY DYSFUNCTION

Disorders of the peripheral and central nervous system (CNS) may result in respiratory insufficiency through different mechanisms. The pattern of respiratory dysfunction primarily depends on the site of the lesion rather than the underlying etiology, whereas prognosis depends on both factors. Weakness of respiratory muscles may result in a restrictive pattern of ventilatory insufficiency. Oropharyngeal and laryngeal weakness can result in an obstructive pattern, especially during sleep. Patients with neuromuscular diseases and bulbar involvement are at risk of recurrent aspiration pneumonia and acute upper airway obstruction.

Central Nervous System Lesions

As discussed in an earlier section, the neurons responsible for generation of respiratory rhythm are located in the medulla, and their output to respiratory muscles through the reticulospinal tract is modulated by chemical and neural afferents. Specific breathing patterns have been reported in neurologic diseases based on the site of lesion.[3]

CHEYNE–STOKES BREATHING

Cheyne–Stokes breathing is characterized by a cyclical escalation of hyperventilation followed by decremental hypoventilation and finally apnea (Fig. 1-2). In humans, cycle lengths from 40 to 100 seconds may occur. During Cheyne–Stokes breathing, analysis of arterial blood gases shows cyclical variations. In the hyperventilation stage, there is a decrease in PaO_2 and pH and an increase in $PaCO_2$, which is followed by an increase in PaO_2 and pH, and a declining $PaCO_2$ during the decremental hypoventilation phase. This pattern may be observed with bilateral cortical or diencephalic dysfunction caused by either structural damage or metabolic problems. It can also occur in patients with cardiac failure and in most normal individuals while sleeping at high altitudes.

HYPERPNEA

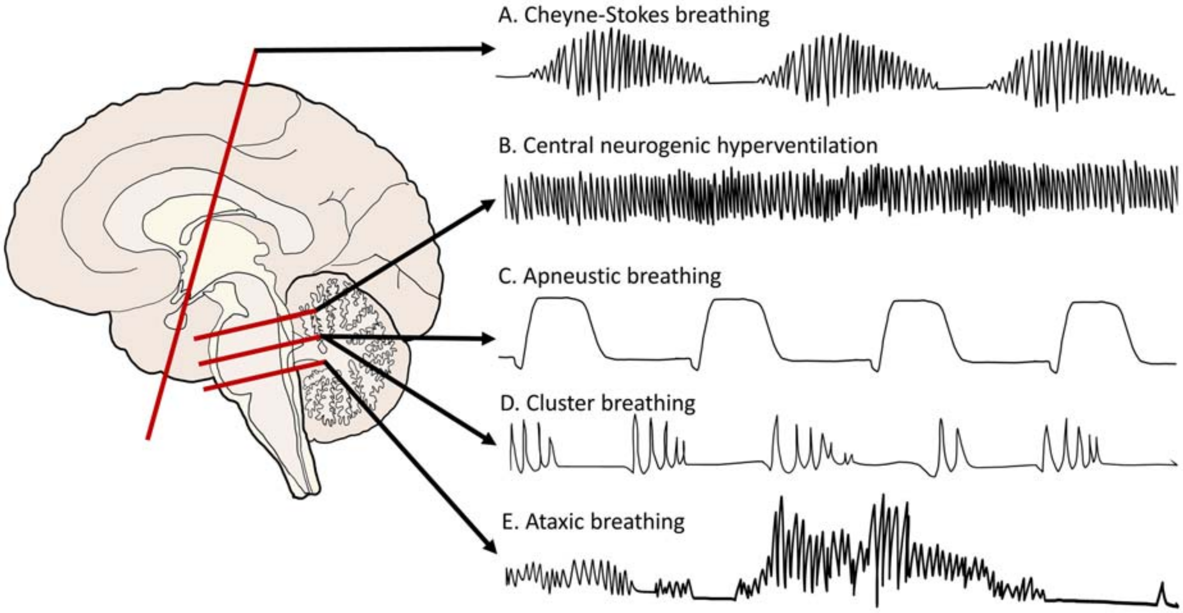
Hyperpnea or hyperventilation with regular deep breaths is indicative of a CNS lesion in rare instances. It is more often observed in patients with underlying medical conditions including sepsis and liver failure.

APNEUSTIC BREATHING

This is a pattern characterized by prominent, prolonged end-inspiratory pauses (Fig. 1-2) and is observed in lesions of rostral pons that involve the pneumotaxic center, that is, the Kölliker-Fuse–parabrachial complex.

ATAXIC BREATHING

Ataxic or irregular breathing is a pattern of breaths that are irregular in duration, frequency, and depth (Fig. 1-2). This pattern is usually observed with lesions of the pontomedullary junction and frequently heralds the onset of respiratory failure.



A. Cheyne-Stokes breathing
B. Central neurogenic hyperventilation
C. Apneustic breathing
D. Cluster breathing
E. Ataxic breathing

FIGURE 1-2 ■ Abnormal patterns of respiration.

Disorders of Involuntary Respiratory Control

CONGENITAL CENTRAL HYPOVENTILATION SYNDROME

Congenital central hypoventilation (Ondine curse) is a rare disorder characterized by intact volitional breathing with the inability to maintain respiration during sleep.[3] Patients experience apnea or hypopnea during sleep, most often during NREM sleep. Mutations of the *PHOX2B* gene have been implicated in this autosomal dominant disease.[1]

ACQUIRED CENTRAL HYPOVENTILATION

A phenomenology similar to congenital central hypoventilation syndrome has been described in bilateral or unilateral medullary infarction, bulbar poliomyelitis, neurodegenerative disorders such as multiple system atrophy (MSA), syringobulbia, paraneoplastic brainstem syndromes, and idiopathic sleep apnea.[3] Iatrogenic injury has been reported following bilateral cervical tractotomy performed for intractable pain, presumably as a result of damage to the descending reticulospinal tracts which activate phrenic motor neurons and the ascending spinoreticular fibers that carry afferent information to brainstem centers.

Disorders of Voluntary Respiratory Control

The relatively pure form of voluntary breathing dysfunction is observed in the “locked-in” syndrome,[3] wherein patients are unable to voluntarily control breathing and cannot speak, but have a regular ventilatory pattern, preserved response to CO_2 stimulation, and experience air hunger. Mid-pontine lesions are usually responsible and may be due to infarctions, hemorrhage, myelinosis, or tumors, which result in disruption of the corticospinal and corticobulbar fibers that control voluntary respiration while sparing the medullary respiratory centers that control automatic ventilation. Disordered voluntary breathing may also be observed in extrapyramidal and cerebellar disorders, to be discussed later.

Miscellaneous Disorders

CENTRAL NEUROGENIC HYPERVENTILATION

This is an abnormal pattern of breathing characterized by deep and rapid breaths of at least 25 breaths per minute (Fig. 1-2). Although central neurogenic hyperventilation was thought to be a classic and specific manifestation of midbrain dysfunction during transtentorial herniation, it is now apparent that this pattern of respiration is more common with unilateral or bilateral hemispheric lesions and is usually a sign of impending coma. This type of breathing may also occur with pontine or medullary lesions. The underlying mechanism of the tachypnea is unknown. It may be the result of either stimulation of receptors in the pulmonary interstitial space secondary to congestion from a neurogenic cause (neurogenic pulmonary edema), or central stimulation of medullary chemoreceptors secondary to local lactate production from tumor or stroke. Rarely, central neurogenic hyperventilation has been reported in anti-NMDA encephalitis.[4]

Other causes of centrally mediated hyperventilation are anxiety, infections, and drugs. The latter either stimulate the central or peripheral chemoreceptors or directly affect the brainstem respiratory neurons.

POSTHYPERVENTILATION APNEA

In normal awake persons, a brief period of apnea follows voluntary hyperventilation. This apnea usually lasts less than 12 seconds and occurs following five deep breaths sufficient to reduce $PaCO_2$ by 8 to 14 mmHg. Apnea lasting more than 12 seconds was found in more than 75 percent of patients with bilateral CNS disease (structural or metabolic), compared to only 1 to 2 percent of normal subjects. It is equally common in patients with unilateral or bilateral brain injury, but is significantly more common in drowsy than alert patients. It is therefore likely that the degree of posthyperventilation apnea is an indicator of depressed CNS function.

APRAXIA OF BREATHING

An inability to take or hold a deep breath in spite of normal motor and sensory functions of bulbar muscles is known as respiratory or breathing apraxia. This abnormality is most often found in elderly patients with cerebrovascular disease, dementia, or lesions of the nondominant hemisphere, and may be associated with frontal lobe release signs, paratonia, or other apraxias.

CLUSTER BREATHING

Cluster breathing is characterized by irregular groups of breaths interspersed with pauses of varying lengths (Fig. 1-2). It may be seen in patients with lower medullary dysfunction or during sleep in patients with MSA.

HICCUP

In hiccup, there is a strong contraction of the diaphragm and intercostal muscles followed by laryngeal closure, usually during inspiration. Hiccup rarely becomes persistent and disabling. A persistent hiccup is associated with lateral medullary lesions, raised intracranial pressure, metabolic encephalopathy from diverse causes such as uremia, and irritation of the diaphragm or phrenic nerves, but in some instances no cause can be found. Uncontrollable hiccups has also been reported in neuromyelitis optica spectrum disorders (NMOSD).

SNEEZING AND YAWNING

These are normal phenomena mediated through respiratory muscles. The center for sneezing is near the nucleus ambiguus, and yawning is coordinated from brainstem sites near the paraventricular nucleus via extrapyramidal pathways. A sneezing reflex triggered by sudden exposure to bright light may be inherited in an autosomal dominant manner. Yawning may initiate temporal lobe seizures, may be associated with arm stretching of the paretic limb in capsular infarction, or occur spontaneously in “locked-in” syndrome.

DIAPHRAGMATIC MYOCLONUS

In diaphragmatic myoclonus or flutter (Leeuwenhoek disease),[5] there is involuntary contraction of the diaphragm during sleep or wakefulness at the rate of approximately 3 Hz. Diaphragmatic contractions cause epigastric pulsations and may be associated with dyspnea, hyperventilation, hiccups, belching, and difficulty in weaning from the ventilator. In the syndrome of isolated diaphragmatic tremor,[6] there is usually no respiratory or functional disability and there is some voluntary control of the phenomenon.

RESPIRATORY DYSFUNCTION FROM NEUROLOGIC DISORDERS

Stroke

The effect of a stroke on respiratory function is highly dependent on the extent and site of the damage.[3] Respiratory compromise in stroke may be due to an infarct or hemorrhage involving structures that regulate breathing or as a consequence of secondary brain edema. In comparison to ischemic strokes, hemorrhagic strokes are more likely to produce early respiratory failure. Neurogenic pulmonary edema is a life-threatening acute respiratory dysfunction that has been reported in a wide range of neurologic conditions such as subarachnoid or intraparenchymal hemorrhage, ischemic stroke, spinal cord and meningeal hemorrhage, head trauma, multiple sclerosis (MS), brain tumor, meningitis and encephalitis, status epilepticus, and acute hydrocephalus. Injury to the brain, specifically the A1 and A5 groups of neurons in the medulla, nucleus of the solitary tract, area postrema, medial reticular nucleus, and dorsal motor nucleus of vagus, has been suggested to produce sympathetic discharges from the hypothalamus, brainstem, and spinal cord that cause severe systemic vasoconstriction and displace blood from the systemic to pulmonary circulation. Concomitantly, there is also reduced left ventricular diastolic and systolic compliance and increased left ventricular volume and left atrial filling pressure. These cardiac changes along with intensive pulmonary vasoconstriction lead to increased pulmonary capillary pressure with endothelial injury and leakage of fluid into the interstitial space and alveoli. This can result in increased pulmonary interstitial and alveolar fluid, leading to pulmonary edema and impaired alveolar gas exchange.

Apnea, hypopnea, ataxic (irregular), tachypneic (central hyperventilation), and periodic (Cheyne–Stokes) breathing patterns have all been reported in stroke, depending on the site of the lesion. Although central neurogenic hyperventilation occurs with midbrain dysfunction from transtentorial herniation, it is also common with unilateral or bilateral hemispheric lesions. Ataxic breathing is more characteristic of medullary lesions and often heralds respiratory failure in patients with large strokes. Breathing abnormalities are common in pontine lesions as well as in secondary brainstem compression from expanding cerebellar hematomas. Infarction of bilateral ventral pons results in the "locked-in" syndrome, where voluntary breathing is paralyzed (and the patient is unable to speak) due to interruption of the corticospinal and corticobulbar pathways. A normally functioning pontine tegmentum, cerebral hemispheres, and medulla results in preserved consciousness and regular automatic ventilation. In contrast, in acquired central hypoventilation syndrome, automatic breathing is disturbed with preserved voluntary breathing. This is usually secondary to bilateral or unilateral medullary infarctions. In focal hemispheric stroke, there may be contralateral dysfunction of chest wall movements.

Apart from anatomic lesions causing respiratory dysfunction, secondary factors following stroke increase the incidence of respiratory failure, such as oropharyngeal hypotonia due to reduced consciousness, impaired swallowing, and aspiration pneumonia.

The need for mechanical ventilation in patients with either brainstem or cerebral hemispheric stroke usually indicates a severe lesion. However, for patients requiring prolonged ventilation and tracheostomy, the likelihood of functional recovery is better in those with brainstem or cerebellar stroke than in those with hemispheric stroke.

Movement Disorders

HYPOKINETIC DISORDERS

Parkinson Disease

Patients with Parkinson disease may have restrictive, obstructive, and mixed types of pulmonary dysfunction, which is more severe in advanced disease and correlates with the degree of rigidity and bradykinesia. The respiratory dysfunction may be categorized as upper airway obstruction, restrictive disorder, a complication of medication intake and withdrawal, and aspiration pneumonia.[5]

Upper airway obstruction is characterized by hypophonia, respiratory flutter, and oro-pharyngeal-laryngeal dystonia. In respiratory flutter, there is regular consecutive flow deceleration and acceleration with a "saw-tooth pattern" on the flow–volume curve resulting from flow oscillation at a frequency of 4 to 8 Hz, which may improve with levodopa. The frequency is similar to that of the limb tremor, and probably results from involuntary movement of intrinsic laryngeal muscles.

The frequency of restrictive respiratory disorders in Parkinson disease ranges from 28 to 85 percent. Rigidity and bradykinesia of the respiratory muscles and loss of chest wall compliance are probably responsible. Respiratory dysfunction can also result from levodopa-induced dyskinesias, which may produce tachypnea, dyspnea, and erratic breathing patterns. Pleuropulmonary fibrosis producing restrictive respiratory dysfunction has been described rarely in patients taking ergot-derived dopamine agonists, such as bromocriptine or pergolide. Acute dopaminergic withdrawal may produce exacerbation of parkinsonism and neuroleptic malignant syndrome. Finally, aspiration pneumonia is the most common cause of death in parkinsonian patients, being implicated in about 70 percent of deaths.

Multiple System Atrophy

Respiratory abnormalities are a major cause of death in MSA, a disorder which often presents with a combination of parkinsonism, autonomic dysfunction, and cerebellar signs. Sleep apneas, both obstructive and central, occur in 15 to 30 percent of patients with MSA.[5] Stridor, including nocturnal stridor, may occur at any stage of the disease and is an important cause of sudden death. Vocal cord dysfunction may result from lower motor neuron weakness of the abducting posterior cricoarytenoid muscles due to degeneration of the nucleus ambiguus or from abnormal overactivity (dystonia) of the adductor muscles due to a defect in central control mechanisms. Other respiratory abnormalities in MSA include central neurogenic hypoventilation resulting in hypercapnic respiratory failure and respiratory dysrhythmias that consist of marked irregularities in tidal and minute volumes, variation of respiratory rate, cluster breathing, apneustic breathing, and periodic breathing.

Perry Syndrome

This is a rare movement disorder characterized by parkinsonism, psychiatric changes, weight loss, and hypoventilation.[7] Respiratory dysfunction is a late feature and the hypoventilation most commonly occurs at night, leading to disrupted sleep. Most patients ultimately die of respiratory failure or pneumonia.

HYPERKINETIC DISORDERS

Tardive Dyskinesia

Respiratory tardive dyskinesia is typically seen in patients already suffering from other symptoms such as oro-lingual-facial stereotypies, body-rocking movements, akathisia, and sensory complaints in addition to tardive dyskinesia.[5] Such patients may present with tachypnea, an irregular respiratory amplitude and rhythm, dyspnea, dysphonia, and vocalizations such as grunting, gasping, and humming.

Dystonia

Severe and acute exacerbations of dystonia are usually observed during a dystonic storm, which is an emergency situation complicated by respiratory failure, muscle breakdown, and myoglobinuria.[5]

Chorea and Huntington Disease

Respiratory dysfunction is frequently observed in the advanced stages of Huntington disease. Patients develop chest wall rigidity, in addition with progressive dysphagia which leads to aspiration pneumonia.[5]

Joubert Syndrome

In Joubert syndrome, episodic hyperventilation and apnea have been reported, probably due to disruption of the cerebellar control pathways for breathing.

Demyelinating Disorders

Respiratory dysfunction contributes significantly to the mortality and morbidity in MS, and respiratory failure is often the cause of death in advanced MS. Demyelinating lesions may involve locations associated with the production or propagation of neural impulses necessary for respiration. The type of dysfunction is dependent on the location and extent of the lesion, and may manifest as either acute or chronic respiratory dysfunction. In MS, the respiratory dysfunction may reflect respiratory muscle weakness, bulbar dysfunction, abnormal control of breathing, sleep-disordered breathing, respiratory failure, or neurogenic pulmonary edema.[8]

Apart from MS, acute respiratory dysfunction has also been reported frequently in other demyelinating disorders such as NMOSD.[9] This group of disorders tends to have a higher frequency of respiratory dysfunction than MS owing to the preferential involvement of the medulla and upper cervical cord.

Neuromuscular Disorders

Neuromuscular disorders (Table 1-1) produce alveolar hypoventilation ($PaCO_2 > 50$ mmHg), hypoxia, and finally apnea in advanced stages. Initially, patients with chronic neuromuscular disorders may not experience dyspnea, as there is decreased exercise demand due to the disease process. Mild respiratory dysfunction may present with signs of anxiety, sweating, tachycardia, and tachypnea, accompanied by a reduced single-breath count, decreased chest expansion, paradoxical inward movement of the abdomen during inspiration (suggesting diaphragmatic weakness), interrupted speech, and poor cough.[10]

TABLE 1-1 ■ Common Neuromuscular Disorders Causing Respiratory Failure

Neuromuscular junction disorders
Myasthenia gravis and congenital myasthenic syndrome
Lambert–Eaton myasthenic syndrome
Toxins and drugs
Myopathies
Muscular dystrophies
Congenital myopathies
Critical illness myopathy

ANTERIOR HORN CELL DISORDERS

Amyotrophic Lateral Sclerosis

Respiratory failure, which usually occurs late in the disease, is the most important cause of death in amyotrophic lateral sclerosis (ALS). The pathogenesis of respiratory failure is multifactorial and includes diaphragmatic weakness from loss of anterior horn cells in the cervical spinal cord, weakness of the chest wall from loss of thoracic spinal motor neurons, bulbar disease, and loss of descending corticospinal projections to the cervical and thoracic anterior horn cells.[10]

Pulmonary function tests (especially the FVC) are useful in monitoring the course of respiratory failure in the disease. Bilevel intermittent positive pressure ventilation improves survival and slows decline of pulmonary function, especially in bulbar-onset forms. This treatment should be offered to patients at the onset of dyspnea, when FVC falls below 50 percent of normal, or when there is a rapid decline in FVC. Rarely, some patients present initially with acute respiratory failure.

The duration of symptoms such as exertional dyspnea or orthopnea varies from weeks to months. Once mechanical ventilation is needed due to hypercapnia, successful weaning is unlikely. Planning in advance for respiratory failure in the terminal stages of ALS is important, and patients' wishes regarding prolonged ventilation and intubation should be discussed.

Other Anterior Horn Cell Disorders

Acute poliomyelitis is now a rare cause of respiratory failure in children, which occurs due to involvement of the anterior horn cells of the spinal cord and brainstem. Occasionally, in survivors of acute poliomyelitis, respiratory weakness may reappear after several years along with limb weakness, especially in those who had the illness after 10 years of age and those who presented initially with respiratory failure.[10] Other viral infections, including West Nile virus encephalomyelitis, are now more common causes of a poliomyelitis-like illness worldwide.

Respiratory insufficiency also occurs in spinal muscular atrophy (SMA), specifically in type 1 (Werdnig-Hoffman disease). It may occur to a variable extent in SMA type 2, and is uncommon in type 3.[10]

NEUROPATHIES

Guillain–Barré Syndrome

Acute inflammatory demyelinating polyneuropathy, of which Guillain–Barré syndrome is the prototype, is one of the most important and common neurologic causes of respiratory dysfunction. The main cause of respiratory failure in these conditions is phrenic nerve demyelination and consequent diaphragmatic paralysis.[10] Other contributory factors include weakness of the intercostal and other accessory muscles of respiration, autonomic dysfunction, retained respiratory secretions, and atelectasis. Approximately one-third of patients are ready for weaning within 2 weeks, but those with axonal forms have a poorer prognosis for respiratory recovery and may therefore require earlier tracheostomy. Immune therapy probably reduces the length of ventilator dependence.

Early respiratory symptoms of discomfort and agitation are accompanied by signs of reduced single-breath count, weak cough, use of accessory muscles, tachypnea, paradoxical abdominal movement, and speech interrupted by brief breaths. There may be frequent awakenings at night resulting from relaxation of voluntarily activated respiratory muscles during REM sleep, which increases demand on an already weakened diaphragm.

Indications for mechanical ventilation include a vital capacity less than 20 mL/kg, maximum inspiratory pressure below 25 cmH_2O, and a maximum expiratory pressure less than 40 cmH_2O. Mechanical ventilation will probably be required within 36 hours if the FVC is less than 50 percent of baseline. Even patients with a normal vital capacity may be at risk of imminent respiratory failure when the phrenic nerves are involved by the demyelinating process. Abnormal phrenic nerve conduction studies and needle electromyography of the diaphragm may predict respiratory insufficiency.

Phrenic Neuropathies

The severity of symptoms in phrenic neuropathies is variable and depends on the underlying cause, such as trauma, tumor infiltration, compression, infection, radiation, or an idiopathic process. Symptoms include exertional shortness of breath, and the respiratory rate may increase when lying flat. In addition to an elevated hemidiaphragm on chest radiography, there may be pulmonary atelectasis on the paralyzed side and mediastinal shift toward the normal side. Clinically, uninhibited movement of the costal margin away from the midline on the side of injury may be observed during inspiration. On fluoroscopy, the affected diaphragm moves paradoxically upward with a vigorous sniff (Kienback sign). Phrenic nerve conduction studies and needle electromyography of the diaphragm are useful for diagnosis and prognosis.

Critical Illness Polyneuropathy

In an intensive care unit, unexplained difficulty in weaning from the ventilator may result from several neuromuscular conditions that may occur in patients with the systemic inflammatory response syndrome. This syndrome occurs in 20 to 50 percent of patients in major medical or surgical care units, and its associated damage to the peripheral nervous system is probably related to the release of inflammatory mediators such as cytokines and free radicals.[10]

Critical illness polyneuropathy is a predominantly motor, axonal polyneuropathy that occurs in 50 to 70 percent of patients with systemic inflammatory response syndrome. The initial manifestation is often difficulty in weaning from the ventilator, despite systemic improvement. Weakness is usually equally distributed in both proximal and distal muscle groups. Severe weakness with muscle wasting is observed in one-third of patients, diminished or absent muscle stretch reflexes in the majority, and distal sensory loss in less than one-third. Electrophysiologic studies show reduced amplitude of compound muscle action potentials as early as 2 weeks from the onset of the systemic inflammatory response syndrome, with abnormal spontaneous activity seen in muscles; sensory nerve action potentials may be normal. Phrenic nerve stimulation and diaphragmatic electromyography are sometimes helpful in critical illness polyneuropathy, and degeneration of the phrenic nerves and denervation atrophy of respiratory muscles may be found at autopsy.

Other Neuropathies

Respiratory failure resulting from phrenic nerve involvement has been reported in other acquired and inherited neuropathies such as those of diabetes mellitus, chronic renal failure, sarcoidosis, leprosy, diphtheria, multifocal motor neuropathy with conduction block, infantile axonal polyneuropathy, hereditary motor and sensory neuropathy type 2C, arsenic exposure, lead toxicity, and acute organophosphate poisoning.[10]

NEUROMUSCULAR JUNCTION DISORDERS

Neuromuscular junction disorders should be suspected in patients with respiratory muscle weakness of unclear origin. These disorders may occur at any age, and the underlying causes include autoimmune, hereditary, paraneoplastic, and toxic diseases.[10]

Progressive respiratory muscle weakness is commonly found in generalized myasthenia gravis. During the course of the illness, 15 to 20 percent of patients will develop a myasthenic crisis, characterized by acute respiratory failure requiring mechanical ventilation, with a mortality rate of up to 5 percent. Infections are the most common trigger for myasthenic crisis; other precipitants include initial corticosteroid therapy, neuromuscular blocking drugs such as aminoglycosides, surgery, pregnancy and delivery, and physical and emotional stresses.

Although myasthenic crisis occurs most often in generalized myasthenia gravis, it may also occur rarely in oculobulbar variants, and isolated respiratory failure may be the initial manifestation of myasthenia gravis. Antibodies against acetylcholine receptors may not be present in patients with predominant respiratory muscle involvement. Instead, some of these patients may have muscle-specific tyrosine kinase receptor antibodies and have predominantly neck, shoulder, and respiratory muscle or oculobulbar weakness.

Excessive administration of anticholinesterase drugs to treat myasthenia gravis may sometimes leads to respiratory weakness. Meiosis, sweating, abdominal cramping and diarrhea, excessive secretions, and muscle fasciculations characterize these cholinergic crises. Bronchospasm, aspiration, and excessive inspissated secretions with weak cough cause the respiratory dysfunction.

In addition to serum antibody tests, the evaluation of patients with respiratory insufficiency and suspected myasthenia gravis may include repetitive nerve stimulation studies, occasionally including the phrenic nerve, and single-fiber electromyography if the diagnosis remains unclear. The edrophonium

(Tensilon) test may not change respiratory muscle strength and is most useful when the patient has ptosis. Phrenic nerve conduction studies may be useful to exclude iatrogenic phrenic nerve injury in post-thymectomy myasthenia gravis patients with respiratory insufficiency.

Other neuromuscular junction disorders that may cause respiratory insufficiency include other forms of myasthenic gravis (neonatal, congenital, and juvenile). Isolated or predominant involvement of the respiratory muscles is not uncommon and may be the presenting feature of Lambert–Eaton myasthenic syndrome. In addition, acquired causes include foodborne or wound botulism, and neuromuscular toxins and drugs.

MYOPATHIES

Muscular Dystrophies

Among the dystrophinopathies, Duchenne muscular dystrophy is the most common cause of respiratory muscle weakness; approximately 40 to 70 percent of these patients die of respiratory failure. Respiratory insufficiency starts at the age of 8 or 9 years and progressively increases with age and functional disability. Those with more severe thoracic scoliosis have earlier onset of respiratory failure. The causes of respiratory failure include weakness of inspiratory and expiratory muscles, progressive kyphoscoliosis, recurrent respiratory tract infections, and pulmonary edema from cardiac failure.[10] Respiratory insufficiency is less frequent in Becker muscular dystrophy. Early respiratory insufficiency and death in infancy may also occur in isolated muscular dystrophy involving the diaphragm.

Respiratory involvement is common in myotonic dystrophy and results from weakness of the diaphragm and the intercostal muscles. The cause of respiratory muscle weakness is due to CNS involvement in 20 percent of patients. Other contributory factors include the concurrence of various types of neuropathy. Alveolar hypoventilation from diaphragmatic weakness and central hypoventilation (from neuronal loss in the dorsal raphe and superior central nuclei) underlie the hypersomnia that is common in myotonic dystrophy.

Respiratory muscle weakness has also been frequently reported in limb-girdle muscular dystrophy, specifically types 2C, 2D, 2E, and 2F, which are sarcoglycanopathies.[10]

Critical Illness Myopathy

Critically ill patients may be affected by a critical illness myopathy in addition to the neuropathy discussed earlier.[10] This includes at least three different types of muscle abnormalities: thick filament myopathy, acute necrotizing myopathy, and cachectic myopathy. Flaccid weakness of the muscles of all limbs, neck flexors, and sometimes the face is accompanied by diaphragmatic weakness and difficulty in weaning from mechanical ventilation. Differentiation of critical illness myopathy from neuropathy may be difficult and some patients, if not most, will have a combination of these two entities. Myopathic features on electrophysiologic studies, an elevated serum creatine kinase level (which is not always present), and demonstration of myopathic features with myosin loss on histopathology are supportive of critical illness myopathy.

Other Muscle Disorders

Many patients with various limb-girdle syndromes have dyspnea on exertion, chronic cough, and recurrent respiratory infections. Those with severe diaphragmatic involvement may have chronic alveolar hypoventilation resulting in morning headaches, excessive sleepiness, fatigue, and altered mentation. Although patients with facioscapulohumeral and scapuloperoneal syndromes are usually spared respiratory muscle involvement, they may develop frequent aspiration pneumonia due to weakness of pharyngeal muscles.[10]

Congenital myopathies are usually nonprogressive or slowly progressive muscle diseases that are present at birth, but in severe cases respiratory insufficiency can occur. Respiratory muscle weakness has been reported in infants with nemaline myopathy, centronuclear myopathy, and multicore myopathy.[10]

In inflammatory myopathies (e.g., polymyositis and dermatomyositis), pulmonary complications are frequently the result of weakness of respiratory muscles, interstitial lung disease, and aspiration pneumonia from weakness of pharyngeal and upper esophageal muscles.

Respiratory insufficiency is a critical component of acid maltase deficiency (Pompe disease). In the infantile form, death usually occurs before age 2 due to respiratory insufficiency. Proximal limb or respiratory muscle weakness is the presenting features in the childhood form. In the adult form, involvement of the respiratory muscles is common and patients may present with an acute-on-chronic respiratory failure.[10] Respiratory muscle weakness has also been reported in corticosteroid-induced myopathy as a result of selective atrophy of type IIB fibers, in HIV myopathy, mitochondrial myopathies, and carnitine palmitoyl transferase deficiency.

Spinal Cord Lesions

Similar to stroke, the effect of a spinal cord lesion on breathing is highly dependent on the level of the lesion.[3] Most often, respiratory dysfunction is reported secondary to trauma. However, similar abnormalities may also be reported in vascular or neoplastic conditions.

CERVICAL SPINAL CORD INJURY

Injury to the upper cervical spinal cord above the phrenic nerve outflow, that is, at C1 or C2, results in paralysis of all the key respiratory muscles due to interruption of descending pathways.[3] In such situations, apnea is rapidly followed by death unless ventilator support is provided. Lower lesions in the cervical cord spinal produce loss of intercostal and expiratory action, with normal diaphragmatic and inspiratory accessory musculature. Delayed apnea in patients with cervical injury may arise secondary to manipulation of the spine in order to stabilize a fracture. In chronic injury, spasticity of the respiratory muscles may compromise vital capacity and inspiratory pressure. Dyspnea and wheezing in patients with spinal cord injury can also result from vagal overactivity due to sympathetic denervation.

THORACIC CORD INJURY

Lesions of the thoracic spinal cord seldom produce significant respiratory abnormalities, and the most important consequence of such an injury is reduced force of coughing due to paralysis or weakness of abdominal muscles.[3]

Miscellaneous Disorders

EPILEPSY

Sudden unexpected death in epilepsy is a major cause of epilepsy-related mortality. A higher prevalence has been reported in patients with generalized tonic-clonic seizures and refractory epilepsy. An epilepsy-related cardiorespiratory autonomic dysfunction has been implicated in its pathogenesis.

BRAIN TUMORS

Brainstem tumors such as gliomas, ependymomas, medulloblastomas, and cerebellar astrocytomas are more likely to cause acute respiratory disturbances than tumors in the cerebral hemispheres. Postoperative ventilatory support is often required. Supratentorial gliomas and other masses may also affect respiration due to tentorial herniation.

DISORDERS OF BREATHING ASSOCIATED WITH SLEEP

Upper Airway Obstruction

Upper airway obstruction during sleep is defined as partial (obstructive sleep hypopnea) or complete (obstructive sleep apnea) obstruction to airflow proximal to the larynx for at least 10 seconds despite ongoing respiratory efforts. There may be a mixed apnea (initial lack of respiratory effort followed by increasing effort) and upper airway resistance syndrome (frequent respiratory effort-related arousals).[1] These conditions are collectively referred to as obstructive sleep apnea/hypopnea syndrome (OSAHS).

Stridor, a harsh or strained, high-pitched inspiratory sound, results from obstruction to inspiration at the level of the vocal cords. Several neurologic causes may result in stridor including brainstem dysfunction (e.g., from Chiari malformation), paralysis of cord abduction from recurrent laryngeal neuropathy, dystonia of the vocal-cord adductor muscles, and MSA.

Both OSAHS and stridor have been observed in anti-IgLON5 disease,[11] a recently described disorder characterized by NREM and REM parasomnias, in addition to OSA and stridor. Symptoms are progressive and can lead to life-threatening respiratory dysfunction such as central hypoventilation.

Central Sleep Apnea Syndromes

CSA syndromes are characterized by disordered breathing during sleep associated with reduced or absent respiratory effort, in addition to excessive daytime sleepiness, frequent nocturnal awakenings, or both. Six types have been identified: primary CSA; CSA due to Cheyne–Stokes breathing; CSA due to medical condition not Cheyne–Stokes; CSA due to high-altitude periodic breathing; CSA due to drugs or substances; and primary sleep apnea of infancy.[12]

CSA may be associated with hypercapnia or normocapnia/hypocapnia. In hypercapnic CSA, the ventilatory response to CO_2 is reduced. The disorder occurs in patients with alveolar hypoventilation caused by neuromuscular disorders, brainstem dysfunction, or in idiopathic alveolar hypoventilation syndrome. Normocapnic or hypocapnic CSA may also be idiopathic or it may occur in the setting of high altitude, with Cheyne–Stokes respiration, or with partial upper airway obstruction.

CSA is less common than OSAHS. Esophageal pressure monitoring is the definitive technique used to differentiate central from peripheral obstructive events. However, the differentiation can usually be made by documentation of cessation of airflow associated with absence of respiratory effort.

Sleep Hypoventilation Syndrome

Sleep hypoventilation syndrome is characterized by both hypercapnia and hypoxemia during sleep, unexplained by discrete apneas or hypopneas. A variety of neurologic disorders may cause this disorder (Table 1-2) by affecting the central respiratory centers or their efferent pathways, or by myopathies or neuropathies affecting the diaphragm or intercostal muscles. Sleep hypoventilation syndrome is initially observed in REM sleep, but eventually daytime respiratory failure occurs. Sleep hypoventilation syndrome results in frequent nocturnal arousals, nocturnal dyspnea on lying flat, morning headaches, and daytime sleepiness. Chronic hypercapnia may result in blunting of respiratory chemoreceptor responses and a secondary reduction in central respiratory drive. Nocturnal hypoventilation results in erythrocytosis, pulmonary hypertension, and, in severe cases, cor pulmonale.

TABLE 1-2 ■ Neurologic Causes of Sleep Hypoventilation Syndrome

Disorders of brainstem respiratory centers
Idiopathic central alveolar hypoventilation
Multiple system atrophy
Infarcts or hemorrhage
Tumors
Infections (e.g., encephalitis)
Arnold–Chiari malformation
Disorders of spinal efferent pathways
High spinal cord trauma
Cervical posterior cordotomy
Multiple sclerosis
Disorders of anterior horn cells and peripheral nerves
Poliomyelitis and postpolio syndrome
Motor neuron diseases
Generalized peripheral neuropathies
Bilateral phrenic neuropathy
Disorders of muscle
Congenital myopathies
Muscular dystrophies
Inflammatory myopathies
Myasthenia gravis
Disorders restricting chest cage movement
Kyphosis
Scoliosis in chronic neurodegenerative disorders

Respiratory Dysrhythmias

Respiratory dysrhythmias are abnormalities of the rhythm of breathing or the relationship of inspiration to expiration. They occur more frequently during sleep and include Cheyne–Stokes breathing, apneustic breathing, irregular or ataxic breathing, and cluster breathing. The clinical features of these abnormal patterns of respiration were discussed earlier. Cheyne–Stokes breathing may be associated with CSA and is often observed in patients with cardiac failure.

Sudden Infant Death Syndrome

Prolonged laryngeal chemoreflex, blunted chemo- and arousal reflexes, autonomic dysregulation, sleep apnea, and genetic polymorphisms have been implicated in the pathogenesis of sudden infant death syndrome.[1]

NEUROLOGIC EFFECTS OF RESPIRATORY DYSFUNCTION

Like other organs in the body, the brain is often affected indirectly by respiratory failure. Neurologic symptoms may be acute or insidious, and signs of primary lung disease may not always be apparent.

Dysfunction Related to Pulmonary Pathology

Chronic or acute hypoxia and hypercapnia, or hypocapnia, can result from diverse primary lung disorders or cardiac illness. These abnormalities can impair the function of the nervous system in several ways.[13]

HYPOXIA

Cerebral dysfunction usually occurs with reduction of partial pressure of oxygen to less than 40 mmHg. The effects of pure hypoxia on the brain (hypoxic hypoxia) are observed in high-altitude sickness. Several days after ascending rapidly (usually to altitudes of 8,000 to 12,000 ft), headache, insomnia, anorexia, nausea, vomiting, and impaired cognitive function may occur. In the more acute and severe form (usually above 10,000 ft), there is severe headache, delirium, hallucinations, ataxia, and occasionally seizures. Papilledema and retinal hemorrhages may occur, probably due to cerebral edema. Prophylactic acetazolamide and dexamethasone are sometimes useful, and dexamethasone is used to treat the disorder when it occurs.

Following cardiac arrest, patients can develop an encephalopathy, primarily as a result of cerebral ischemia rather than pure hypoxia. Structural abnormalities usually do not occur in the brain in the setting of hypoxia without ischemia. Several movement disorders such as dystonia, chorea, myoclonus, tremor, and akinetic-rigid syndromes also have been known to arise as a consequence of hypoxia.

HYPERCAPNIA

Chronic pulmonary insufficiency is one of the important causes of chronic hypercapnia ($PaCO_2$ levels ranging from 39 to 68 mmHg). Headache, papilledema, tremulousness, asterixis, altered consciousness, and generalized slowing of the electroencephalogram may be observed secondary to the hypercapnia. Raised intracranial pressure from chronic CO_2 narcosis is believed to be the underlying factor causing headache and papilledema. Management strategies include discontinuation of sedative drugs, avoidance of vigorous hyperventilation, and ventilatory support. Cognitive impairment in the domains of attention, memory, learning, executive skills, language, visuospatial and constructional abilities, and psychomotor speed have been reported in patients with chronic obstructive pulmonary disease. Chronic hypercapnia, hypoxemia, and hypoventilation are implicated in the above impairment.[14]

Encephalopathy and occasionally seizures are the main symptoms of acute severe hypercapnia with CO_2 levels ranging from 75 to 110 mmHg. CO_2 narcosis results in reduced pH of the CSF and subsequent respiratory acidosis. Acute encephalopathy probably results from hydrogen ion-induced inhibition of glutamate receptors.

Dysfunction Related to Obstructive Sleep Apnea

OSA is the most common sleep-related breathing disorder and several studies have reported the impact of OSA on neurocognitive functions, and neurologic deficits, specifically neurodegeneration, epilepsy, stroke, and headache.[15]

VASCULAR DISORDERS

OSA-related hypoxemia has been reported to change the structure and function of blood vessels. Furthermore, snoring is a risk factor for stroke, and a higher frequency of OSAHS has been observed in patients who had suffered a stroke. Hypertension, cardiac arrhythmias, increased platelet aggregation, increased blood viscosity, decreased fibrinolysis, sympathetic hyperactivity, and changes in cerebral blood flow are each a potential mechanism for stroke in patients with OSAHS.

COGNITIVE DYSFUNCTION

Patients with OSA have been reported to demonstrate cognitive impairment in the domains of concept formation, executive functioning, attention, speed of processing, working and verbal memory, nonverbal memory, psychomotor speed, motor control and performance, construction, verbal functioning and verbal reasoning, and perception. These abnormalities have been attributed to sleep fragmentation and hypoxemia, which can produce structural brain damage and excessive daytime sleepiness. Continuous positive airway pressure has been found to be moderately effective in reducing the neurocognitive deficits in patients with OSA and excessive daytime sleepiness.

HEADACHE

Early morning headache and cluster headache have been associated with OSAHS, and treatment with positive airway pressure improves headache in these patients. Hypoxia or hypercapnia-induced cerebral vasodilation is the most likely mechanism of the headache. Although the exact frequency of headache in OSAHS is not known, it is more frequent in OSA and snorers than those without these disorders.

EPILEPSY

Several studies have investigated the relationship and prevalence of OSA in patients with epilepsy. OSA may be implicated as a trigger for seizures by producing sleep disruption, sleep deprivation, and cerebral hypoxemia.

CONCLUDING COMMENTS

Respiration involves a complex interplay between the nervous and respiratory systems. The nervous system plays a critical role in the maintenance of this predominantly involuntary function via anatomic and functional pathways that span the neuraxis. Damage to either the central or peripheral components of these pathways can adversely affect respiration. Conversely, hypoxia and hypercapnia secondary to respiratory dysfunction may also produce neurologic complications. A thorough understanding of respiratory physiology, detailed clinical examination, and judicial use of investigations are crucial for appropriate management of patients.

  - *Intraoperative Adjuncts to Avoid Spinal Cord Ischemia*

The aorta is the main conduit through which the heart supplies blood to the body, including the brain, brainstem, and spinal cord. In addition, this vessel is situated close to important neural structures. In consequence, both disease of the aorta and operations on it may have profound but variable effects on nervous system function. Often the neurologic syndrome produced by aortic disease or surgery depends more on the part of the aorta involved than on the nature of the pathologic process itself. For example, either syphilis or atherosclerosis may produce symptoms of cerebral ischemia if the disease affects the aortic arch or of spinal cord ischemia if the pathologic process is in the descending thoracic aorta. Even when the nature of the pathologic process is important in determining the resultant neurologic syndrome, several diseases may result in the same pathologic process. Thus, atherosclerosis, infection, inflammation, and trauma may each result in the formation of aortic aneurysms; similarly, coarctation of the aorta may be congenital, a result of Takayasu arteritis, or a sequela of radiation exposure during childhood.

The initial focus of this chapter is on the three major areas of neurologic dysfunction resulting from aortic disease and surgery: spinal cord ischemia, cerebral ischemia, and peripheral neuropathy. Specific conditions that merit special consideration are then discussed individually. The normal anatomic relationships are also considered in order to provide insight into the pathogenesis of the resulting neurologic syndromes.

CLINICAL NEUROLOGIC SYNDROMES DUE TO AORTIC PATHOLOGY

Aortic disease may produce a variety of neurologic syndromes. The specific syndrome depends to a large extent on the site of involvement along the aorta.

FIGURE 2-1 ■ Extraspinal contributions to the anterior spinal arteries showing the three arterial territories. In the cervical region, an average of three arteries (derived from the vertebral arteries and the costocervical trunk) supply the anterior spinal artery. The anterior spinal artery is narrowest in the midthoracic region, often being difficult to distinguish from other small arteries on the anterior surface of the cord; occasionally it is discontinuous with the anterior spinal artery above and below. In addition, this region is often supplied by only a single small radiculomedullary vessel. The lumbosacral territory is supplied by a single large artery, the great anterior medullary artery of Adamkiewicz, which turns abruptly caudal after joining the anterior spinal artery. If it gives off an ascending branch, that branch is usually a much smaller vessel. This artery is usually the most caudal of the anterior radiculomedullary arteries, but when it follows a relatively high thoracic root, there is often a small lumbar radiculomedullary artery below. In this and subsequent illustrations, *a* indicates artery; *m*, muscle; *n*, nerve.

Spinal Cord Ischemia

ANATOMY

Embryologic Development

During embryologic development, primitive blood vessels arise along the spinal nerve roots bilaterally and at each segmental level. Each of these segmental vessels then divides into anterior and posterior branches, which ramify extensively on the surfaces of the developing spinal cord. As development proceeds, most of these vessels regress and a few enlarge, so that by birth, the blood supply to the spinal cord depends on a small but highly variable number of persisting segmental vessels (Fig. 2-1). In the thoracic region, where the aorta is situated to the left of the midline, the persisting vessels entering the spinal canal are those from the left in 70 to 80 percent of cases.

Anterior Spinal Artery

The anterior spinal artery is formed rostrally from paired branches of the intracranial vertebral arteries that descend from the level of the medulla (Fig. 2-1). These two arteries fuse to form a single anterior spinal artery that overlies the anterior longitudinal fissure of the spinal cord. This artery is joined at different levels by anterior radiculomedullary arteries,

which are branches of certain segmental vessels (Fig. 2-2). The number of these vessels is variable among individuals, ranging from 2 to 17, although 85 percent of individuals have between 4 and 7.

The anterior spinal artery in the region that includes the cervical enlargement (C1 to T3) is particularly well supplied, receiving contributions from an average of three segmental vessels. One constant artery arises from the costocervical trunk and supplies the lower segments; the others arise from the extracranial vertebral arteries and supply the middle cervical segments. In addition, branches of the vertebral arteries have rich anastomotic connections with other neck vessels, including the occipital artery, deep cervical artery, and ascending cervical artery.

The anterior spinal artery in the midthoracic portion of the cord (T4 to T8) often receives only a single contribution from a small artery located at about T7, most often on the left. The anterior spinal artery has its smallest diameter in this region, and it is sometimes—but not usually—discontinuous with the vessel in more rostral or caudal regions.

The anterior spinal artery in the region of the lumbar enlargement (T9 to the conus medullaris) is, as at the cervical enlargement, richly supplied, deriving its blood supply predominantly from a single large (1.0 to 1.3 mm in diameter) artery, the great anterior medullary artery of Adamkiewicz. This artery almost always accompanies a nerve root between T9 and L2, usually on the left, although rarely it may accompany a root above or below these levels. Identification of the actual location of this great vessel has become an important part of the planning and execution of operations on the aorta such as repair of thoracoabdominal aortic aneurysms. Although digital subtraction angiography has been used for this purpose, the use of contrast-enhanced magnetic resonance angiography is a noninvasive alternative. Caudally, at the conus medullaris, the anterior spinal artery anastomoses with both posterior spinal arteries.

Posterior Spinal Arteries

The paired posterior spinal arteries form rostrally from the intracranial portion of the vertebral arteries. They are distinct paired vessels only at their origin, however, and thereafter become intermixed with an anastomotic posterior pial arterial plexus (Fig. 2-3). This plexus is joined at different levels by a variable number (10 to 23) of posterior

FIGURE 2-3 ■ Vascular anatomy of the spinal cord. The anterior spinal artery gives off both peripheral and sulcal branches. The sulcal branches pass posteriorly, penetrating the anterior longitudinal fissure. On reaching the anterior white commissure, they turn alternately to the right and to the left to supply the gray matter and deep white matter on each side. Occasionally two adjacent vessels pass to the same side, and on other occasions, a common stem vessel bifurcates to supply both sides. Terminal branches of these vessels overlap those from vessels above and below on the same side of the cord. The peripheral branches of the anterior spinal artery pass radially and form an anastomotic network of vessels, the anterior pial arterial plexus, which supplies the anterior and lateral white matter tracts by penetrating branches. The posterior pial arterial plexus is formed as a rich anastomotic network from the paired posterior spinal arteries. Penetrating branches from this plexus supply the posterior horns and posterior funiculi.

radiculomedullary vessels that accompany the posterior nerve roots.

Intrinsic Blood Supply of the Spinal Cord

In contrast to the extreme interindividual variability in the extraspinal arteries that supply the spinal cord, the intrinsic blood supply of the cord itself is more consistent. The anterior spinal artery gives off central (sulcal) arteries that pass posteriorly, penetrating the anterior longitudinal fissure and supplying most of the central gray matter and the deep portion of the anterior white matter (Fig. 2-4). The number of these sulcal vessels is variable, with 5 to 8 vessels per centimeter in the cervical region, 2 to 6 vessels per centimeter in the thoracic region, and 5 to 12 vessels per centimeter in the lumbosacral region.

The anterior spinal artery also gives off peripheral arteries that pass radially on the anterior surface of the spinal cord to supply the white matter tracts anteriorly and laterally. These arteries form the anterior pial arterial plexus, which is often poorly anastomotic with its posterior counterpart. The posterior horns and posterior funiculi are supplied by penetrating vessels from the posterior pial arterial plexus.

critical feeding vessels or by aortic hypotension. The resulting neurologic syndrome depends on the location of ischemic lesions along and within the spinal cord, which depends, in turn, on the vascular anatomy discussed previously. A wide variety of pathologic disturbances of the aorta result in spinal cord ischemia. As reviewed elsewhere,[1] they include both iatrogenic causes, such as surgery and aortography, and intrinsic aortic diseases, such as dissecting and nondissecting aneurysms, inflammatory aortitis, occlusive atherosclerotic disease, infective and noninfective emboli, and congenital coarctation. Spinal cord ischemia is a rare complication of pregnancy, possibly due to aortic compression, which can occur toward the end of gestation.

Some authors have suggested that the midthoracic region (T4 to T8) is particularly vulnerable to ischemia because of the sparseness of vessels feeding the anterior spinal artery in this region and its poor anastomotic connections. Others have stressed the vulnerability of the watershed areas between the three anterior spinal arterial territories. Although the concept is theoretically appealing, documentation of the selective vulnerability of these regions is not completely convincing. For example, a review of 61 case reports with respect to the distribution of ischemic myelopathies resulting from surgery on the aorta does not especially suggest that either of these areas is more vulnerable than other cord segments (Table 2-1).[1] Even when the operation was performed on the thoracic aorta (and thus the proximal clamp was placed above the midthoracic cord feeder), the lumbosacral cord segments were the site of the ischemic damage more often than the supposedly more vulnerable midthoracic segments (Table 2-1). Similarly, the watershed area between these two arterial territories (T8 to T9) does not seem particularly vulnerable. In fact, the most frequently affected cord segment within each vascular territory in these 61 cases was centrally placed—T6 in the midthoracic territory and T12 in the lumbosacral territory—rather than at the borders, as might be anticipated with watershed vulnerability (Fig. 2-5).

Moreover, of the 25 cases of spinal cord infarction in an unselected autopsy series of 300 cases, two-thirds were in cervical cord segments; the most commonly affected segment was C6. Such a distribution would be unexpected if either the midthoracic or the watershed area was particularly vulnerable. It may be that the poorly vascularized thoracic cord, which has much less gray matter than the cervical and lumbar enlargements, actually matches its sparse blood supply with its reduced metabolic requirements.[2]

The site of aortic disease also plays an important role in the location of the lesion along the spinal cord. For example, distal aortic occlusion often presents with lumbosacral involvement, whereas dissecting aneurysm of the thoracic aorta commonly presents with infarction in the midthoracic region. Similarly, cord ischemia following surgery on the abdominal aorta is essentially confined to the lumbosacral territory, whereas surgery on the thoracic aorta not infrequently involves the midthoracic segments (Table 2-1). Regardless of the pathologic process affecting the aorta, however, it generally involves the suprarenal portion if there is cord ischemia because the important radiculomedullary arteries usually originate above the origin of the renal arteries.

Ischemic spinal cord syndromes can be subdivided into several different categories including those with either bilateral or unilateral involvement restricted to the anterior or posterior spinal artery territories, those with involvement restricted to the central gray matter and, less commonly, those with a complete transverse myelopathy.

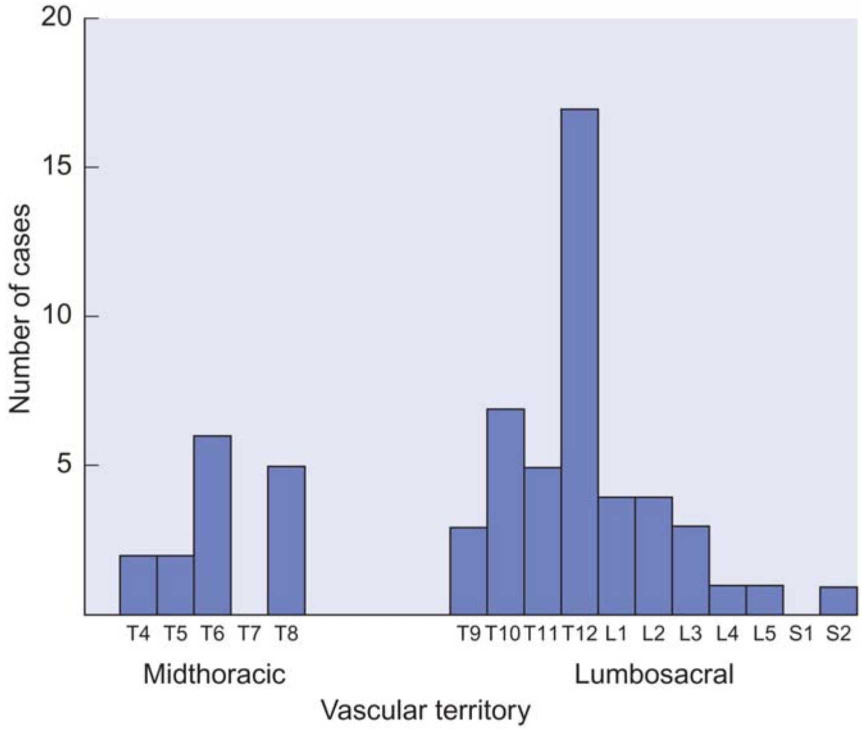

FIGURE 2-5 ■ Upper segmental level of spinal cord involvement in 61 cases of spinal cord ischemia after surgery on the aorta (based on previously published reports).

Anterior Spinal Artery Syndrome

Ischemic injury of the spinal cord at a particular segmental level may present with a complete transverse myelopathy. Within the spinal cord, however, there are certain vascular territories that can be affected selectively.[3] In particular, the territory of the anterior spinal artery, especially its sulcal branch, is prone to ischemic injury.[3] This increased vulnerability probably relates to two factors. First, the anterior circulation receives a much smaller number of feeding vessels than the posterior circulation. Second, the posterior circulation is a network of anastomotic channels and therefore probably provides better collateral flow than the single and sometimes narrowed anterior artery. The relative constancy of the resulting syndrome presumably reflects the relative constancy of the intrinsic vascular anatomy of the cord.

As mentioned earlier, the anterior spinal artery supplies blood to much of the spinal gray matter and to the tracts in the anterior and lateral white matter. Ischemia in this arterial territory therefore gives rise to a syndrome of diminished pain and temperature sensibility with preservation of vibratory and joint position sense. Weakness (either paraparesis or quadriparesis, depending on the segments involved) occurs below the level of the lesion and may be associated with other evidence of upper motor neuron involvement, such as Babinski signs, spasticity, and hyperreflexia. Bowel and bladder functions are affected, owing to interruption of suprasegmental pathways. Segmental gray matter involvement may also lead to lower motor neuron deficits and depressed tendon reflexes at the level of the lesion. Thus, a lesion in the cervical cord may produce flaccid areflexic paralysis with amyotrophy in the upper extremities, spastic paralysis in the lower extremities, and dissociated sensory loss in all limbs. In contrast, a lesion in the thoracic cord typically presents with only spastic paraplegia and dissociated sensory loss in the legs. The syndrome usually comes on abruptly, although occasionally it is more insidious and progressive. Occasionally, also, a transverse myelopathy can result from ischemia to the spinal cord.[3]

Motor Neuron Disease

On occasion, diseases of the aorta (e.g., dissecting aneurysms or atherosclerosis) that interfere with the blood supply to the anterior spinal artery result in more restricted cord ischemia. This may occur because of better anastomotic connections between the anterior and the posterior pial arterial plexuses in some individuals or because of greater vulnerability of the anterior horn cells with their greater metabolic activity. The ischemic injury in these circumstances is limited to the central gray matter supplied by the sulcal branches (Fig. 2-6). Clinical impairment is then confined to the motor system and is associated with amyotrophy. When the onset is abrupt, the ischemic nature of the lesion usually is apparent, but when the onset is more gradual, and especially when pyramidal signs are also present, it may mimic other diseases, such as amyotrophic lateral sclerosis or spinal cord tumors.

Posterior Spinal Artery Syndrome

In contrast to the anterior spinal artery syndrome, selective ischemia of the posterior circulation, characterized by prominent loss of posterior column function with relative sparing of other functions, is rarely recognized clinically and only occasionally reported pathologically.[4,5] For example, in two reviews of a total of 63 cases of nonsurgical spinal cord ischemia, only 7 (9%) had posterior spinal artery patterns.[3,4] The relative infrequency of this syndrome presumably relates to the more abundant feeding vessels

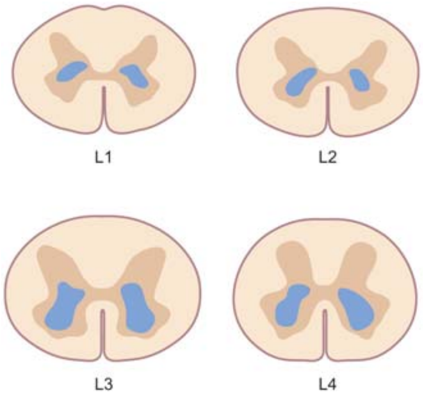

FIGURE 2-6 ■ Area of infarction within the spinal cord over four adjacent spinal segments in a patient reported by Herrick and Mills (Herrick MK, Mills PE: Infarction of spinal cord. Two cases of selective gray matter involvement secondary to asymptomatic aortic disease. Arch Neurol 24:228, 1971). The infarction was extensive but limited to the gray matter, particularly the anterior horns.

and better anastomotic connections in this arterial system compared to the anterior spinal artery.

Unilateral Cord Syndromes

In some cases, the area of ischemic damage can be confined to only a small portion of the spinal cord. For example, in the reviews cited previously,[3,4] 22 (35%) of the patients with nonsurgical spinal cord ischemia had unilateral syndromes involving either the anterior or posterior aspects of the spinal cord.

Intermittent Claudication

Intermittent claudication (limping) refers to a condition in which a patient experiences difficulty in walking that is brought about by use of the lower extremities. The evolution of concepts of intermittent claudication is of historical interest and is described elsewhere.[1] In brief, Charcot initially described this syndrome in 1858 and related it to occlusive peripheral vascular disease in the lower extremities. In 1906, Dejerine distinguished claudication caused by ischemia of the leg muscles from that caused by ischemia of the spinal cord. In the latter condition, the arterial pulses in the legs tend to be preserved, pain tends to be dysesthetic or paresthetic in quality and may not occur, and neurologic signs are frequently present, especially after exercise. In 1961, another form of neurogenic claudication was identified, caused by ischemia or compression of the cauda equina, which resulted from a narrowed lumbosacral canal (either congenital or due to degenerative disease). This condition is similar to that produced by ischemia of the spinal cord, but there are important differences. Thus, the sensory complaints tend to have a more radicular distribution, numbness and pain are aggravated by certain postures (e.g., lumbar extension when walking or standing) and relieved by other postures (e.g., lumbar flexion when riding a bike or sitting), and signs of cord involvement (e.g., Babinski signs) are not present.

The clinical distinction between various types of claudication, particularly between the two neurogenic varieties, is sometimes difficult. The cauda equina variety, however, is more common than the spinal cord form. Intermittent spinal cord ischemia, when it occurs, can be associated with intrinsic diseases of the aorta, such as coarctation or atherosclerotic occlusive disease although, more commonly, it is due to degenerative disease of the cervical and thoracic spine. Bony erosion through vertebral bodies from an abdominal aortic aneurysm with direct compression of the spinal nerve roots has also been reported to produce intermittent neurologic symptoms. The clinical details of the single reported case, however, are not sufficient to determine whether the symptoms resemble those of intermittent claudication.

Cerebral Ischemia

ANATOMY

The aortic arch gives rise to all the major vessels that provide blood to the brain, brainstem, and cervical spinal cord (Fig. 2-7). The first major branch is the innominate (brachiocephalic) artery, which subsequently divides into the right common carotid and right subclavian arteries. The latter artery subsequently gives rise to the right vertebral artery, which ascends through the foramina of the transverse processes of the upper six cervical vertebrae to join with its counterpart on the left and form the basilar artery. The basilar artery provides blood to the posterior fossa and posterior regions of the cerebral hemispheres. The second major branch of the aortic arch is the left common carotid artery, and the third is the left subclavian artery, which, in turn, gives rise to the left vertebral artery.

STROKES AND TRANSIENT ISCHEMIC ATTACKS

Diseases of the aortic arch, such as atherosclerosis, aneurysms, and aortitis as well as surgery on this segment of the aorta, may give rise to symptoms of cerebrovascular insufficiency, such as strokes or transient ischemic attacks (TIAs). A young woman has even been reported with a stroke secondary to an occlusion of the aorta that was associated with the use of birth control pills and recurrent venous thromboses.[1] Cerebral ischemia is produced either by occlusion of a major vessel or by embolization of atheromatous or other material to more distal arteries. The resulting neurologic syndromes are not specific for any disease process but depend on the location and duration of the vascular occlusion.

FIGURE 2-7 ■ Vascular anatomy of the aortic arch and its branches.

Atherosclerosis

Atherosclerosis of the aortic arch and its branches, compared with atherosclerosis at the origin of the internal carotid artery, is an infrequent cause of stroke or TIAs, probably for two reasons. First, atherosclerosis is much less common in this location than at the carotid bifurcation (Table 2-2). Second, the anastomotic connections between the major vessels in the neck are extensive, and an occlusion at their origin from the aortic arch is therefore less likely to be associated with symptoms of ischemia than a more peripheral obstruction.

Transient Emboligenic Aortoarteritis

Transient emboligenic aortoarteritis has been reported by Wickremasinghe and colleagues to be a cause of stroke in young patients. They described 10 patients (aged 16 to 36 years), all of whom had presented with pathologically verified thromboembolic strokes, and 3 of whom had a history of TIAs preceding the event by as much as 4 years.[6] All these patients had both active and healed inflammatory lesions of the central elastic arteries, such as the aorta, innominate, common carotid, and proximal subclavian arteries. Active lesions were small (200 to 300 μm in diameter) and associated with a mural thrombus on the intimal surface. Healed lesions usually were associated with fibrous plaques but not with a mural thrombus. More peripheral arteries supplying the brain were normal. This condition seems to be distinct from segmental aortitis of the Takayasu type. Clinically it is an acute, intermittent disorder with an approximately equal sex incidence, whereas Takayasu disease is more chronic and has a strong female predominance. The systemic symptoms of Takayasu disease are absent, and occlusion of the central arteries does not occur in this condition.

Subclavian (Cerebral) Steal

Disease of the aortic arch may result in occlusion of either the innominate artery or the left subclavian artery proximal to the origin of the vertebral artery. This, in turn, may result in the reversal of the usual cephalad direction of blood flow in the ipsilateral vertebral artery (Fig. 2-8), depending on individual variations in the collateral circulation, and may result in ischemia in the posterior cerebral circulation.[7] In some patients, this is particularly evident when the metabolic demand (and therefore the blood flow) of the affected arm is increased

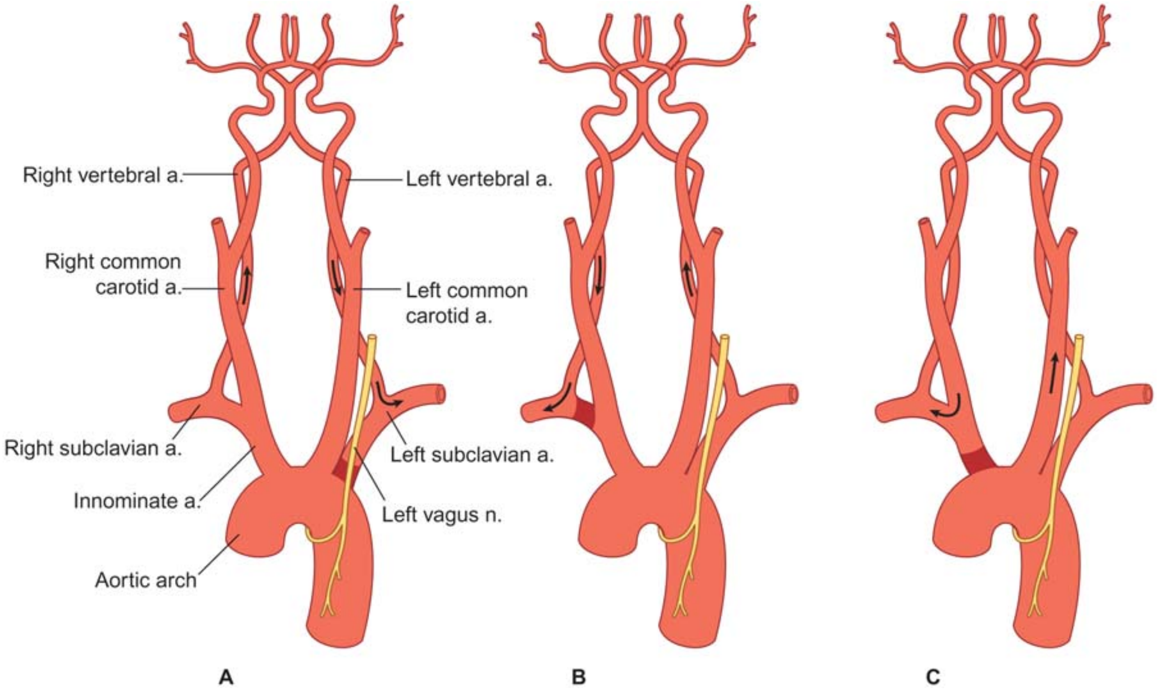

FIGURE 2-8 ■ Mechanisms producing subclavian steal syndrome in diseases of the aortic arch and its branches. *A*, Obstruction of the left subclavian artery at its origin, resulting in reversal of blood flow in the left vertebral artery. *B*, Obstruction of the right subclavian artery distal to the takeoff of the right common carotid artery, resulting in reversal of blood flow in the right vertebral artery. *C*, Obstruction of the innominate artery at its origin, producing reversal of blood flow in the right common carotid artery.

during exercise. If the innominate artery is blocked proximally, it may also cause a reversal of blood flow in the right common carotid artery, resulting in anterior circulation ischemia (Fig. 2-8).

Killen and colleagues reviewed the clinical features of a series of patients with demonstrated reversals of arterial blood flow in a vertebral artery (i.e., with flow from the vertebral artery into the ipsilateral subclavian artery).[8] The left subclavian artery was affected more than twice as often as the right subclavian and innominate arteries combined, probably as a result of the more frequent involvement of this artery by atherosclerosis (Table 2-2). Men were affected three times as often as women, probably reflecting the greater prevalence of atherosclerosis in men. Of the 87 patients in this series with symptoms that were adequately described, 75 (86%) had symptoms referable to the central nervous system (CNS). These symptoms were usually transient, lasting seconds to a few minutes, although the deficits were sometimes permanent. The neurologic manifestations of steal varied but most frequently included motor difficulties, vertigo, visual deficits, or syncope. Ischemic symptoms in the arms occurred in only a few patients, and precipitation of CNS symptoms by exercise of the arm ipsilateral to the occlusion was uncommon. Although reconstructive surgery relieved symptoms in most patients in this series,[8] the frequent failure of surgery to correct these nonspecific symptoms has led to a reassessment of the clinical importance of cerebral steal. Thus, when noninvasive techniques such as Doppler ultrasonography have been used to define the direction of blood flow in the great vessels in a large spectrum of patients with vascular disease, the majority (50 to 75%) of patients with documented subclavian steal are found to be asymptomatic, even when the steal is bilateral.[1,7] When symptoms do occur, they are suggestive of transient vertebrobasilar insufficiency in only 7 to 37 percent of patients with steal; the occurrence of infarcts in this vascular territory is distinctly rare.[1] For this reason, a review of the topic led to the conclusion that subclavian steal is actually a marker of generalized atherosclerotic disease and that it is rarely a cause for symptoms of cerebral ischemia.[9]

Nevertheless, a related syndrome, the coronary subclavian steal syndrome, seems well documented. This syndrome consists of angina (with or without posterior circulation symptoms such as vertigo) induced by upper limb exercise. It follows a coronary artery bypass graft using the left internal mammary artery in the setting of a hemodynamically significant subclavian stenosis.

Peripheral Neuropathy

The peripheral nervous system is sometimes affected by aortic disease or surgery. The syndromes produced may be the presenting manifestations of aortic disease and may mimic less life-threatening conditions.

MONONEUROPATHIES

Left Recurrent Laryngeal Nerve

The left recurrent laryngeal nerve descends in the neck as part of the vagus nerve and wraps around the aortic arch just distal to the ligamentum arteriosum (Fig. 2-7) before reascending in the neck to innervate all the laryngeal muscles on the left side except the cricothyroideus. It may be compressed by disease of the aortic arch, such as dissecting and nondissecting aneurysms or aneurysmal dilatation proximal to a coarctation of the aorta.[9] The resulting hoarse, low-pitched voice may be one of the earliest presenting symptoms of these conditions, although it is often overshadowed by other symptoms or signs, such as chest pain, shortness of breath, congestive heart failure, or hypertension.

Femoral Nerve

The femoral nerve arises from the nerve roots of L2, L3, and L4. It forms within the belly of the psoas muscle and then exits on its lateral aspect to innervate the quadriceps femoris, iliacus, pectineus, and sartorius muscles and the skin of the anterior thigh and medial aspect of the leg. The nerve is located considerably lateral to the aorta (Fig. 2-9) and hence is rarely involved by direct compression. It may, however, be compressed by a hematoma from a ruptured aortic aneurysm into the psoas muscle and thereby signal a life-threatening condition that requires an urgent operation.

The femoral nerve may also be injured as a consequence of aortic surgery. The mechanism of injury in such cases is presumed to be ischemic and related

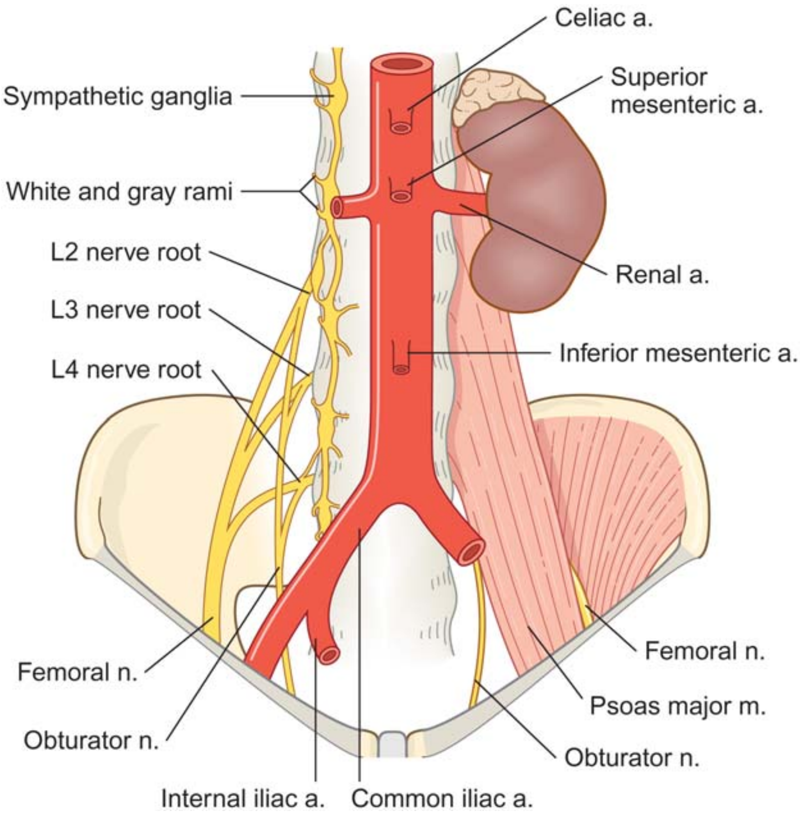

FIGURE 2-9 ■ Anatomy of the abdominal aorta showing its relationship to the femoral and obturator nerves, which form within the psoas muscle from branches of the L2, L3, and L4 segmental nerves.

to poor collateral blood supply to the intrapelvic portions of the femoral nerves.

Obturator Nerve

The obturator nerve also forms within the belly of the psoas muscle by the union of fibers from the L2, L3, and L4 segments, but, in contrast to the femoral nerve, exits medially from this muscle (Fig. 2-9). It innervates the adductors of the leg and the skin on the medial aspect of the thigh. It too is lateral to the aorta and not usually involved by direct compression. Like the femoral nerve (and often together with it), the obturator nerve may be compressed by a hematoma in the psoas muscle.

RADICULOPATHIES

Nerve roots, particularly L4, L5, S1, and S2, which lie almost directly underneath the terminal aorta and iliac arteries (Fig. 2-10), may be directly compressed by an aortic aneurysm in this region. The syndromes produced are typical of radicular disease, with unilateral radiating pain and a radicular pattern to the sensory and motor findings.

Radiculopathies may also be produced by erosion of one or more vertebral bodies by an aortic aneurysm, with consequent compression of the nerve roots in the cauda equina or at the root exit zones. The syndrome produced is not necessarily associated with back pain; it may result in multisegmental involvement on one side or even in paraplegia.[10]

POLYNEUROPATHIES

Ischemic Monomelic Neuropathy

Ischemic monomelic neuropathy was described in detail by Wilbourn and co-workers, who reported 3 patients (and alluded to another 11) who had a distal "polyneuropathy" in one limb after sudden occlusion of a major vessel.[11] One of their patients had a saddle embolus to the distal aorta that occluded the right common iliac artery, another had a superficial femoral artery occlusion after

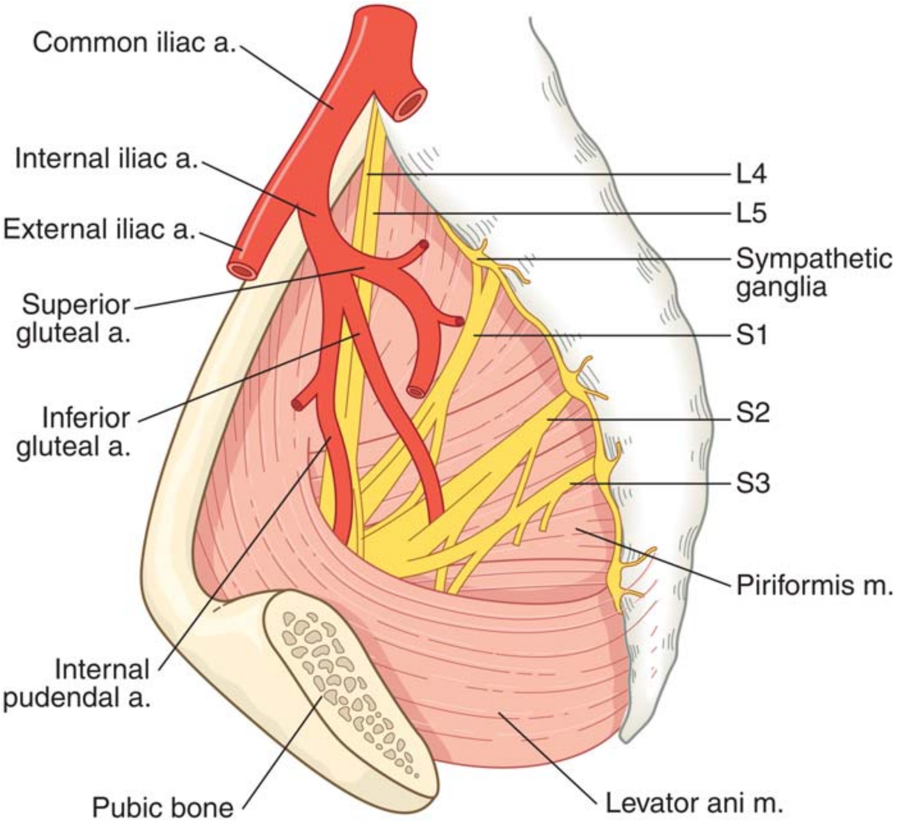

FIGURE 2-10 ■ Anatomy of the terminal branches of the aorta in relationship to the nerve roots that subsequently join to form the sciatic nerve. Aneurysmal dilatation of the abdominal aorta often includes dilatation of these branch vessels, which can compress the nerve roots, particularly the L4, L5, S1, and S2 nerve roots, which lie directly underneath.

placement of an intra-aortic balloon pump, and the third had upper extremity involvement. The syndrome consists of a predominantly sensory neuropathy with a distal gradient. It affects all sensory modalities and is associated with a constant, deep, causalgia-like pain. The symptoms persist for months, even after revascularization or without evidence of ongoing ischemia. The results of nerve conduction studies and needle electromyography suggest an axonal neuropathy. There is no evidence of ischemic muscle injury, such as induration, muscle tenderness, or elevated serum creatine kinase levels. Most recent reports of this condition seem to be as a complication of vascular access for dialysis, and the syndrome appears to be quite rare as a manifestation of aortic disease.

AUTONOMIC NEUROPATHIES

Anatomy

The autonomic nerves, particularly the lower thoracic and lumbar sympathetic fibers that lie close to the aorta and its branches, may be injured by disease of or surgery on the aorta. The preganglionic efferent sympathetic nerve fibers originate in the intermediolateral cell column in the spinal cord (Fig. 2-4) and exit segmentally between T1 and L2 with the ventral roots. The sympathetic fibers part company with the segmental nerves through the white rami communicantes (Fig. 2-2), which enter the paravertebral sympathetic ganglia and trunks to form bilateral sympathetic chains; these chains are situated lateral to and parallel with the vertebral column (Fig. 2-11). Some of these fibers synapse on postganglionic neurons in the ganglia of their segmental origin, whereas others ascend or descend in the trunk to different segmental levels before making such synapses. In the lumbosacral and cervical segments, where there are no white rami (i.e., below L2 or above T1), the segmental ganglia receive preganglionic contributions only from cord segments either above them (lumbosacral ganglia) or below them (cervical ganglia). The postganglionic fibers rejoin the segmental nerves through the gray rami communicantes (Fig. 2-2) to provide vasomotor, sudomotor, and pilomotor innervation throughout the body.

Some of the preganglionic fibers, in contrast, do not synapse in the paravertebral ganglia but pass through them to form splanchnic nerves, which then unite in a series of prevertebral ganglia and plexuses (many of which overlie the thoracic and abdominal aorta). These structures, in turn, provide sympathetic innervation to the viscera. The plexus that overlies the aorta in the region of its bifurcation, the superior hypogastric plexus (Fig. 2-11), is responsible (via the inferior hypogastric and other pelvic plexuses) for sympathetic innervation of the pelvic organs, including the prostate, prostatic urethra, bladder, epididymis, vas deferens, seminal vesicles, and penis in men (Fig. 2-12) and the uterus, bladder, fallopian tubes, vagina, and clitoris in women. This plexus is formed by the union of the third and fourth lumbar splanchnic nerves with fibers from the more rostral inferior mesenteric plexus. Its segmental contribution usually derives from T11 to L2.

through the trunk, ganglia, and white rami to reach their nerve cells of origin in the dorsal root.

Postsympathectomy Neuralgia

Operations on the distal aorta to treat symptomatic aortic disease from atherosclerosis or other causes frequently include intentional sympathectomy as part of the effort to improve blood flow to the legs. This is usually done by dividing the sympathetic chain below the last white ramus at L2, thereby depriving the lower lumbar and sacral ganglia of their preganglionic innervation. Such an operation is often followed by a distinctive pain syndrome, termed *postsympathectomy neuralgia*. The syndrome occurs typically in patients in whom the sympathetic chain is interrupted at L3 by removal of the segmental ganglion. The pain is characterized as deep, boring, nonrhythmic, and nonradiating; onset is abrupt but delayed usually for several days. It is located predominantly in the thigh, either medially or laterally, and is associated with tenderness in the area of pain. The course is self-limited, with an average duration of 3 weeks.

Disorders of Sexual Function

Normal male sexual function has two distinct components. The first, erection, is a response mediated predominantly through the parasympathetic nervous system by the pelvic splanchnic nerves (nervi erigentes) arising from segments S2, S3, and S4 (Fig. 2-12). Activation of these nerves causes vasodilatation of the penile cavernosal artery and engorgement of the penile musculature and sinuses. The blood supply to the penis is provided by the internal pudendal artery via the internal iliac artery (Fig. 2-10). The sympathetic nervous system, however, must have at least a modifying influence on erection because bilateral sympathectomy may disturb it. By contrast, unilateral sympathectomy seems not to affect sexual function. The second component, orgasm and ejaculation, can be divided into two phases. The first phase, expulsion of seminal fluid into the prostatic urethra, is a response mediated predominantly by the sympathetic nervous system through the superior hypogastric plexus. A mucous-like liquid (preejaculate), which lubricates the ejaculation pathway, is added to the seminal fluid by paired bulbourethral (Cowper) glands, located inferior to the prostate. The second phase, orgasm and emission, is produced by the rhythmic (clonic) contraction of penile musculature (bulbocavernosus and ischiocavernosus) innervated by somatic (pudendal) nerves (Fig. 2-12).

Normal female sexual function is quite similar. During the first component of the response (arousal), blood flow to the clitoral, cavernosal, and labial arteries is increased, leading to elevation of clitoral intracavernous pressure, tumescence and protrusion of the clitoris, and engorgement and eversion of the labia minora. There is also vasodilatation and engorgement of the vaginal wall, which produces an increase in both its length and diameter and causes a transudation of plasma through the vaginal epithelium, thereby producing a lubricant for the inner vaginal surface during intercourse. Additional moistening is provided by secretions from the paired greater vestibular (Bartholin) glands, located slightly posterior to the vaginal opening and homologous to the Cowper glands in men. During the second component of the response (orgasm) there are rhythmic (clonic) contractions of the genitopelvic and anal smooth muscles.

Male sexual function may be disturbed by aortic disease or surgery. Female sexual function has not been as well studied in these circumstances, although it seems to be affected to a similar degree as in men. Because the superior hypogastric plexus lies close to the aortic bifurcation (Fig. 2-11), most preoperative and postoperative sexual disturbances occur with disease of this portion of the aorta and, in men, most involve ejaculation (Table 2-3). The pelvic splanchnic nerves are not situated near the aorta (Fig. 2-11) and usually are not affected by aortic disease or surgery. Disturbances in erection (arousal), however, do occur, possibly because of sympathetic dysfunction, a reduction in blood flow to the internal pudendal artery and penis, or cavernovenous leakage. To determine whether blood flow or sympathetic function was more important in this regard, Ohshiro and Kosaki examined the outcome of (1) terminal aortic operations either done traditionally or designed to spare the superior hypogastric plexus and (2) operations that did or did not preserve blood flow in the internal iliac arteries.[12] Their results indicated that preservation of the hypogastric plexus appeared to be more important for maintenance of normal erection and ejaculation than was preservation of blood flow in the internal iliac arteries (Table 2-4). Other authors have also found that modification of operative technique to spare the superior hypogastric plexus considerably improves postoperative sexual function.

Despite the importance of operative technique in preserving sexual function, preservation of blood flow is probably also important. Thus, Nevelsteen and colleagues reported a clear relationship between the occurrence of preoperative impotence and the adequacy of blood flow through the internal iliac arteries.[13] In this study, however, no special attempt was made to improve blood flow in the internal iliac artery during surgery, so that it is unclear whether a different operative approach might have been beneficial in restoring postoperative sexual function.

TABLE 2-3 ■ Male Sexual Dysfunction in Patients with Disease of or Surgery on the Aorta

Patient Status		Sexual Function	
Preoperative Status (All Patients)	Number of Patients	Normal (%)	Abnormal (%)
Iliac occlusion	22	82	18
Terminal aortic occlusion	10	40	60
Abdominal aortic aneurysm	12	83	17
Postoperative Status*		Impaired Ejaculation (%)	Impaired Erection (%)
Iliac occlusion	18	28	17
Terminal aortic occlusion	4	75	25
Abdominal aortic aneurysm	10	70	30

*All patients had normal preoperative sexual function.
Based on data from Ohshiro T, Takahashi A, Kosaki G: Sexual function in patients with aortoiliac vascular disorders. Int Surg 67:49, 1982.

TABLE 2-4 ■ Influence of Blood Flow and Sympathetic Function on Male Sexual Function After Abdominal Aortic Operations

		Postoperative Sexual Disturbance	
Parameter	Number of Patients	Ejaculation (%)	Erection (%)
Internal Iliac Blood Flow			
Bilaterally good	29	31	21
Unilaterally good	12	42	8
Bilaterally poor	4	50	25
Type of Surgery			
Classic	32	47	25
Nerve sparing	13	8	8

AORTIC DISEASES AND SURGERY

Certain conditions affecting the aorta merit special consideration because of the variety of nervous system syndromes that each can produce.

Aortitis

Injury to the aorta by a variety of infectious, toxic, allergic, or idiopathic causes may produce similar inflammatory pathologic changes in the elastic media

TABLE 2-5 ■ Causes of Aortitis

Stenosing Aortitis
Takayasu arteritis
Postradiation during infancy
Nonstenosing Aortitis
Syphilis
Mycobacterial infections
Other bacterial infections (e.g., *Salmonella* or *Staphylococcus*)
Human immunodeficiency virus infection
Mycotic aneurysms
Rheumatic fever
Rheumatoid arthritis
Giant cell arteritis
Collagen vascular and other diseases*
Ankylosing spondylitis
Relapsing polychondritis
Reiter syndrome
Behçet disease
Cogan syndrome

*Systemic lupus erythematosus, scleroderma, psoriasis, Crohn disease, and ulcerative colitis.

(Table 2-5). Such aortic damage may lead to neurologic syndromes either primarily through direct involvement of important branch arteries by the pathologic process or secondarily through the development of aneurysms, aortic stenosis, or atherosclerosis. The neurologic syndromes produced either primarily or secondarily by aortitis depend on both the nature and the location of the resulting aortic lesion.

SYPHILITIC AORTITIS

During the prepenicillin era, syphilis was a common cause of aortitis, although by the 1950s its occurrence had markedly declined. A report in 1958 on the relative occurrence of atherosclerotic and syphilitic thoracic aortic aneurysms showed cases of syphilis outnumbering atherosclerosis by a ratio of 1.3:1. A similar report published in 1982 gave this ratio as 0.13:1. The pathologic process in syphilitic aortitis is almost always in the thoracic aorta, in contrast to the distribution of atherosclerosis, which is more prevalent in the abdominal aorta (Table 2-2). The aortitis is accompanied by aneurysmal dilatation of the aorta in approximately 40 percent of cases. Rarely, it presents with multiple arterial occlusions and mimics Takayasu arteritis, although patients are generally older than those with Takayasu arteritis and are usually men.

TAKAYASU ARTERITIS

Takayasu arteritis is an idiopathic inflammatory condition affecting the large arteries, particularly the aorta and its branches.[14] The pathogenesis seems to involve cell-mediated autoimmunity, although the responsible antigen is unknown. The onset of disease is typically between the ages of 15 and 30 years, and the condition seems most prevalent in Asian and Hispanic populations.[14] More than 85 percent of affected individuals are women. In the early (prepulseless) phase, the disease may be characterized by systemic symptoms such as fever, night sweats, weight loss, myalgia, arthralgia, arthritis, and chest pain. In some patients, however, the systemic symptoms are either inconspicuous or absent. The later (pulseless) phase of the disease is characterized by occlusion of the major vessels of the aortic arch, producing symptoms such as Takayasu retinopathy, hypertension (secondary to renal artery stenosis, coarctation, or both), aortic regurgitation, and aortic aneurysms. Symptoms of cerebral ischemia can occur; however, they are typically reported in only a few patients. Nevertheless, a report from South Africa on 272 patients who were diagnosed with Takayasu arteritis, based on the criteria of the American College of Rheumatology, found that 20 percent of the cohort had symptoms of cerebrovascular disease, including TIAs and stroke.[15] In addition, 32 percent of this cohort experienced intermittent claudication of either upper or lower limbs. Seizures and headaches have also been reported but are uncommon. Involvement along the aorta is typically diffuse, although some patients (perhaps as many as 20%) present with symptoms related to more restricted aortic involvement.[14,15] The disorder is discussed further in Chapter 50.

GIANT CELL ARTERITIS

Giant cell arteritis (GCA) seems to be a particularly important cause of aortitis in the elderly; although it typically affects medium-sized vessels, as many as one-fourth or more of affected individuals have large-artery involvement. In a series of 45 patients undergoing aortic resection and who had microscopic evidence of active noninfectious aortitis, the majority had either unclassifiable aortitis (47%) or GCA (31%), two entities that were histopathologically indistinguishable.[16] The presenting symptoms in patients with GCA or unclassified aortitis are generally nonspecific and include exhaustion, night sweats, weight loss, chest and back pain, headache, fevers of unknown origin, TIAs, and arm claudication.[16] Typically, all segments of the aorta (ascending aorta, arch, and descending aorta) are involved in the inflammatory process, although involvement can be more restricted. Between 10 and 20 percent of patients with unclassified aortitis or GCA will subsequently develop either dissecting or, more commonly, nondissecting aortic aneurysms.

Aortic Aneurysms

NONDISSECTING ANEURYSMS

Nondissecting aortic aneurysms can be caused by any pathologic process that weakens the arterial wall, such as inflammation, infection, or atherosclerosis. In the past, syphilis was an important cause, but at present almost all these aneurysms are caused by atherosclerosis. As a result, the distribution of aortic aneurysms essentially parallels the distribution of atherosclerosis within the aorta, with most occurring in the abdominal aorta (Tables 2-2 and 2-6).

TABLE 2-6 ■ Distribution and Nature of Aortic Aneurysms

Site	Number of Cases
Nondissecting Aneurysms	
Aortic arch	56
Descending thoracic aorta	116
Thoracoabdominal aorta	25
Abdominal aorta	829
Dissecting Aneurysms	
Thoracic aorta	62

Based on data from Crawford ES, DeBakey ME, Cooley DA, et al: Surgical considerations of aneurysms and atherosclerotic occlusive lesions of the aorta and major arteries. Postgrad Med 29:151, 1961.

The incidence and prevalence of abdominal aortic aneurysms, which depend on age and sex, and are influenced by smoking history and hypertension, have declined since the 1990s both in Europe and the United States, as also has the prevalence of ruptured aneurysms. Since 1990, mortality rates from abdominal aortic aneurysms for both men and women have decreased in many developed countries.[17] The basis for this shift in natural history is unclear.

Disturbances of neurologic function in aortic aneurysms are uncommon, but when they occur, they are variable and depend in part on the location and extent of the lesion. Abdominal aneurysms may result in sexual dysfunction, compressive neuropathies, or, rarely, spinal cord ischemic syndromes, including intermittent claudication, asymmetric paraparesis, and paraplegia; descending thoracic aneurysms may produce spinal cord ischemia, and aortic arch aneurysms may result in cerebral ischemia or recurrent laryngeal nerve dysfunction. Most commonly, neurologic symptoms are produced by either rupture or direct compression. Even when aneurysms result in paraplegia, the neurologic deficit is often caused by bony erosion through the vertebral bodies and direct compression of the spinal cord or cauda equina rather than by ischemia.

DISSECTING AORTIC ANEURYSMS

Dissecting aortic aneurysms, in contrast to nondissecting aortic aneurysms, predominantly involve the thoracic aorta, either at the beginning of the ascending segment (type A) or immediately distal to the left subclavian artery at the aortic isthmus (type B). Their etiology has not been established. Atherosclerosis is probably not a major factor because atherosclerosis is seldom found in the region of the intimal tear because the distribution of these aneurysms along the aorta is unlike that of atherosclerosis and because atherosclerosis is only infrequently present. Nevertheless, hypertension probably is a factor as it is present in the large majority of patients with either type A or type B dissections. Moreover, dissecting aortic aneurysms have been associated with cystic medial necrosis, a degenerative condition focally affecting the arterial media, which may itself be related to hypertension. This condition is increased in patients with Marfan syndrome, as are dissecting aneurysms.

Most aneurysms, however, do not occur in patients with Marfan syndrome or other identifiable collagen disorders, and the pathophysiology remains unknown. It has been estimated that 60 percent of thoracic aortic aneurysms involve the aortic root or ascending aorta, 10 percent the arch, 40 percent the descending thoracic aorta, and 10 percent the thoracoabdominal aorta.[18] More than 95 percent of thoracic aortic aneurysms are asymptomatic and their prevalence (prior to rupture or dissection) has been estimated to be greater than 0.16 to 0.34 percent.[18] There may be a familial tendency for their occurrence and, for larger aneurysms (> 6 mm), the 5-year survival may be as low as 50 percent.[18] Neurologic involvement from dissecting aneurysms (due to the cut-off of important arteries by the dissection or by embolization) is well described but uncommon. It occurs more frequently with type A than type B dissections, and it usually involves either spinal or cerebral ischemia. Neurologic involvement may also occur during surgery to repair the aneurysm. Patients with aortic dissection usually present with acute chest or back pain, which generally leads to the proper diagnosis. On occasion, however, pain is absent, and the neurologic syndrome is the presenting feature. Moreover, the neurologic deficit produced by the dissecting aneurysm is sometimes only transient, lasting for several hours, and thereby mimicking other transient disturbances of neurologic function.

TRAUMATIC AORTIC INJURY

Brutal deceleration injuries to the chest, especially from motor vehicle accidents, may result in traumatic rupture of the thoracic aorta, often just distal to the left subclavian artery at the aortic isthmus (i.e., the slight constriction of the aorta at the point where the ductus arteriosus attaches). Many of these patients die immediately, but some present with an acute paraplegia. Still others have a chronic aortic aneurysm that may present years later with acute spinal cord ischemia or other neurologic symptoms. Some patients with traumatic aortic injury have a less critical condition (e.g., limited intimal flaps) and may not warrant immediate surgical treatment. Nevertheless, they will still need to be monitored closely for signs of progression that would prompt urgent intervention.

Coarctation of the Aorta

Coarctation of the aorta, a relatively common congenital condition, typically results in constriction of the thoracic aorta just distal to the origin of the left subclavian artery. Less commonly, it occurs as part of Takayasu arteritis, and this condition should be suspected if the location of the coarctation is atypical. It may also follow radiation exposure during infancy; in these cases, the pathologic process is focal and limited to the segment of aorta that was in the field of irradiation. Coarctation can result in a variety of neurologic symptoms (Table 2-7). Cerebral infarcts probably result from embolization of thrombotic material in the dilated aorta proximal to the obstruction.

Subarachnoid hemorrhage from ruptured saccular aneurysms can occur with coarctation. In the general population, aneurysmal hemorrhage has an annual incidence of approximately 8 per 100,000 and rarely occurs before the age of 20 years. Accordingly, the reported occurrence of ruptured aneurysms in 2.5 percent of patients with coarctation of the aorta suggests an association of these two disorders, although the coincidental occurrence of the two conditions cannot be completely excluded.

Headache is a common accompaniment of coarctation, perhaps as a result of secondary hypertension, but, again, the incidental occurrence of two unrelated conditions cannot be excluded.

TABLE 2-7 ■ Neurologic Sequelae of Coarctation of the Aorta*

Sequela	Incidence (%)
Ruptured intracerebral aneurysms	2.5
Ischemic stroke during childhood	1.0
Neurogenic intermittent claudication†	7.5
Headache	25.0
Episodic loss of consciousness	3.0
Intracerebral hemorrhage‡	<1.0
Spinal cord compression‡	<1.0

*Based on a review of 200 patients with coarctation of the aorta. Tyler HR, Clark DB: Neurologic complications in patients with coarctation of aorta. Neurology 8:712, 1958.

†Patients with exercise-induced motor or sensory disturbances in the lower extremities.

‡These complications were not found in the series reported by Tyler and Clark but have been reported by others, as described elsewhere.[1]

Episodic loss of consciousness may occur in patients with coarctation of the aorta. It may result either from syncope due to associated cardiac abnormalities or from seizures. It is unclear, however, whether seizures unrelated to cerebrovascular disease are more prevalent in these patients than in the general population.

Neurogenic intermittent claudication can result from aortic coarctation. In patients with coarctation of the aorta, blood flow to the legs is often provided by collateral connections between the spinal arteries and the distal aorta. In these situations, the blood flow through the radiculomedullary and intercostal arteries distal to the obstruction is reversed, and the exercise-related spinal ischemia may be related to "steal" by the increased metabolic demands (and thus increased blood flow) of the legs rather than aortic hypotension distal to the coarctation (Fig. 2-13). These collaterals are sometimes so extensive that they cause spinal cord compression and mimic (clinically and radiologically) vascular malformations of the spinal cord. Spinal cord injury can rarely follow surgical repair of a coarctation, and this complication may be delayed by several months following the repair.

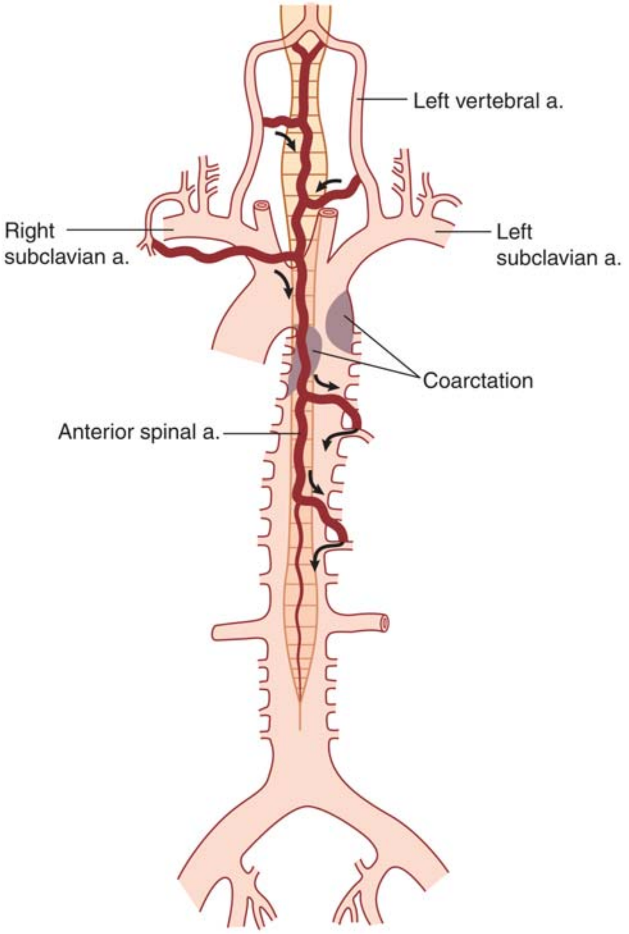

FIGURE 2-13 ■ Mechanism of steal in coarctation of the aorta. Obstruction of the aorta at the isthmus causes dilatation of the anterior spinal artery and reversal of blood flow in anterior radiculomedullary arteries distal to the obstruction. In this circumstance, the blood flow to the lower extremities is provided by these (and other) collaterals, and use of the lower extremities may cause shunting of blood from the spinal circulation to the legs, which, in turn, sometimes results in spinal cord ischemia.

Surgery and Other Procedures

AORTIC SURGERY

As with diseases of the aorta, the risks of aortic surgery depend in part on the site of operation. Thus, operations on the aortic arch may produce cerebral ischemia either by intraoperative occlusion of major vessels or by embolization of material such as calcified plaque loosened during surgery. Operations on the suprarenal aorta may result in spinal ischemia, whereas operations on the distal aorta may result in sexual dysfunction or ischemia of the femoral nerve.

The major complication of all aortic operations, however, is intraoperative spinal cord ischemia with resultant paraplegia or paraparesis. The occurrence of this complication varies with the location of the surgery and the nature of the pathologic process affecting the aorta (Table 2-8). Thus, operations on dissecting or nondissecting aortic aneurysms that are entirely abdominal are associated with a lower incidence of this complication than operations on aneurysms confined to the thoracic aorta. Surgery on aneurysms involving the entire abdominal and thoracic aorta carries the highest risk of producing cord ischemia. Operations on the distal aorta for occlusive disease only rarely result in spinal ischemia, especially when confined to the infrarenal portion. This variability presumably occurs because important feeding arteries to the spinal circulation are more likely to be ligated during surgery, included within the segment of the aorta that is cross-clamped, or subjected to distal hypotension when the aortic lesion is above the level of origin of the renal arteries.

Operations on the thoracic aorta for coarctation are much less frequently complicated by spinal ischemia than thoracic operations done for other reasons.

TABLE 2-8 ■ Spinal Cord Ischemia During Surgery and Procedures on the Aorta

Diagnosis	Number of Patients	Percentage with Spinal Cord Damage
Nondissecting aortic aneurysm		
Abdominal	1,724	0.46
Thoracic	585	6.3
Thoracoabdominal	102	21.6
Dissecting aortic aneurysm	102	30.4
Abdominal aortic occlusion	1,089	0
Coarctation of aorta	12,532	0.41
Aortography	17,949	0.01

From Goodin DS: Neurologic sequelae of aortic disease and surgery. p. 23. In Aminoff MJ (ed): Neurology and General Medicine. 4th Ed. Churchill Livingstone Elsevier, Philadelphia, 2008, with permission.

There are probably at least two reasons for this difference. First, the former patients are younger, and the extent of overall arterial disease is therefore less. Second, as mentioned earlier, the flow in the radiculomedullary vessels below the coarctation is frequently reversed, so obstruction of blood flow in them (either by ligation or cross-clamping the aorta above and below their origin) may actually result in an increased blood supply to the spinal cord.

Aortography and Other Procedures on the Aorta

Aortography may be associated with either spinal or cerebral ischemia, depending on the portion of the aorta visualized. This complication, however, is distinctly rare (Table 2-8). Paraplegia may also occur during intra-aortic balloon assistance after myocardial revascularization.

Intraoperative Adjuncts to Avoid Spinal Cord Ischemia

Several adjuncts are commonly used during surgery in an attempt to avoid spinal cord injury. They include the use of hypothermia and maintenance of mild intraoperative hypertension in addition to thiopental anesthesia and/or the administration of naltrexone and intraoperative corticosteroids, all of which are thought to reduce the metabolic requirements of the spinal cord or otherwise enhance tolerance to ischemia. In addition, many authors have reported that minimization of cross-clamp time results in a lower incidence of spinal ischemia.

Other adjunctive methods such as the reattachment of intercostal arteries, the use of shunts to maintain distal perfusion pressure, and the use of cerebrospinal fluid drainage have not proved consistently effective at preventing spinal cord ischemia, although the more recent experience with such adjunctive techniques has been quite favorable.[19] Part of the difficulty with these procedures may relate to the extreme variability of the blood supply to the spinal cord. For example, if a crucial spinal artery leaves the aorta within the cross-clamped section, the preservation of distal blood flow is irrelevant. Furthermore, because the important intercostal arteries are few and unpredictably situated, the random reattachment of a few intercostal arteries may be fruitless. Spinal cord ischemia can also be delayed and occur hours to days following the aortic operation. In these circumstances, the maintenance of mild hypertension coupled with the use of supplemental oxygen and cerebrospinal fluid drainage may mitigate the consequences.

There has been considerable interest in the use of somatosensory evoked potentials (SEPs) and motor evoked potentials (MEPs) for assessing spinal cord function during operations on the aorta. The combined use of SEPs and MEPs may ultimately prove better than either technique alone, and, indeed, the most recent reports with both techniques have been encouraging. An approach that seems particularly valuable is the use of intraoperative MEPs or SEPs to identify those vessels that perfuse the spinal cord and therefore need reattachment, should not be sacrificed, or should not be included within the aortic cross-clamp. Another approach that has been reported to be useful is the use of intraoperative MEPs to monitor patients and to quickly increase both the distal aortic pressure and the mean arterial pressure in response to a drop in MEP amplitude. Nevertheless, although these reports are encouraging, the best method of monitoring intraoperative spinal cord function and how best to use the information to alter the operative technique so that postoperative spinal cord function is maintained are yet to be determined.

PREOPERATIVE PREVENTION OF NEUROLOGIC COMPLICATIONS
NEUROLOGIC SEQUELAE OF CARDIAC TRANSPLANTATION

Cardiac surgery, including coronary artery bypass grafting (CABG), extracorporeal circulation, and aortic valve replacement, has the potential to significantly improve patients' functional status and reduce mortality; however, neurologic complications of surgery can limit and even eradicate these potential benefits. Perioperative and postoperative central and peripheral nervous system injury, especially stroke and delirium, can lead to permanent disability and hinder recovery from surgery. These complications can prolong hospitalization stay and increase the risk of medical complications and mortality. Identification of high-risk patients, enactment of preventive measures, and early recognition of reversible neurologic injury remains challenging but an important problem for both the cardiac surgical team and the consulting neurologist.

NEUROLOGIC SEQUELAE OF CORONARY ARTERY BYPASS GRAFTING

Although there has a been a decline in the number of CABG procedures in the United States over the last decade, due to an increase in percutaneous revascularization procedures, it remains one of the most commonly performed major surgical procedures, with approximately 400,000 operations done annually per year. CABG involves the use of autologous arteries and veins as grafts to bypass partially or completely obstructed coronary arteries affected by atherosclerotic disease. The most commonly used bypass conduits are the left internal thoracic artery and the greater saphenous vein, with left internal thoracic artery grafts to the left anterior descending coronary artery in particular associated with higher long-term patency rates and clinical outcomes. The heart is usually arrested during the grafting procedure, necessitating the use of a cardiopulmonary bypass machine, which then provides perfusion pressure (including cerebral perfusion) and oxygenation during the typical 1 to 2 hour period of cardiac arrest. Due to an increased frequency of percutaneous revascularization and more recently developed minimally invasive grafting options—which often do not require cardiopulmonary bypass—patient selection for CABG is rigorous, with major considerations involving coronary artery anatomy, extent of disease, prior failed procedures, and medical comorbidities.[1]

Stroke After Coronary Artery Bypass Grafting

The rate of stroke in patients undergoing CABG has decreased over the past few decades, with most series reporting a rate of less than 2 percent.[1] Clinically silent stroke detected by magnetic resonance imaging (MRI) may occur at a higher rate, and often these strokes are multifocal. A large single-center review of more than 40,000 patients found that the rate of stroke decreased over a 30-year span despite increasing patient risk profile.[2] When stroke does occur, it leads to a significant increase in hospital mortality, prolongs length of stay in the intensive care unit and the hospital, results in significant disability, and typically requires inpatient rehabilitation or nursing home placement at the time of hospital discharge.

In patients with acute neurologic symptoms concerning for stroke, brain imaging is important to rule out alternative etiologies and to help elucidate the etiology of stroke and overall burden to inform prognosis for neurologic recovery. Ischemic stroke following cardiac surgery is usually the result of either emboli or hypoperfusion. Watershed infarction occurs at the border zone between major cerebral arteries and often involves the subcortical white matter on MRI scans; it is suggestive of stroke due to hypoperfusion and is a common pattern of ischemia in patients who were exposed to decreased cerebral perfusion. Embolic stroke is often related to emboli from the heart or proximal aorta and is typically multifocal on imaging, involving all vascular territories. Although patients in the postoperative period following CABG are not candidates for systemic intravenous thrombolysis therapy, given the advent of extended windows for endovascular therapy it is important to pursue computed tomography (CT) angiography to identify large-vessel occlusions and facilitate thrombectomy discussions with a local stroke center.

Intracerebral hemorrhage is rare after CABG but may necessitate urgent medical and surgical treatment and decompression. It can occur during cardiopulmonary bypass due to effects on platelet adhesion and coagulation factors, but it most commonly occurs due to hemorrhagic conversion of an area of cerebral infarction. Rarely, cardiopulmonary bypass is complicated by pituitary apoplexy resulting from acute hemorrhage or infarction of an unrecognized pituitary adenoma during surgery; patients awaken with headache, ptosis, visual impairment, and ophthalmoplegia and may require transsphenoidal surgical decompression.

Intraoperative stroke represents between 30 and 50 percent of all strokes associated with CABG, and about half of these events are felt to be due to hypoperfusion. A decrease of mean arterial pressure of more than 10 mmHg is an important predictor of watershed strokes, and a prolonged cardiopulmonary bypass time exceeding 2 hours is associated with a higher rate of stroke.

Thromboembolic stroke also occurs intraoperatively and is related to specific surgical factors. For example, manipulation of the aorta during cannulation and cross-clamping can lead to dislodgement of atheroma or calcium. Studies using ultrasound to detect cerebral emboli have noted increased frequency of emboli during these moments of aortic manipulation. Stroke also occurs at higher frequency when valvular heart surgery is combined with CABG due to the additional risk of cerebral macroemboli associated with removal or repair of diseased heart valves. There have been multiple studies comparing the risk of stroke between "off pump" CABG techniques, wherein cardiopulmonary bypass machines were not used, compared to "on pump" CABG, and the overall results are conflicting, with rates likely varying due to differences in patient selection and preoperative risk factors.[2–4] Less common causes of embolic stroke include surgical complications such as air emboli, which can propagate into the cerebral vasculature and often present with focal stroke symptoms, encephalopathy, or seizures.

The majority of postoperative strokes following CABG occurs during the first 7 days after surgery. New-onset postoperative atrial fibrillation occurs in up to 30 percent of patients following CABG, especially within the first 3 days, and is associated with a higher risk of stroke. Low cardiac output after CABG is also associated with stroke due to hypoperfusion. After the first week, patients post-CABG remain at higher risk for stroke although this is largely related to a greater risk for thromboembolic events due to comorbidities such as older age, hypertension, diabetes mellitus, dyslipidemia, peripheral vascular disease, higher rates of chronic atrial fibrillation, and the need for further revascularization procedures.[2–4]

Ischemic complications following CABG can lead to visual disorders and symptoms. Retinal abnormalities on examination are common after CABG, including multifocal areas of retinal nonperfusion and cotton wool spots or retinal emboli; these findings are usually not associated with diminished visual acuity. Much less common, but more likely to cause visual impairment, is ischemic optic neuropathy. Anterior ischemic optic neuropathy due to infarction of the optic nerve head is associated with monocular, painless, and often permanent visual impairment along with optic disc swelling on examination. Visual testing may reveal central scotoma or altitudinal deficits. Retrobulbar or posterior ischemic optic neuropathy is rare and is often seen after a period of hypoperfusion; it is due to infarction of the intraorbital nerve and presents with acute blindness, which can be bilateral, without optic disc swelling on fundoscopic examination. The presence of a homonymous visual field deficit or cortical blindness (associated with normal pupillary and retinal examination) should prompt urgent imaging to evaluate for occipital lobe injury. Similarly, gaze deviation or gaze paralysis in the postoperative setting may suggest brainstem or hemispheric stroke.

Nonstroke Neurologic Complications After Coronary Artery Bypass Grafting

Encephalopathy is common after CABG surgery, occurring in between 10 and 30 percent of patients, and has a variety of etiologies. Delirium, an acute disorder of fluctuating attention and confusion, is more common in patients older than 65 years, and is associated with prolonged hospital length of stay and complications following surgery. Patients may present with hyperactive agitation, visual hallucinations, confusion, or hypoactive states. Aside from older age, preoperative risk factors for the development of delirium after cardiac surgery include baseline neurocognitive dysfunction, a history of prior stroke, a history of depression, baseline renal dysfunction, and a low serum albumin level. Postoperative associations with delirium include the need for mechanical ventilation for more than 24 hours, prolonged operating time, postoperative stroke, worsening renal function, and the use of benzodiazepines.[5] Onset of encephalopathy should also prompt an appropriate diagnostic work-up to rule out and correct inciting factors such as multifocal stroke, metabolic disorders including sodium disturbances and hypoglycemia due to excess insulin and decreased nutritional states around the time of surgery, and systemic infection including pneumonia and urinary tract infection.

Encephalopathy presenting as persistent coma is rare but usually suggests severe neurologic dysfunction with a poor neurologic prognosis. The most common causes include a large burden of stroke (usually involving the brainstem or bilateral cerebral hemispheres) or global hypoxic ischemic injury. The latter is often due to dysrhythmia, mechanical injury to the heart, or frank cardiac arrest.[5]

Seizures occur in up to 1 percent of patients after cardiac surgery including CABG and may be due to acute or recent stroke, metabolic derangements, hypoxic ischemic brain injury, or exposure to medications including high-dose tranexamic acid, procainamide, and lidocaine. Unrecognized alcohol dependence or inadvertent cessation of chronic medications such as benzodiazepines or anticonvulsants in the perioperative period may also cause seizures due to withdrawal. Seizures without clear tonic-clonic or focal motor manifestations may be difficult to recognize and patients may present with prolonged alteration in mental status or subtle findings such as intermittent gaze deviation or nystagmoid movements. As such, evaluation with electroencephalography can be valuable in the encephalopathic postoperative patient.

Peripheral nervous system complications after CABG are often related to mechanical factors leading to compression or stretch injury of nerves adjacent to the surgical field or those that are susceptible due to patient positioning factors. Brachial plexopathy has been reported to occur after cardiac surgery in 1 to 5 percent of patients who undergo median sternotomy. The lower trunk is the most commonly involved and clinically may mimic an ulnar neuropathy; the loss of the triceps reflex on the affected side helps distinguish plexopathy from a more peripheral lesion. There is usually weakness of intrinsic hand muscles, sensory loss or pain over the medial hand, and rarely, Horner syndrome. Risk factors include sternal retraction, direct trauma due to first rib fracture, and adducted arm position. Deficits usually reverse within 1 to 3 months, but may lead to more prolonged and permanent disability in some patients. Intraoperative electrophysiologic monitoring of sensory nerve conduction may help to detect and predict postoperative nerve injury and potentially allow for adjustment of intraoperative factors to decrease the incidence and severity of injury. Prevention strategies including more precise midline sternotomy, more caudal placement of retractors, avoiding asymmetric retraction, and maintaining neutral head and arm abduction positioning with appropriate cushioning, may help reduce the frequency of brachial plexopathy.[6]

Unilateral phrenic nerve injury, leading to hemidiaphragmatic paralysis, occurs in over 10 percent of patients after open-heart surgery. The left phrenic nerve lies along the pericardium between the lung and the mediastinal aspect of the pleura, making it particularly vulnerable to injury from manipulation and the effects of topical hypothermia related to cold cardioplegia. Although unilateral phrenic nerve injury may increase the risk of respiratory complications and atelectasis, the overall morbidity is generally low, and patients often experience recovery by around 6 months. Bilateral phrenic nerve injury is a much more rare complication and leads to prolonged mechanical ventilation.[6]

Less common mononeuropathies relate to injury of the recurrent laryngeal nerve and saphenous nerve. Similar to phrenic nerve injury, complications of internal thoracic artery dissection in combination with topical hypothermia can be associated with recurrent laryngeal nerve injury; patients present with hoarseness, ineffective cough, and aspiration when severe. Harvesting of the saphenous vein for CABG can lead to saphenous nerve injury, leading to decreased sensation, hyperesthesia, and pain along the medial lower leg.[6]

Although not unique to cardiac surgery, there is also growing recognition of surgery as a risk factor for development of acute inflammatory demyelinating polyradiculoneuropathy as a cause of postoperative quadriparesis and respiratory failure. Critical illness polyneuropathy and myopathy may develop in patients whose postoperative course has been complicated by sepsis, multi-organ failure, and prolonged use of paralytic medications or steroids. It can lead to difficulty weaning from mechanical ventilation and a higher risk of complications related to immobility in the hospital.

Neuropsychologic studies of cognitive function before and after CABG have identified both a short-term early cognitive decline immediately after surgery and a later-onset decline about 3 to 5 years after surgery. The early decline is usually reversible on the order of weeks or a few months, and is often associated with delirium during hospitalization. Similar short-term declines have also been reported in patients who underwent noncardiac surgery, suggesting that exposure to anesthesia may contribute to symptoms in vulnerable patients, and formal studies with serial neuropsychologic testing up to 1 year after CABG have showed that cognitive changes over this time are similar compared to patients who received percutaneous coronary intervention; therefore, common pretreatment cardiac and cerebrovascular disease and vascular risk factors likely also contribute to development of symptoms.[1,5,7]

Later-onset cognitive decline was found in up to 40 percent of patients after CABG at long-term follow-up 5 years after surgery when performance on cognitive testing was compared to baseline testing. At that time, it was assumed not only that late cognitive decline was common, but also that it was due to "on pump" cardiopulmonary bypass time in particular and the delayed effect of diffuse microemboli exposure during CABG. However, these initial studies lacked both unoperated patients with coronary artery disease and healthy patient control comparison groups. Subsequent studies shows that this delayed cognitive decline is not specific to patients who had "on pump" CABG. There are no significant differences in cognitive function 3 years after surgery in patients who had CABG with and without cardiopulmonary bypass, patients with nonsurgically treated coronary artery disease, and healthy controls; at 6 years, all three groups with coronary artery disease showed a similar degree of cognitive decline that was greater than the healthy control group. Studies of patients treated "on pump" and "off pump" during CABG showed no difference in cognitive performance 5 years after surgery. Taken together, there is no clear evidence that cardiopulmonary bypass is the major contributor to this observed late cognitive decline.[1,7]

It therefore seems that preoperative cerebrovascular disease is more closely associated with the risk of delayed onset cognitive decline, due to a slow accumulation of ischemic brain injury related to ongoing vascular risk factors. Patients who had brain MRI scans showing evidence of prior cerebral ischemia before CABG have been found to have higher risk of subsequent cognitive decline. These findings highlight the importance of medical control of vascular risk factors to potentially reduce the risk of slow cognitive decline in this patient population.[7]

NEUROLOGIC SEQUELAE OF EXTRACORPOREAL CIRCULATION

The introduction of cardiopulmonary bypass over 70 years ago was the crucial development that led to modern cardiac surgery. However, it is associated with neurologic complications that are related to the procedure itself and which increase in likelihood as its duration is extended. Over the last decade, there has been a marked increase in the use of extracorporeal membrane oxygenation (ECMO), which allows for more prolonged cardiopulmonary support in patients with refractory respiratory or cardiac failure, and this patient population is at high risk for neurologic complications including ischemic stroke, cerebral hemorrhage, and hypoxic-ischemic brain injury.

For open-heart surgery, cardiopulmonary bypass requires cannulation of the ascending aorta and vena cava or right atrium, with drainage of venous blood to a reservoir which is then pumped through a membrane oxygenator and then routed via a filter to a cannula of the aortic arch (Fig. 3-1). The procedure requires clamping and cannulation of the aorta, which can lead to dislodging of atheromatous material in a diseased aorta and cause cerebral ischemia via embolization. Similarly, the high-velocity or turbulent blood flow from the end of the cannula can also lead to embolization of atheroma. As atherosclerotic disease is exceedingly common in patients with coronary artery disease, especially in patients over the age of 70, identification of aortic atheroma with intraoperative transesophageal echocardiography or epiaortic ultrasound may help dictate surgical planning.[8]

Extracorporeal circulation is facilitated by systemic heparinization and hemodilution, as the exposure

FIGURE 3-1 ■ Schematic of an extracorporeal circulation circuit used in cardiopulmonary bypass surgery. (Modified from Machin D, Allsage C: Principles of cardiopulmonary bypass. Contin Educ Anaesth Crit Care Pain 6:176, 2006 with permission from Oxford University Press.)

to bypass circuits leads to a prothrombotic systemic inflammatory response. As such, anticoagulation is used to prevent thrombus formation, and hemodilution helps reduce blood viscosity. In addition, hypothermia is often used for neuroprotection during cardiac bypass for surgery, and it is recommended that rewarming occur slowly, with care to avoid temperatures above 37°C in order to prevent secondary neurologic injury; this is felt to be of particular importance in patients with known cerebrovascular disease prior to surgery. Evidence-based intraoperative guidelines for heart surgery with cardiopulmonary bypass have been published with an aim of minimizing risk of brain ischemia. One set of guidelines is summarized in Table 3-1.[8]

TABLE 3-1 ■ Evidence-Based Cardiopulmonary Bypass Practices that May Improve Neurologic Outcome

Practice	Class/Level of Evidence*	Mechanism
Arterial filtration	Class I/Level A	Minimize emboli
Intraoperative aortic imaging	Class I/Level B	Identify aortic plaque
	Class IIb/Level B	Reduce emboli
Minimize direct reinfusion of pericardial suction blood	Class I/Level B	Reduce emboli and prothrombotic systemic inflammatory response
Process and filter pericardial suction blood before reinfusion	Class IIb/Level B	
Alpha-stat pH management	Class I/Level A	Maintain metabolic coupled cerebral blood flow
Limit arterial line temperature to 37°C during rewarming	Class IIa/Level B	Avoid brain hyperthermia
Reduce blood contact with nonbiocompatible surface of cardiopulmonary bypass circuits	Class IIa/Level B	Reduce prothrombotic systemic inflammatory response
Maintain normal perioperative glucose levels	Class I/Level B	Avoid hyperglycemia
Reduce hemodilution	Class I/Level A	Avoid very low hematocrit

*Class I—Procedure or treatment should be performed. Class IIa—Reasonable to perform procedure or treatment; additional focused studies needed. Class IIb—Consider procedure or treatment; additional broad studies needed. Level A—Recommendation derived from multiple randomized studies. Level B—Recommendation derived from single randomized or multiple nonrandomized studies.

Neurologic Complications of Extracorporeal Membrane Oxygenation

Analogous to cardiopulmonary bypass for cardiac surgery, ECMO is increasingly used for the management of severe cardiac or respiratory failure, affording longer-term cardiopulmonary support either as a bridge to other therapies or to allow more time for recovery when conventional therapies are unsuccessful. Venous drainage usually occurs from the inferior vena cava or right atrium with extracorporeal oxygenation performed via artificial membranes. Oxygenated blood is returned via the femoral artery or ascending aorta in venoarterial (VA) ECMO which is often used for cardiogenic shock and cardiac failure as a bridge to recovery, ventricular assist device insertion, or cardiac transplantation. Venovenous (VV) ECMO involves return of blood through the superior vena cava, and is often used for respiratory failure due to infection, interstitial lung disease, or aspiration. The use of ECMO has dramatically increased over the last decade following worldwide influenza pandemics, but mortality and morbidity remain high, with neurologic complications being associated with particularly high mortality.[9]

Exact estimates of the rates of neurologic complications are challenging across series of ECMO patients given variable definitions and methodologies for detection, but overall they seem to be underestimated and occur in at least 10 to 15 percent of cases. In general, neurologic complications are reported more frequently with VA ECMO compared to VV ECMO, and although the mortality of patients on ECMO is already high due to the severity of the underlying disease state, mortality is substantially higher in patients who develop neurologic complications on ECMO compared to those who do not, approaching 100 percent in some series. Complications are more common in patients with pre-ECMO pyrexia, hypoglycemia, and need for inotropes, and also in patients whose ECMO indication is cardiac arrest or shock. Rapid correction of severe hypercapnia due to respiratory failure has also been implicated as a contributor to neurologic complications due to resultant cerebral vasoconstriction and impairment of cerebral autoregulation.[9,10]

Intracerebral hemorrhage is the most frequent neurologic complication associated with ECMO, with reports ranging from 5 to 10 percent of all patients, and it also carries the highest mortality, ranging from 90 to 100 percent. Risk factors for intracerebral hemorrhage include female sex; renal dysfunction and need for dialysis; coagulopathy including thrombocytopenia and decreased fibrinogen levels; and prolonged duration of mechanical ventilation and ECMO. Mechanistically, the need for anticoagulation likely contributes to the risk of hemorrhage and hematoma expansion after onset, but changes in cerebral vascular tone and hemorrhagic conversion of ischemic tissue are also key factors contributing to the high rate of hemorrhage. The systemic inflammatory response that is initiated when blood contacts ECMO circuitry also leads to an increased risk of hemorrhage. Treatment including reversal of anticoagulation, surgical decompression, and hematoma evacuation, has not been shown to clearly impact the high rates of mortality or permanent disability.[9,10]

Ischemic stroke is the second most common neurologic complication for patients on ECMO. Data regarding the most likely patterns or size of ischemic strokes are lacking, but mortality approaches 50 percent in multiple patient series. Disease-related risk factors include underlying coagulopathy, atrial fibrillation, and decreased cardiac output and hypotension, while ECMO-specific factors include impaired cerebral vascular autoregulation and embolic disease related to clots or air within the extracorporeal system. The rate of ischemic stroke is higher in VA ECMO as blood is returned directly into the arterial system. There are reports of successful acute treatment of large-vessel occlusion with mechanical thrombectomy in patients on ECMO but this intervention requires rapid detection and diagnosis of acute stroke which can be difficult in these patients who often require sedation while on ECMO. Spinal cord ischemia has also been reported in patients on ECMO, often when patients also require an intra-aortic balloon pump.[9,10]

Other neurologic complications include seizures, which may be related to cerebral hypoxia, focal hemorrhage, or stroke. Patients on ECMO are also at risk for peripheral nerve injury including compressive neuropathies during cannulation (depending on the site), secondary nerve injury if ECMO is complicated by local limb compartment syndrome or limb ischemia, or from prolonged static positioning and immobility. Femoral and sciatic neuropathy can occur with proximal leg vascular access in particular. Global cerebral hypoxic ischemic encephalopathy and brain death are commonly reported in patients with neurologic injury on ECMO.

Prevention of neurologic injury is challenging given that many of these risk factors are not easily modifiable. Avoidance of atheromatous segments of arteries during cannulation can help reduce procedure-related stroke, and care should be taken to avoid a rapid reduction of carbon dioxide. Anticoagulation goals can be adjusted and lowered in particularly high-risk patients. Mobility programs can be used to avoid prolonged immobility and to help prevent compressive neuropathies. As some acute neurologic processes such as large-vessel occlusion or seizures can be treated and reversed, it is also important to develop protocols to ensure daily neurologic examination with interruption of sedation and neuromuscular blockade to allow for detection of injury. Electroencephalograpic monitoring may be helpful, especially to look for nonconvulsive seizures. MRI is usually not possible with patients on ECMO, so CT imaging should be performed when there are concerns for acute cerebral injury. In the future, other biomarkers such as near-infrared spectroscopy monitoring of cerebral oxygen saturation and serum testing for markers of neuronal injury such as glial fibrillary acidic protein and neuron-specific enolase may be used more routinely to help guide hemodynamic parameters, identify changes due to acute neurologic injury, and prognosticate the degree of cerebral injury and recovery potential.[9,10]

NEUROLOGIC SEQUELAE OF CARDIAC VALVULAR SURGERY

Symptomatic severe aortic stenosis is associated with progressive congestive heart failure and exertional dyspnea, syncope, and angina, and carries a high mortality if not treated. Valve repair or replacement is considered definitive treatment and should be considered for patients with symptomatic stenosis and asymptomatic patients with imaging evidence of severe stenosis and either decreased cardiac output or symptoms on exercise testing; it should also be considered in those who are undergoing other cardiac surgery or those with very severe stenosis alone who are simply felt to be at low surgical risk.

Surgical aortic valve replacement classically involves sternotomy and open-heart surgery with cardiopulmonary machine bypass, similar to CABG. Transcatheter aortic valve replacement (TAVR) has become an established and increasingly frequent treatment alternative to surgical repair and involves a transfemoral, transapical, or transaortic catheter approach with endovascular placement of a balloon-expandable valve device to replace the native diseased valve. The decision regarding surgical versus transcatheter valve replacement is made by a multidisciplinary clinical team and involves assessment of surgical risk, risk of mortality and likelihood of improvement of quality of life, anatomic features of the aortic valve and vascular system, age of the patient, and the need for other cardiac surgery.

Surgical valve replacement is often preferred in younger patients, those with lower surgical risk, those who need mechanical valves, and those with specific anatomic considerations that require an open-heart approach. The rate of ischemic stroke in the early postoperative period (less than 30 days) is around 1 to 5 percent for isolated aortic valve surgery, and the risk is increased if valve surgery is combined with CABG. Surgical repair carries the risk of gas emboli from the release of intracardiac air and the procedure requires adequate de-airing and clearing of blood surrounding the aortic root, atria, and ventricles. Life-long anticoagulation is needed after mechanical valve placement for stroke and systemic embolus prevention, usually with a goal for an international normalized ratio of 2.5 to 3.5. Bioprosthetic valve embolus prevention often includes 1 year of aspirin and anticoagulation, followed by aspirin alone.[11]

Early trials involving TAVR in high-risk surgical patients revealed a higher rate of ischemic stroke in the early post-procedure period compared to surgical replacement. However, more recent trials have shown either no difference in the stroke rate or lower early stroke rates following TAVR, a difference that has been attributed to more precise neurologic injury detection methods compared with previous trials as well as presumed technical improvements in devices and delivery systems.[11] Trials have also demonstrated similar rates of stroke events up to 1 year after the procedure. The rate of stroke is highest in the immediate post-procedural time window (usually the first 48–72 hours), and the vast majority of strokes are thromboembolic in nature. Strokes occurring after 30 days involve hemorrhagic events in a quarter of patients. Periprocedural stroke after TAVR is often secondary to catheter wire manipulation or advancement of devices through an atherosclerotic aortic arch, root, or calcified aortic valve. Balloon post-dilation aortic insufficiency after TAVR can also increase risk of embolic stroke.[11,12]

Stroke after surgical valve replacement and TAVR is associated with an increased mortality and decreased quality of life. Efforts to reduce the risk of stroke after TAVR have included the use of cerebral embolic protection devices during the procedure, various different antiplatelet (monotherapy versus dual therapy) or anticoagulant strategies, preprocedure imaging evaluation of vascular structures to help with catheter advancement planning, and technical improvements reducing aortic manipulation time.[12] A retrospective cohort of over 100,000 patients who received TAVR between 2011 and 2017, however, found that there was no change in the rate of stroke at 30 days after the procedure, staying at around 2 percent over the time period. Additional strategies to lower rates of stroke after TAVR remain an active area of research.[13]

Nonstroke complications after TAVR include encephalopathy and seizures. One trial found that the rate of encephalopathy was up to 8 percent in patients following surgical valve replacement compared to 2 percent in patients after TAVR.[12] Patients who have undergone aortic stenosis surgery are also at risk for hyperperfusion injury to the cerebrum due to preoperative impaired cerebral autoregulation and a post-procedure sudden increase in cardiac output; patients may present with focal neurologic deficits or global encephalopathy, often due to intracerebral hemorrhage or seizures. Careful and tight control of post-procedure blood pressure can potentially reduce the risk of both hyperperfusion injury and hypotensive-related ischemia.

PREOPERATIVE PREVENTION OF NEUROLOGIC COMPLICATIONS

Identification and modification (when possible) of preoperative risk factors that place patients at higher risk of neurologic complications is an important part of the cardiac surgery evaluation and treatment plan (Table 3-2). Older age is associated with a higher rate of neurologic complications after CABG, with risk increasing with every decade of life. Preoperative history of hypertension, diabetes mellitus, tobacco smoking, and dyslipidemia are independently associated with risk of stroke following CABG and efforts should be made to address these risk factors prior to surgery when possible. Preoperative statin and beta-blocker initiation may reduce the risk of postoperative stroke, and the latter may also potentially reduce the rate of postoperative atrial fibrillation. Early postoperative use of aspirin decreases ischemic complications after surgery.[4,7]

Prior stroke or transient ischemic attack (TIA) is also a risk factor for postoperative stroke, and

TABLE 3-2 ■ Risk Factors for Cerebral Ischemia During Cardiac Surgery

Preoperative
Older age > 70 years[4]
Hypertension[7]
Diabetes mellitus[4,7]
Smoking[4]
History of cerebrovascular disease[4,7]

Intraoperative
Prolonged cardiopulmonary bypass[4]
Combined coronary artery bypass and valvular surgeries
Large hemodynamic fluctuations[7]
Aorta cannulation and manipulation[7]
Postoperative
Atrial fibrillation[4,7]

timing of CABG or cardiac surgery following stroke depends on many factors including the size of the cerebral infarct and the urgency of cardiac intervention. Modern preoperative evaluation includes stroke risk assessment tools that account for the above factors, which can then be used to decide the most appropriate intervention for an individual patient (e.g., CABG versus percutaneous coronary revascularization) as well as technical operating factors (e.g., strategy for aortic manipulation and cannulation in a patient with identified atherosclerotic disease).

Symptomatic carotid stenosis, defined as a patient having a TIA or stroke in the distal circulation of an ipsilateral extracranial internal carotid artery with significant stenosis based on imaging criteria, is associated with a higher rate of stroke in patients undergoing CABG, although the mechanism of stroke is not usually related to carotid disease itself. Consensus clinical society guidelines note that in patients over the age of 65 and in those with left main coronary stenosis, peripheral vascular disease, a history of cigarette smoking, a history of stroke or TIA, or a carotid bruit on examination, it is reasonable to screen patients for carotid stenosis with duplex ultrasound screening prior to elective CABG surgery (Class IIa recommendation). In those who have greater than 80 percent carotid stenosis and have experienced ipsilateral retinal or hemispheric cerebral ischemic symptoms within 6 months of the planned surgery, carotid revascularization via carotid endarterectomy or carotid artery stenting before or concurrent with myocardial revascularization surgery is reasonable (Class IIa recommendation). In patients with asymptomatic carotid stenosis, even if severe, the safety and efficacy of carotid revascularization before or concurrent with myocardial revascularization are not well established (Class IIb recommendation).[14]

There is a lack of clear clinical trial data to definitively guide decisions about carotid revascularization technique and timing in preparation for cardiac surgery. However, expert recommendations suggest that carotid revascularization should be considered in patients with recently symptomatic carotid stenosis (50 to 99% in men, 70 to 99% in woman), bilateral asymptomatic carotid stenosis of 80 to 99 percent, or in unilateral asymptomatic stenosis of 70 to 99 percent when the contralateral vessel is 100 percent occluded. Choice of carotid stenting versus carotid endarterectomy may depend on numerous patient-specific factors including operative risk, but since stenting requires dual antiplatelet therapy after the procedure, it is not the ideal choice in patients with urgent indication for CABG given the higher risk of bleeding complications. As a result, endarterectomy may be a more favorable choice in patients with urgent indications for CABG. Carotid stenting prior to CABG has been associated with a lower risk of neurologic complications in some series compared to patients receiving combined endarterectomy with CABG, and this sequential strategy can be considered in patients who can wait longer for coronary revascularization procedure.[14]

NEUROLOGIC SEQUELAE OF CARDIAC TRANSPLANTATION

As with all cardiac surgery, cardiac transplantation for patients with end-stage cardiac failure refractory to medical therapy can substantially prolong life and decrease mortality. However, neurologic complications can significantly limit these potential benefits. In a series of over 300 patients who received cardiac transplantation, a perioperative neurologic complication occurred in nearly one-fifth of patients, most commonly encephalopathy and delirium followed by cerebrovascular complications.[15] Complications such as encephalopathy and peripheral nervous system disorders were often reversible, but cerebrovascular complications were associated with unfavorable functional outcome at 1 year after transplant. Follow-up occurred for up to 18 years and, over this time frame, there was an incidence of neurologic complications approaching 80 percent, most commonly sleep disorders, depression, and polyneuropathy. Cerebrovascular events occurred at a higher rate than in the general population over this follow-up period, with higher rates of intraparenchymal hemorrhage in particular. Central nervous system infections were uncommon, but were predictive of mortality.[15] For a more detailed discussion regarding neurologic complications after heart transplantation, see Chapter 44.

NEUROLOGIC MANIFESTATIONS OF BRAIN DYSFUNCTION
- Acute-Onset Movement Disorders
- Acute Symptomatic Seizures
- Epilepsy
- Neurodevelopmental Disability

Congenital heart disease (CHD) is the most common major congenital malformation, occurring in approximately 1 percent of live births worldwide. Among the 40,000 children born with CHD annually in the United States, one-quarter require surgical intervention in the first year of life. With advances in surgical technique and perioperative care, survival has dramatically improved for even the most complex cardiac defects, and currently, greater than 90 percent of children with severe CHD requiring early cardiac surgery are expected to live to adulthood. Despite these successes, the neurodevelopmental sequelae of complex CHD and its treatment have increasingly emerged. Children with CHD are at risk for a myriad of neurologic complications ranging from delayed brain development in utero to arterial ischemic stroke (AIS) in childhood and adulthood, often resulting in lasting neurodevelopmental disabilities. This chapter provides a review of important neurologic abnormalities seen in the context of CHD and its treatment.

COMPLEX CONGENITAL HEART DISEASE

Complex CHD is often defined as cyanotic heart defects or CHD requiring a neonatal operation (i.e., within the first 30 days of life). Children with complex CHD are at higher risk for neurologic complications, although all individuals with CHD, regardless of complexity, are at some risk. There is significant variability in the surgical management (corrective vs. palliative) and expected anatomic outcomes of each cardiac lesion. For example, children with hypoplastic left heart syndrome (HLHS) undergo single ventricle palliation, which requires a series of palliative surgical procedures typically culminating in a Fontan procedure, allowing passive flow of systemic venous return directly to the lungs while the single ventricle provides oxygenated blood to the body. Individuals with HLHS never achieve normal circulation, and despite these multiple operations, have prolonged periods of cyanosis. In contrast, neonates with transposition of the great arteries (TGA) or other biventricular defects undergo corrective operations (e.g., arterial switch operation for TGA patients), eventually restoring normal cardiac physiology. Even these children who achieve normal cardiac physiology after corrective neonatal surgery remain at risk of varying degrees of neurodevelopmental impairments. Because HLHS and TGA account for the majority of complex CHD, much of our understanding of the impact of complex CHD

Aminoff's Neurology and General Medicine, Sixth Edition.

on the brain and neurodevelopment is based on studies of children with these lesions.

Delayed Brain Development

Quantitative and qualitative magnetic resonance imaging (MRI) studies demonstrate that brain development is delayed in the context of CHD beginning in fetal life and persisting into childhood. Fetal brain MRI shows progressive impairment of brain volume during the third trimester in fetuses with complex CHD, particularly those with left-sided obstructive cardiac lesions.[1] In addition, fetuses with CHD have significant delays in brain metabolism, specifically the normal increase of brain *N*-acetyl-aspartate to choline ratios measured by magnetic resonance spectroscopy (MRS); these delays have been shown to be most prominent in fetuses with no antegrade flow in the aortic arch. Brain maturation is delayed by approximately 4 to 6 weeks in full-term newborns with complex CHD such as HLHS or TGA when compared to normal term infants in studies using brain MRI with diffusion-weighted imaging (DWI) and spectroscopy.[2] Morphometry studies have revealed lower total and regional brain volumes in newborns as well as adolescents with CHD compared to controls.

Aberrant cardiac physiology and abnormal blood flow in children with complex CHD is thought to result in delayed brain maturation beginning in the fetal period. Human cardiac development is largely completed by gestational week seven, while human brain development extends over a much longer period of time. In utero brain growth, myelination, and development of neuronal networks are dependent upon nutrients and oxygen pumped by the heart. To support rapid fetal brain maturation, blood flow to the brain increases throughout fetal life. By the third trimester, the brain is estimated to receive one-quarter of the total ventricular output, demonstrating the critical relationship between the heart and the brain. In the normal fetus, oxygenated blood from the placenta flows through the ductus venosus and preferentially streams across the foramen ovale to the left atrium and ventricle, providing highly oxygenated blood to the brain. In fetuses with TGA, the aorta and pulmonary artery are transposed and the highly oxygenated blood flows preferentially to the pulmonary vasculature rather than the cerebral vasculature. Similarly, in HLHS, inadequate left heart structures lead to reversal of blood flow through the foramen ovale with mixing of oxygenated and deoxygenated blood in the right ventricle and, in cases of aortic atresia, retrograde flow in the ascending aorta. This abnormal physiology results in decreased nutrient and oxygen delivery to the brain during critical fetal development.

Combined brain and cardiac MRI to measure fetal blood flow and oxygen saturation can be used to study the relationship between fetal hemodynamics and brain maturation. Fetuses with complex CHD demonstrate significantly lower cerebral oxygenation consumption and reduced brain volume compared with fetuses without CHD, supporting a link between brain hypoxia and impaired brain maturation. A previous investigation found that delayed surgery beyond 2 weeks of age in infants with TGA is associated with impaired brain growth on MRI and slower language development at 18 months of age compared to surgery before 2 weeks of age.[3] Prolonged periods of cyanosis and pulmonary overcirculation in children without early surgical repair may have adverse effects on brain growth and subsequent neurodevelopment.

Co-existing Genetic Disorders and Brain Malformations

Most congenital heart defects are thought to have a genetic basis, and the presence of a genetic condition is an independent risk factor for adverse neurodevelopmental outcome. Currently however, a genetic etiology is identified in only one-third of children with CHD. A few well-described chromosomal disorders (e.g., trisomies 21, 18, and 13), microdeletions (e.g., 22q11), and specific mutations (e.g., Noonan syndrome) account for a minority of patients with CHD and are associated with cognitive impairment. Nonsyndromic genetic abnormalities have also been associated with neurodevelopmental outcome. For example, in infants with complex CHD, the Apolipoprotein E ε2 allele is associated with worse early neurodevelopmental outcome, particularly motor development, independent of patient and operative factors. Currently unknown genetic and epigenetic factors may play an important additional role, as identified patient risk factors account for only about 30 percent of the expected variation in neurodevelopmental outcomes in children with CHD. In a recent study, pathogenic copy number variants were identified in greater than 10 percent of children with single ventricle lesions, only a minority of whom were noted to be dysmorphic on examination by a clinical geneticist. Genetic testing is now considered a part of standard care for all children with complex CHD.

In addition to delayed maturation, many children with CHD have structural brain malformations that may affect neurodevelopment. The prevalence of brain dysgenesis in children with CHD approaches 30 percent in some fetal MRI and autopsy studies, and varies according to the severity of CHD and the specific underlying cardiac lesion. Infants with HLHS may be at particular risk of developmental brain lesions including microcephaly, focal cortical dysplasia, agenesis of the corpus callosum, and holoprosencephaly. Brain and cardiac anomalies may occur together as a result of genetic and environmental factors, although in many children the specific genes or combination of genes that influence early anomalous development are not identified.

"Silent" Brain Injury in the Neonate

Neonates with complex CHD are at risk for acquired brain injury both pre- and postoperatively. The most common brain injuries observed in newborns with CHD are focal white matter injury (WMI) and small focal infarcts (defined as <1/3 of the arterial distribution), which are often missed by screening cranial ultrasound and more reliably detected with conventional MRI (Fig. 4-1). This type of brain injury typically occurs in the absence of neurologic signs and symptoms (i.e., "clinically silent"). Several large prospective studies using pre- and postoperative brain MRI to identify acquired brain injury in newborns with CHD have shown that up to 60 percent demonstrate evidence

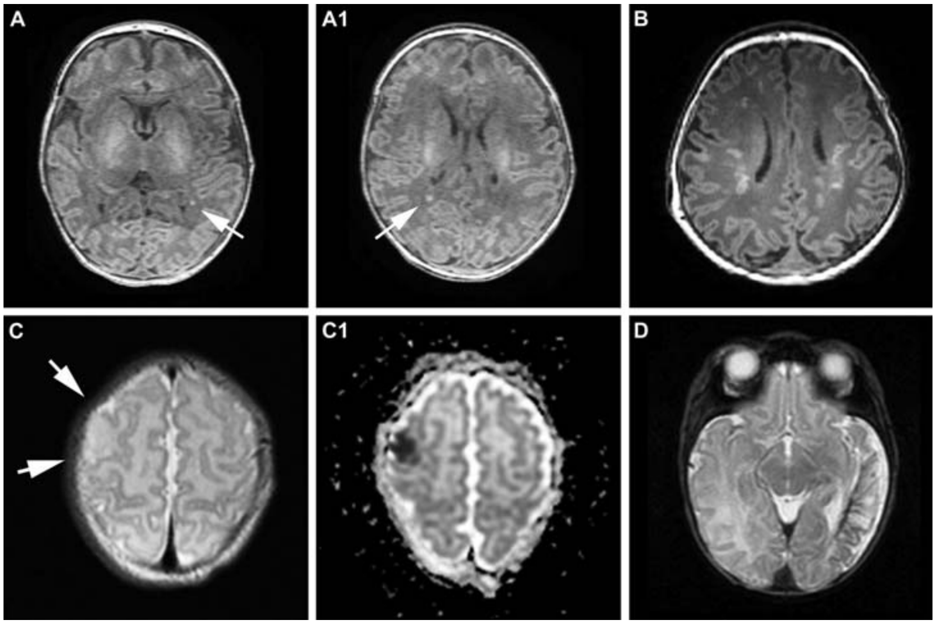

FIGURE 4-1 ■ Brain magnetic resonance imaging examples of subjects with varying degrees of white matter injury or stroke. *A, A1,* Preoperative T1-weighted images from a subject with hypoplastic left heart syndrome and moderate white matter injury (>3 foci or any foci >2 mm). There are at least two (*arrows*) small foci of hyperintensities consistent with white matter injury. *B,* Preoperative T1-weighed image from a subject with hypoplastic left heart syndrome and severe white matter injury (>5% of white matter volume). *C,* T2-weighed image from a preoperative scan on a subject with d-transposition of the great arteries. Arrows demonstrate a small focal stroke manifest as hyperintense cortical signal in the middle cerebral artery. *C1,* The corresponding average diffusivity map demonstrates reduced water diffusivity (*dark spot*) in the same region. *D,* T2-weighted image from a postoperative scan on a subject with d-transposition of the great arteries with a large subacute/chronic stroke in the middle cerebral artery distribution. (Adapted from Peyvandi S, Chau V, Guo T, et al: Neonatal brain injury and timing of neurodevelopmental assessment in patients with congenital heart disease. J Am Coll Cardiol 71:1986, 2018.[6])

of injury. Those with cyanotic heart disease are at the greatest risk.

WMI in term neonates with CHD is characterized by punctate periventricular lesions associated with T1 hyperintensity with or without DWI lesions suggesting acute injury. This pattern of injury is similar to that seen in premature infants termed "periventricular leukomalacia." The mechanism of brain injury in premature infants is thought to be due mainly to brain immaturity; oligodendrocytes during the third trimester are selectively vulnerable to hypoxia-ischemia, and therefore premature infants have a white matter-predominant pattern of injury. This mechanism of injury likely plays a key role in neonates with CHD who have preoperative brain injury. Qualitative MRI measurements of maturity have suggested that brain immaturity is a risk factor for both pre- and postoperative brain injury. Quantitative MRI techniques (e.g., diffusion tensor imaging and MRS), however, have demonstrated an association between brain immaturity and the risk of preoperative, but not postoperative, brain injury.[4] Given that WMI impacts neurodevelopmental outcomes, there remains a need for in utero strategies to improve brain development.

Estimates of the prevalence of preoperative brain injury in neonates with CHD requiring surgery range from 25 to 50 percent. Reported risk factors for preoperative brain injury include hypoxemia and time to surgery, preoperative base deficit, cardiac arrest, male sex, and the presence of aortic atresia (e.g., lack of antegrade flow in the aorta). Balloon atrial septostomy in neonates with TGA has been associated with preoperative AIS in some studies. Worse severity of preoperative injury has been shown to be significantly associated with higher neonatal illness severity scores, lower preoperative oxygen saturation, hypotension, and septostomy.[4] The clinically "silent" brain injuries identified preoperatively in neonates with CHD have a low risk of progression with surgery and cardiopulmonary bypass, and in most cases should not delay clinically necessary cardiac surgery, though expert multidisciplinary discussion is required for each case.[5]

New postoperative WMI is common, and several intra- and postoperative risk factors have been identified. Some, but not all, studies have identified circulatory arrest as a risk factor for new postoperative WMI on MRI. Other reported intraoperative risk factors include the method of blood pH management (alpha stat versus pH stat), hematocrit level, and maintaining regional cerebral perfusion during aortic arch reconstruction. In the postoperative period, overall hemodynamic stability plays an important role in mitigating the risk of new brain injury. Hypotension and hypoxemia related to low cardiac output syndrome increase the risk of brain injury. Patients with single ventricle heart disease in particular carry a higher risk of postoperative hemodynamic instability, correlating with higher risks for both postoperative brain injury as well as overall morbidity and mortality.

The "clinically silent" descriptor is misleading because these brain injuries influence later neurodevelopmental outcomes. A recent prospective longitudinal cohort study enrolled full-term newborns with single ventricle physiology or TGA, obtained pre- and postoperative MRI, and then conducted neurodevelopmental testing at 12 and 30 months of age.[6] Children with moderate to severe WMI in the neonatal period were found to have significant motor impairments at 30 months of age. However, no association was seen between small focal infarcts and outcome. Others have found that moderate-to-severe WMI is associated with reduced short-term cognitive scores and lower full-scale IQ during early childhood compared to the scores of those who have no or mild WMI.

Acute Cerebrovascular Complications

Children with cardiac disease often have disruptions in the balance of hemostasis, which may result in thrombosis, bleeding, or both. Timely and accurate diagnosis of these conditions have significant acute and longer-term management implications. Two American Heart Association/American Stroke Association (AHA/ASA) scientific statements provide a detailed review of the diagnostic evaluation and treatment of stroke in infants and children and identify important knowledge gaps in the field.[7,8]

Arterial Ischemic Stroke

Up to one-third of AISs in children results from cardiac disease. Children with CHD have a nearly 20-fold increased risk of AIS compared to the general population, and a history of cardiac surgery increases stroke risk more than 30-fold. The estimated incidence of AIS in children with cardiac disease is over 130 per 100,000 children per year, comprised primarily of children with CHD and only a small number who have acquired cardiac disease. The incidence of AIS in patients with single ventricle CHD is higher compared to those with other cardiac diagnoses (over 1,300 per 100,000 children per year). In most of these cases, the underlying cardiac disease has already been identified at the time of the stroke. While the majority of childhood strokes related to CHD occur in those who have complex congenital heart lesions with right-to-left shunting and cyanosis, stroke has been described in association with essentially all types of CHD (Table 4-1). Recent data in adults show increased risk of arrhythmia and stroke in the setting of a history of a congenital atrial septal defect. The clinical significance of patent foramen ovale in childhood stroke is currently uncertain and is an area that requires further study.

Children with complex CHD are at particularly increased risk of AIS during the neonatal period, but this increased risk extends throughout childhood and into adulthood. About one-quarter to one-half of symptomatic AIS in children with complex CHD occurs during the first month of life. Detection of acute focal neurologic injury among neonates with CHD is challenging as neurologic deficits are often subtle. New-onset seizure is the most frequent clinical manifestation of acute neonatal AIS. In older children with CHD who present with a stroke, hemiparesis is seen in up to three-quarters and seizures in up to half.

Children with AIS in the setting of CHD have significant neurologic morbidity following stroke. About three-quarters will have persistent focal neurologic deficits, and 20 percent go on to develop epilepsy. Mortality after stroke may be higher in children with CHD compared to children with stroke and no CHD, likely reflecting the severity of underlying cardiac disease. In a study of children with CHD at the Toronto site of the Canadian Pediatric Ischemic Stroke Registry, the case fatality rate was 15 percent at a median of 2 months following initial stroke, and another 16 percent died within 10 days of stroke recurrence.[9]

TABLE 4-1 ■ Congenital Heart Defects Reported with Pediatric Ischemic Stroke

Transposition of the great vessels
Hypoplastic left ventricle
Ventricular septal defect
Atrial septal defect
Tetralogy of Fallot
Pulmonary stenosis
Pulmonary atresia
Coarctation of the aorta
Eisenmenger complex
Truncus arteriosus with decreased flow
Endocardial cushion defect
Ebstein anomaly
Congenital valvular abnormalities
Patent foramen ovale (PFO) with paradoxical embolism

Data on recurrence risk following initial stroke in children and adults with CHD are scant, though one large stroke registry-based study reported a 27 percent recurrence risk at 10 years of age in children with CHD.[9] About 50 percent of these children were taking antithrombotic therapy at the time of stroke recurrence. Recurrence risk in children with CHD is equally elevated following neonatal stroke and stroke that occurs later in childhood. The risk of recurrence is highest in the period immediately following the sentinel stroke and decreases over time. Predictors of recurrent stroke include the presence of a mechanical valve, a prothrombotic condition, and an acute infection at the time of sentinel stroke. Children with non-procedure-related sentinel stroke are at greatest risk of recurrence.

All three key elements of thrombus formation—alterations in blood flow, blood composition, and vessel wall integrity—are potentially active in children with CHD. Alterations in blood flow may arise from abnormal cardiac anatomy and function or from intraluminal lines and catheters. Blood composition abnormalities including alterations in a variety of hemostatic proteins contribute to a predisposition to thrombosis. Genetic and acquired thrombophilias (due to treatment of CHD) appear to be more common in children with cardiac disease than in the general population, particularly in children with cyanotic CHD. In cyanotic CHD, endothelial injury occurs as a result of hypoxia-induced neutrophil activation, with subsequent activation of platelets and coagulation. Vessel wall integrity is further altered by central lines, cardiopulmonary bypass, or both.

Periprocedural periods are a particularly high-risk time for thromboembolic stroke. Studies report that one-quarter to two-thirds of acute AIS in children with CHD occurs around the time of procedures, with around two-thirds occurring in the post-surgical period and one-third post-catheterization. Periprocedural strokes are most common in patients with cyanotic CHD undergoing palliative surgery with a residual right to left shunt postoperatively. Other groups of children with cardiac disease who have been found to be at particularly high risk of stroke include children with a Berlin Heart EXCOR ventricular assist device (21% for ischemic stroke, 28–34% for combined ischemic and hemorrhage stroke), children treated with ECMO (7–11% for combined ischemic and hemorrhagic stroke), and children treated with the Fontan procedure (1.4–19% with various definitions of stroke).[8] While the perioperative period is a time of increased risk, about 30 percent of strokes in children with CHD occur years after palliative or corrective surgery is completed.[10] As the majority of children with CHD now survive into adulthood, recent large studies report up to a 12-fold increased risk of AIS in young adults with CHD compared to the general population. In adults with cyanotic CHD, nearly half have MRI evidence of a prior infarct.

In children with CHD, the mechanism of AIS is usually thromboembolic, specifically either cardioembolic (e.g., an intracardiac embolic source, including mural or heart valve thrombus), paradoxical (e.g., a cardiac lesion that permits an embolus of systemic venous origin access to the cerebral circulation), or from an arterial source. Infective endocarditis is a potential source of septic embolism, particularly in children with complex CHD. An intracardiac thrombus can be identified in up to 16 percent of children with cardiac disease. Cardiopulmonary bypass generates particulate or gaseous material which is not filtered by the pulmonary bed and gains direct entry into the systemic arterial circulation.

Neuroimaging for stroke in children with CHD often shows a cardioembolic stroke pattern with involvement of multiple vascular distributions. These lesions have a relatively high rate of hemorrhagic conversion likely related to the underlying embolic mechanism or the greater prevalence of anticoagulation therapy at the time of stroke. Often there is no clear source of emboli found after thorough investigation.

Cerebral or cervical vascular abnormalities may contribute further to stroke risk in children with heart disease. Up to 25 percent of children with stroke and CHD will demonstrate abnormal vascular imaging, including arterial tortuosity, developmental variants, and rarely moyamoya syndrome. Several well described disorders can be associated with both heart disease and cerebral vasculopathy including trisomy 21, Williams syndrome, neurofibromatosis type I, PHACE syndrome (posterior fossa brain malformations, hemangiomas, arterial abnormalities, cardiac anomalies, eye abnormalities), Alagille syndrome, and Noonan syndrome.

Diagnostic evaluation and treatment should follow current expert recommendations. When AIS is suspected, emergent neuroimaging is warranted if a child is a candidate for thrombolysis or thrombectomy. Typically, MRI with DWI and MRA is the preferred method of childhood AIS diagnosis due to the frequency of stroke mimics in children. When MRI is contraindicated in a child with cardiac hardware or is too difficult to obtain due to critical illness, noncontrast head CT with CT angiography and perfusion is preferred. In infants with an open fontanelle, bedside cranial ultrasound is often used to screen for large ischemic or hemorrhagic stroke, but this technique will miss smaller ischemic stroke in over half of cases.

Emergent thrombolysis and mechanical thrombectomy may be considered for older children with ischemic stroke and large-vessel occlusion at stroke centers who meet adult criteria for hyperacute treatment. These therapies have not been studied extensively in children, and potential benefits and risks need to be weighed carefully in each case. The 2019 AHA/ASA scientific statement for management of stroke in neonates and children recommends limiting consideration of hyperacute therapy to children with disabling neurologic deficits and radiographically confirmed cerebral large-artery occlusion.[8] Treatment decisions should be made in conjunction with neurologists with expertise in the treatment of children with stroke. Interventional procedures should be performed by an endovascular surgeon with experience in both treating children and performing thrombectomy in adult stroke patients. Size-based limitations for smaller arteries, contrast dye exposure, and radiation dose should be carefully considered. Centers that elect to offer hyperacute therapies should have pre-established institutional pediatric hyperacute stroke pathways.

Standard of care for management of acute AIS includes supportive neuroprotective measures including optimization of oxygenation, avoidance of hypotension, normalization of serum glucose levels, and prevention of fever. Seizures should be controlled, with a low threshold for placing an electroencephalogram to guide treatment. Initial and maintenance antithrombotic treatment for secondary stroke prevention should be considered. Transthoracic echocardiogram with bubble study should be performed to evaluate for intracardiac thrombi, infective vegetations, and risk factors for thrombi (e.g., ventricular dysfunction, right-to-left shunt). Neck imaging should be considered if no immediate cause is determined. A thrombophilia evaluation should also be considered in consultation with a hematologist.

Hemorrhagic Stroke

Few studies have examined primary hemorrhagic stroke in children with CHD, but available data suggest that the risk of hemorrhagic stroke is 13 times higher in children with CHD compared to the general population.[10] In addition to the bleeding risk associated with exposure to anticoagulation therapy, hemorrhage occurs in children with CHD as a result of decreased levels of coagulation proteins, increased fibrinolysis, or decreased platelet number or function. Cyanotic CHD can result in polycythemia, hyperviscosity, thrombocytopenia, platelet function abnormalities, disseminated intravascular coagulation, and abnormal fibrinolysis; each of these may increase the likelihood of systemic or intracranial hemorrhage.

Outcome studies of children with CHD and hemorrhage often have limited generalizability due to the high variability of underlying cardiac disease. However, acute intracranial hemorrhage can be life-threatening, and several studies indicate that hemorrhagic stroke likely worsens overall morbidity and mortality. Isolated parenchymal hemorrhage is associated with greater odds of in-hospital mortality. Hemosiderin staining on brain MRI, suggesting previous brain hemorrhage, without radiologic evidence of ischemic brain injury has been associated with worse neurodevelopmental outcomes. When intracranial hemorrhage is suspected, prompt imaging to identify the source and severity of bleeding is warranted, with rapid decision-making to stabilize the patient, balance risk and benefit of continued antithrombotic treatment to reduce the risk of rebleeding, and treat the hemorrhage. Further research focusing on hemorrhagic stroke in children with CHD is needed with special consideration of risk, benefit, and safety implications for antiplatelet and anticoagulant medications.

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis (CVST) can occur in children with CHD preoperatively or postoperatively. Often, multiple sinuses are involved, with associated ischemic or hemorrhagic intraparenchymal brain injury. Possible risk factors for CVST in children with CHD include infection, dehydration, anemia, thrombophilia, lower weight, prolonged use of a central venous catheter, or a catheter placed in the jugular vein. CVST with associated brain injury can result in significant neurologic morbidity. Diagnostic investigation for suspected CVST should include brain MRI with MR venography to evaluate for clots within the venous sinuses as well as for parenchymal injury. Specific diagnostic evaluation and treatment for CVST in general is reviewed in AHA/ASA Scientific Statements.[7,8] Supportive measures include correction of dehydration, treatment of underlying infection, control of seizures if they occur, and evaluation for signs of increased intracranial pressure. Repeat imaging at 5 to 7 days should be considered to evaluate for sinus recanalization or thrombus propagation. Older children with CVST are typically managed with anticoagulation, but for neonates with CVST there is considerable practice variation in the approach to anticoagulation, particularly in the presence of intracranial hemorrhage. Among experts who favor anticoagulation for treatment of CVST, opinion is mixed, with some support for immediate initiation of anticoagulation and others who recommend anticoagulation only after evidence of thrombus extension on serial imaging or clinical deterioration.

Septic Embolism

Infective endocarditis with secondary embolism occurs in various forms of CHD, particularly in children with cyanotic CHD, prior palliative shunt procedures, complex intracardiac repair, prosthetic valves, indwelling central venous catheters, and extensive hospitalizations with frequent use of broad-spectrum antibiotics. A prolonged course of appropriate antibiotics is the mainstay of treatment, but children with a history of prior cardiac surgery may meet indications for surgical management. Even with appropriate antibiotics, neurologic complications occur in about one-third of children with infective endocarditis involving the left side of the heart. Larger vegetations or infection with high-risk organisms are associated with an increased risk for cerebral embolization and may be an indication for early surgical intervention. Infarction can occur in any vascular distribution, but the anterior circulation is most common. Brain abscesses, meningitis, vasculitis, and hemorrhage from mycotic aneurysms are also potential complications. The risk of cerebral hemorrhage from mycotic aneurysms or large ischemic infarcts is often considered a contraindication for anticoagulation, but in the presence of a mechanical valve, the risk versus benefit of anticoagulation must be weighed carefully. If anticoagulation for a mechanical valve is temporarily interrupted because of infective endocarditis, timing of reintroduction of anticoagulation should be considered carefully.

NEUROLOGIC MANIFESTATIONS OF BRAIN DYSFUNCTION

Acute-Onset Movement Disorders

Choreoathetosis was once a common neurologic complication following cardiac surgery in children, but the incidence has decreased substantially with modifications in perioperative management. Nevertheless, in the first week after surgery some children will develop a movement disorder characterized by hyperkinetic movements involving the face and extremities. When they occur, these movement disorders tend to be refractory to a wide range of drugs, and often are only controlled by sedating medications. Some mild forms resolve, but severe forms can persist long term. Brain MRI rarely reveals a focal lesion and more often shows diffuse cerebral atrophy without typical features of infarction. Classes of medications used for treatment of these movement disorders are similar in this population as in others. In addition, agitation and insomnia can frequently develop, and treatment should include strategies to address these complications.

Acute Symptomatic Seizures

Children undergoing cardiac surgery for repair of complex CHD are at risk for acute symptomatic seizures in the early postoperative period, and these events often signal newly acquired brain injury. Several large cohorts of neonates and infants undergoing continuous EEG monitoring (cEEG) following cardiac surgery have demonstrated seizures in about 10 percent of patients, with the majority occurring without any clinical manifestation and only identified on EEG. Seizure onset typically occurs within the first few days postoperatively, most often between 12 and 36 hours. The seizure burden is often high, with status epilepticus occurring in greater than 50 percent of patients with seizures.

The American Clinical Neurophysiology Society's 2011 guideline on neonatal EEG monitoring recommends consideration of cEEG following neonatal cardiac surgery. Using this guideline, a 2015 single-center study reported an electrographic seizure incidence of 8 percent among neonates with CHD who received cEEG following surgery with cardiopulmonary bypass; 85 percent of these seizures were not detected clinically.[11] In this study, bedside providers indicated clinical concern for abnormal movements and vital sign instability in numerous patients that were nonepileptic on EEG, highlighting the difficulty of accurately diagnosing seizures without EEG in young patients.

Risk factors for seizures have been reported in various CHD cohorts and include co-existing genetic defects, increasing duration of circulatory arrest, delayed sternal closure, and aortic arch obstruction. Seizures are also more likely in neonates who suffer cardiac arrest or require extracorporeal membrane oxygenation (ECMO) postoperatively. Overall, neonates with seizures may have higher illness severity than those without seizures. Among neonates who were monitored by cEEG after surgery with cardiopulmonary bypass, neonates with seizures had a significantly higher mortality than neonates without seizures.[11]

Newly acquired brain injury is the most important concern when new-onset seizures occur in a child with CHD. Numerous studies have shown that most children with postoperative EEG-confirmed seizures have a variety of imaging abnormalities including hypoxic-ischemic injury, WMI, focal or multifocal ischemic infarcts, or intracranial hemorrhage. However, seizures in children with CHD may also be related to acute metabolic abnormalities such as hypoglycemia, hypocalcemia, fever, infection, or an underlying predisposition to seizures in children with cerebral dysgenesis. Delayed brain maturation seen in children with CHD may also play a role by increasing excitatory mechanisms that predispose them to seizures. Postoperative seizures in children with complex CHD are associated with worse neurodevelopment outcomes, in part because they often indicate an acquired brain injury or underlying genetic syndrome. In the Boston Circulatory Arrest Study, which measured neurodevelopmental outcomes of children with TGA following arterial switch surgery, the presence of a postoperative seizure was the medical factor most consistently associated with worse neurodevelopmental outcome at 16-year follow up.[12]

Seizures should be treated promptly when they occur. The choice of antiseizure medication is not unique for this population, although the hemodynamic status of these patients can sometimes pose particular challenges. Avoidance of medication-related hemodynamic instability is important. Acute seizures are often difficult to treat, particularly in cases of status epilepticus, frequently requiring multiple antiseizure medications to achieve control. Postoperative seizures should prompt neuroimaging after seizures are controlled and hemodynamic changes are stabilized.

Epilepsy

The prevalence of epilepsy in children and adults with CHD is higher than in the general population. Children who have acute symptomatic seizures after cardiac surgery in particular have a high frequency of developing epilepsy. In a case-control study of 15,222 children born and diagnosed with CHD between 1980 and 2010, the overall cumulative incidence of epilepsy in children with CHD was 5 percent by 15 years of age, excluding epilepsy diagnoses made 7 days before and 30 days after surgery.[13] In the subgroup of children with CHD who were born at term without extracardiac anomalies or genetic syndromes, the cumulative epilepsy incidence was 3 percent by 15 years of age. Overall, people with CHD were nearly four times as likely to develop epilepsy compared with the general population before 5 years of age, and over twice as likely from 5 to 32 years of age. The risk of epilepsy was highest in those who underwent multiple surgeries, but remained elevated compared to the general population even in those who received no surgical intervention and who had no history of prematurity or extracardiac defects.

Neurodevelopmental Disability

As survival of children with complex CHD has improved, neurodevelopmental disability has emerged as the most common comorbid outcome. Overall, children with complex CHD who survive surgery in infancy have more problems with learning, reasoning, executive function, attention and impulse control, language, and social behavior compared with children without CHD. While outcomes can vary significantly by cardiac lesion, the unique developmental profile of children with CHD has been termed the “neurodevelopmental signature of complex CHD.” Although children without genetic syndromes or severe neurologic events have near normal intelligence, some have pervasive, but often subtle, cognitive and behavioral problems. The developmental profile of these children changes in each stage of life, and early testing may underestimate ultimate functional impairments. To address this health concern, guidelines have been created for performing serial neurodevelopmental assessments of at-risk children with CHD.[14] In addition to having a high-risk cardiac lesion, the guidelines recommend serial screening for patients with CHD in combination with: prematurity (<37 weeks), developmental delay recognized in infancy, suspected genetic anomaly, history of ECMO, heart transplantation, a history of cardiopulmonary resuscitation, prolonged perioperative hospitalization, perioperative seizures, and abnormal neuroimaging. Early detection of impairments and appropriate intervention services are important to optimize functional outcome.

Neurodevelopmental outcomes related to CHD have been studied in most detail in children with TGA and single ventricle CHD. The Boston Circulatory Arrest Study was a randomized trial comparing the neurodevelopmental outcomes of children with TGA who underwent the arterial switch operation using deep hypothermia with either total circulatory arrest or continuous low-flow bypass as the main method of vital organ support.[12] This cohort was followed for both short- and long-term neurodevelopmental outcomes at 1, 4, 8, and 16 years. At 16 years of age, both groups continued to exhibit deficits in academic achievement, memory, executive function, visuospatial skills, attention, and social cognition compared to expected population means. The majority of these adolescents had a history of frequent use of special services (65%) including tutoring (37%), grade retention (17%), special education (25%), and psychotherapy or counseling (25%). In addition, 12 percent were taking at least one medication for a psychiatric disorder (often attention deficit hyperactivity disorder, ADHD), representing a fourfold increased rate compared to the reference group. More recently, these investigators found that deficits in attention at 8 years of age strongly predicted worse psychosocial health status at 16 years of age, and therefore, early detection and treatment of ADHD may have a meaningful impact on long-term psychologic well-being in this population. Patients with single ventricle heart disease, particularly those with HLHS, are known to have the highest degree of neurodevelopmental impairment, particularly when it comes to motor outcomes. Several studies have noted that children with HLHS also tend to have lower IQs and problems with visuospatial skills, expressive language, attention, and externalizing behavior.

Risk factors for adverse neurodevelopmental outcomes are multifactorial and cumulative over time. Neurologic and developmental impairments may be influenced by multiple contributing factors including co-existing genetic disorders, congenital brain anomalies, nongenetic patient factors, type of cardiac lesion (particularly those with abnormal fetal cerebral oxygenation and postnatal cyanosis), perioperative factors associated with prolonged postoperative course, and acquired brain injury. Early studies of neurodevelopmental outcomes following cardiac surgery in infancy focused primarily on surgical techniques. These studies led many institutions to adjust intraoperative management strategies, particularly avoidance of deep hypothermic circulatory arrest. However, factors other than intraoperative management strategies may be more important determinants of neurodevelopmental outcomes for many children. In a 2015 study of combined participant data from all of the single-center studies of individuals with CHD undergoing cardiac surgery in infancy, cognitive and motor outcomes were more highly associated with innate patient and preoperative factors (e.g., race, gender, birth weight, genetic anomalies, type of CHD, and maternal education) and postoperative factors (e.g., use of ECMO and longer postoperative length of stay) than with specific techniques used during surgery.[15]

In adolescent survivors of neonatal cardiac surgery, white matter abnormalities and volume loss persist, and are associated with neurodevelopmental disabilities at this age. In addition, delayed brain maturation and vulnerability to white matter injury likely plays a further role. Persistent abnormal brain maturation seen on MRI in adolescent survivors of surgery with cardiopulmonary bypass who did not have other MRI abnormalities, particularly those with cyanotic heart disease, has been shown to be associated with adverse cognitive, motor, and executive function outcomes. At 16-year follow up of the Boston Circulatory Arrest Study, the strongest predictor of neurodevelopmental outcome was not a medical risk factor but rather family socioeconomic status, which accounted for the largest percentage of explained variance in outcomes.[12]

Neurocognitive function has not yet been well studied in adults with complex CHD, although limited research shows that they continue to demonstrate deficits across various domains as seen in children. During the transition years from childhood to adulthood, more than half of individuals with CHD stop accessing medical care. This may be influenced, at least in part, by neurodevelopmental disabilities including executive dysfunction. Studies are needed to determine if early neurodevelopmental evaluation and intervention, with ongoing information from medical providers about the importance of follow-up care, can help to address this problem. Additionally, ongoing research will address how cognitive and behavioral deficits may impact educational achievement, employment opportunities, relationships, and quality of life for adults with CHD.

CARDIOMYOPATHIES WITH ASSOCIATED NEUROLOGIC MANIFESTATIONS

INTRODUCTION

The neurologic manifestations of acquired cardiac disease include (1) the sudden onset of a focal neurologic deficit due to occlusion of a cerebral or retinal artery by an embolus that has developed within the heart (cardiogenic embolism) and (2) transient, self-limited episodes of generalized cerebral ischemia that occur as a consequence of brief failure of cardiac output, due to rhythm disturbances or outflow obstruction, resulting in presyncope or syncope. Exceptions to these categorizations include atrial fibrillation (AF), an arrhythmia that is associated with embolus formation rather than syncope, and chronic sinoatrial disorder, which predisposes to both syncopal and embolic disturbances. This chapter reviews these neurologic manifestations, including the acute management and prevention of cardioembolic stroke, and also briefly discusses cardiomyopathies and their associated neurologic manifestations beyond stroke and syncope.

CARDIOEMBOLIC STROKE

Ischemic stroke or transient ischemic attack (TIA) results from the sudden interruption of perfusion

Aminoff's Neurology and General Medicine, Sixth Edition.

to a region of neural tissue, causing an abrupt interruption of behavior that corresponds to that region's topographic function. Many ischemic strokes are embolic. While most emboli are composed of thrombus, some—depending on their etiology—may be composed of tumor cells, calcific fragments, or infective components.[1] Arterial emboli may originate from the heart chambers or valves, from the aortic arch or the large extracranial and intracranial arteries (atherosclerotic plaque or dissection), paradoxically from the venous system through a right-to-left shunt, or systemically during prothrombotic states.

Cardiogenic embolism accounts for about 20 percent of ischemic strokes.[1] Approximately 25 percent of ischemic strokes are due to large-artery atherosclerotic disease, 25 percent relate to intracranial disease of small arteries, and 25 percent are cryptogenic, having no identifiable cause. The term *embolic strokes of undetermined source* (ESUS) has been defined as follows: (1) nonlacunar ischemic stroke on computed tomography (CT) scan or magnetic resonance imaging (MRI), (2) absence of extracranial or intracranial atherosclerosis causing more than 50 percent stenosis in arteries supplying the region of ischemia, (3) no major-risk cardioembolic source of embolism identified, and (4) no other specific cause of stroke identified (arteritis, dissection, recreational drug use, migrainous infarction, or vasospasm).[1]

Cardiogenic brain embolism often manifests with greater clinical severity than strokes of other etiologies. In a population-based study of first stroke, patients with cardioembolic stroke had the lowest 2-year survival rate (55%) and were three times more likely to die than those with small-artery occlusion. The major etiologic categories of cardiogenic embolism are arrhythmias, atrial structural abnormalities, valvular heart disease, cardiomyopathies, cardiac tumors, infective and noninfective endocarditis, paradoxical emboli, and iatrogenic.

The most common cardiac cause of ischemic stroke is AF, which accounts for at least one-sixth of all strokes, and this proportion increases with increasing patient age.[1–3] In addition to persistent or paroxysmal AF, other major-risk cardiac sources of emboli include intracardiac thrombus, mechanical cardiac valve, atrial myxoma and other cardiac tumors, rheumatic valve disease, recent myocardial infarction (within 4 weeks), left ventricular ejection fraction less than 30 percent, and endocarditis. Other cardiac causes of stroke are listed in Table 5-1.

TABLE 5-1 ■ Established and Putative Cardiac Causes of Stroke

Major Etiologic Category	Subtypes
Arrhythmia	Atrial fibrillation* Atrial flutter* Atrial high-rate episodes† Atrial asystole and sick sinus syndrome†
Left atrial abnormalities	Left atrial or appendage thrombus* Spontaneous echo contrast (smoke)† Atrial myopathy† Atrial septal aneurysm† Chiari network†
Valvular heart disease	Mechanical valves* Rheumatic heart disease* Mitral valve prolapse Myxomatous valvulopathy with prolapse† Mitral annular calcification† Aortic valve calcification† Aortic valve stenosis† Lambl excresences†
Left ventricular abnormalities	Acute myocardial infarction (<4 wk)* Left ventricular systolic dysfunction (ejection fraction <30% or regional akinesis)* Left ventricular diastolic dysfunction† Left ventricular endomyocardial fibrosis†
Cardiac masses	Atrial myxoma* Papillary fibroelastoma* Cardiac thrombus* Metastasis
Endocarditis	Infective* Marantic (thrombotic, nonbacterial)*
Paradoxical embolus	Patent foramen ovale† Atrial septal defect† Pulmonary arteriovenous fistula†
Aortic arch	Complex aortic arch atheroma*
Iatrogenic	Cardiac surgery Cardiac catheterization Percutaneous coronary intervention Cardioversion for atrial fibrillation and flutter

*High-risk cardiac sources of embolism.[4]
†Minor-risk sources.[1]

Some patients with ESUS may have cardiogenic embolism as many are found to have some of the common minor-risk cardiac sources of embolism listed in Table 5-1. Long-term follow-up of patients with ESUS reveals paroxysmal AF in up to 30 percent. Emerging evidence suggests that some cryptogenic strokes may arise from an enlarged, fibrotic, and poorly contractile left atrium (i.e., “atrial myopathy”) in the absence of AF.[4] Other cardiac abnormalities found in ESUS patients include ventricular systolic or diastolic dysfunction, left ventricular wall motion abnormalities, myxomatous mitral valve, mitral annular calcification, atrial septal defects, and aortic stenosis.[1] These abnormalities are common and, in large population studies, have been associated with increased risk of stroke, but whether their presence implies causality in an individual patient with ESUS remains uncertain.

Clinical Features

Clinical features alone cannot reliably reveal the underlying type or etiology of ischemic stroke. This determination requires brain imaging, vascular imaging, and cardiac assessment by echocardiography and electrocardiography (ECG). Nonetheless, some clinical clues may be suggestive of a cardioembolic source of embolism.

Cardioembolic strokes often present with sudden neurologic deficits which are maximal at onset. This is in contrast to some cases of small-vessel occlusion where the onset of stroke deficits may begin with a gradually progressive or fluctuating course, probably reflecting fluctuations in blood pressure.

Furthermore, “cortical signs” are more common in cardioembolic stroke as emboli are more likely to lodge in distal arteries supplying the cortex. This is in contrast to occlusion of small vessels that supply the subcortical gray and white matter, sparing cortical regions. Cortical signs include forced gaze deviation, homonymous visual field deficits respecting the vertical meridian, hemispatial neglect, and aphasia of all types. Importantly, neurologic deficits that localize to multiple different vascular territories are also highly suggestive of a cardiogenic mechanism of stroke (Table 5-2).

Investigations

BRAIN AND VASCULAR IMAGING

The first diagnostic investigation for suspected acute stroke is usually a noncontrast CT scan of the brain to exclude intracranial hemorrhage.[2] Cardioembolic strokes can cause isolated cortical infarcts, combined

TABLE 5-2 ■ Clinical Features Suggestive of Cardioembolic Stroke

Clinical Entity	Descriptor
Onset/course	Sudden onset, reaching maximal deficit within 5 min of onset Nonfluctuating neurologic deficits Rapid dramatic neurologic recovery
Severity	Impaired consciousness at stroke onset* High score on NIH stroke scale
Cortical signs	Aphasia Neglect (tactile or visuospatial; localizing to parietal lobe) Homonymous visual field deficit (localizing to temporal or parietal optic radiations or occipital cortex) Forced eye deviation (localizing to frontal eye field)
Clinical localization	Neurologic deficits localize to more than one vascular territory
Systemic signs	Fever† Livedo reticularis (suggestive of Sneddon syndrome, APLA, or SLE) Evidence of systemic embolization (Janeway lesions†, Osler nodes†, septic arthritis†, Roth spots†, cellulitis†, discitis†, signs of spinal cord infarct or ischemic limb) Venous thrombosis in legs (suggestive of hypercoagulable state)
Cardiac auscultation	Murmur of mitral stenosis Murmur of mitral regurgitation†
Investigations	ECG–ST elevation myocardial infarct, atrial fibrillation, atrial flutter TTE–evidence of intracardiac thrombus, vegetations†, wall motion abnormality, aneurysm, intracardiac tumor, valvular heart disease or left atrial enlargement Neuroimaging–acute strokes in multiple vascular territories Imaging evidence of systemic embolization–renal infarct or splenic infarct†

cortical and subcortical infarcts, infarcts in the territory of large vessels, or showers of multiple acute small emboli. Acute embolic ischemic lesions that are bilateral or affecting different vascular territories in the same hemisphere simultaneously (e.g., anterior and posterior circulation) are highly suggestive of a cardiac source of embolism. In contrast, isolated deep subcortical infarcts smaller than 1.5 cm (lacunes) are usually due to small-vessel cerebrovascular disease rather than cardioembolism.[3] A hyperdense vessel sign on noncontrast head CT may indicate an acute thrombus. For evaluating early acute ischemic changes on head CT in patients presenting within the first hours of symptom onset, a popular rating scale is the Alberta Stroke Program Early CT score (ASPECTS). CT scans have some limitations—acute ischemic stroke may not become visible for several hours, artifact may partially obscure the posterior fossa, and ischemia in the brainstem and cerebellum can be difficult to identify.

CT angiography (CTA) and magnetic resonance angiography (MRA) are important vascular imaging tests for the diagnostic evaluation of patients with stroke or TIA. CTA can be acquired rapidly and has become the vascular imaging procedure of choice at many emergency departments for patients presenting with stroke symptoms. CTA aids patient selection for acute stroke treatments (thrombolysis, endovascular therapy) and helps guide secondary stroke prevention management. It can identify embolic occlusions, vascular stenosis, and other vasculopathies within the major intracranial and extracranial arteries. When acquiring CTA it is important to capture the arch of the aorta; the origins of the common carotid and vertebral arteries and their course to the circle of Willis; and the branches off the circle of Willis to their distal termination. CTA can visualize aortic arch atheroma that can be a source of cerebral emboli, especially if large, mobile, or ulcerated.[3] In the assessment of acute stroke, multiphase CTA permits an assessment of the integrity of the collateral vessels, and CT perfusion studies measure cerebral blood volume, blood flow, and mean transit time.[2] The ability to identify potentially salvageable brain tissue with advanced imaging such as CT perfusion has enabled extended time windows (beyond 4.5 hours) for stroke treatment to be evaluated in clinical trials. The acute occlusion of a blood vessel causes a local core of infarction surrounded by brain tissue that is ischemic but not yet infarcted (penumbra). This brain tissue may survive temporarily by recruiting blood from collateral arteries and more permanently if perfusion can be restored expeditiously. Acute treatments are discussed later in this chapter.

MRI with diffusion-weighted imaging (DWI) sequences is far superior to noncontrast CT for identifying acute ischemia and small infarcts.[2] As there are many stroke and TIA mimics (e.g., seizure, hypoglycemia, metabolic derangements, and migraine), MRI is invaluable in distinguishing between the various possibilities.[2] The pattern of DWI abnormalities can help also to determine the most likely etiology of stroke. Acute strokes in more than one vascular territory are highly suggestive of a shower of emboli from a proximal source.[2] The anterior circulation is affected four times more frequently than the posterior in cardioembolic stroke. MRI is the best modality to evaluate for ischemia acutely in the posterior circulation given the limitations of CT. On MRI, the presence of multiple acute infarcts, simultaneous infarcts in different circulations, multiple infarcts of different ages, and isolated cortical infarcts predict a greater 90-day risk of stroke recurrence.[2] CT or MRI is also important in evaluating for and predicting hemorrhagic transformation after an acute infarct. Predictors of hemorrhagic transformation include larger infarcts, greater stroke severity, treatment with tPA or anticoagulation, and older age.

ECHOCARDIOGRAPHY

Echocardiography plays an important role in the diagnostic work-up of embolic stroke. Transthoracic echocardiography (TTE) is easily administered and is noninvasive, but transesophageal echocardiography (TEE) is more sensitive and specific for detecting cardiac sources of embolism. TTE can image the left ventricle well, assess left ventricular function, identify akinetic segments, and reveal thrombus (may require contrast), prosthetic valve thrombus, endocarditis, cardiac tumors, and patent foramen ovale (PFO). TEE is better for assessing the left atrium, appendage, interatrial septum for PFO and valve vegetations. Echocardiography should be ordered judiciously; appropriate use criteria have been published.[4]

For PFO detection, the diagnostic sensitivity is about 50 to 60 percent with TTE (with saline bubble study) and 90 percent with TEE. Transcranial Doppler (TCD) ultrasound has a 96 percent sensitivity for detecting right-to-left cardiac shunts by identifying microbubbles reaching the middle cerebral artery. In cryptogenic stroke cases where PFO may be causal, lower limb venous Doppler ultrasound can evaluate for deep vein thrombosis (DVT).

ELECTROCARDIOGRAPHIC MONITORING

ECG is necessary for the diagnosis of AF. Given that AF is frequently paroxysmal and asymptomatic, it can easily be missed by a single 12-lead ECG or short-duration ECG monitoring. In patients with ischemic stroke presenting in sinus rhythm, ECG monitoring for 24 to 72 hours permits a new diagnosis of paroxysmal AF to be made in about 5 percent of patients. Randomized controlled trials have demonstrated that after an ischemic stroke, prolonged ECG monitoring with external wearable monitors (or implantable loop recorders) significantly increases the detection of AF. The longer the duration of monitoring, the greater is the probability of finding AF. The goal of such monitoring is to find a sufficient burden of AF to benefit from anticoagulant treatment. When only very brief, subclinical AF is detected, the clinical significance and treatment implications are still a matter of uncertainty and debate. In patients with pacemakers, subclinical AF is common and is associated with an increased risk of stroke. However, the stroke risk associated with brief device-detected subclinical AF appears lower than the stroke risk with clinical AF and the role of anticoagulant therapy in such cases is currently being tested in randomized trials. Reports by the AF-SCREEN International Collaboration provide a review and recommendations regarding AF screening after stroke and in the general population.[5,6]

CARDIAC CAUSES OF ISCHEMIC STROKE

Left Atrium

ATRIAL FIBRILLATION AND FLUTTER

AF is the most common serious arrhythmia and is associated with a three- to fivefold increase in the risk of stroke.[3] It is also associated with an increased risk of cognitive impairment and dementia. AF accounts for nearly half of all cardiac causes of stroke and more than one-quarter of strokes in the elderly. Strokes associated with AF tend to be more severe, more disabling, and have a higher mortality than ischemic strokes due to other causes.

The prevalence of AF in the general population is age dependent, ranging from 0.1 percent among adults younger than 55 years of age to 10 percent in those 80 years or older.[3,5] AF currently affects 33 million people worldwide. With an aging population, the prevalence of AF and of AF-associated strokes is projected to increase.[5] Atrial flutter also confers a greater risk of thromboembolism and often co-exists with AF, as they share similar pathophysiologic substrates.

Risk factors for AF include advanced age, hypertension, obesity, diabetes mellitus, underlying cardiac pathologies,[5] hyperthyroidism, heavy alcohol consumption, and a sedentary lifestyle.[5] Cardiac conditions associated with AF include valvular heart disease, rheumatic heart disease, congestive heart failure, coronary artery disease, cardiomyopathy, mitral valve prolapse, mitral annular calcification, and left atrial enlargement.[5] However, AF may also occur as "lone AF" in young patients who do not have structural cardiac disease.

AF is not a binary entity and there are varying degrees of AF burden—the amount of time spent in AF—that vary between patients and over time in individual patients. AF can be symptomatic or asymptomatic and is classified as paroxysmal (self-terminating episodes lasting less than 7 days), recurrent (two or more episodes), persistent (more than 7 days), or permanent (continuous for more than 12 months). Paroxysmal AF is the most common subtype and is associated with a lower risk of stroke and lesser stroke severity than persistent AF.

Reversible or temporary causes of AF include acute systemic illness such as sepsis or pneumonia, alcohol, surgery, hyperthyroidism, acute myocardial infarction, pulmonary embolism, and pericarditis. In these precipitated settings, AF has been termed "secondary AF" and previously was thought not to increase stroke risk. However, studies now show that those with secondary AF may have an equivalent stroke risk to those with spontaneous AF. This highlights the fact that the acute medical precipitant of secondary AF merely reveals an underlying vulnerable atrial substrate which can confer an independent risk of stroke.

In patients with atrial flutter, the risk of thromboembolism is less than that of AF, but higher than for patients in sinus rhythm. Patients with atrial flutter often develop AF and the two atrial tachyarrhythmias frequently co-exist. For practical purposes, the anticoagulant treatment recommendations for atrial flutter are the same as those for AF.

Pathophysiology

The pathogenesis of AF relates to atrial cardiopathy. Histologically, atrial cardiopathy is characterized by interstitial fibrosis, loss of sarcomeres, and accumulating glycogen granules within atrial cardiomyocytes.[5,7] This process is likely driven by a multifactorial interaction of risk factors including increasing age, genetic predisposition, dysrhythmias, local and systemic inflammation, endothelial dysfunction, and left atrial dilatation/myocardial stress (caused by systemic hypertension, pulmonary hypertension, elevated left ventricular filling pressure, heart failure, and/or mitral valve dysfunction). With increasing age, in conjunction with the aforementioned risk factors and left atrial dilatation, structural remodeling of the left atrial connective tissue occurs with the formation of atrial fibrosis.[7] Furthermore, a critical component of AF pathogenesis is that the electrical disturbance of AF begets the formation of additional aberrant left atrial fibrotic substrate that propagates further AF.

As mentioned, myocardial stress promotes left atrial dilatation and further atrial fibrotic remodeling. An established biomarker of myocardial dysfunction is N-terminal fragment B-type natriuretic peptide (NT-proBNP), which is secreted in the atrium secondary to atrial or ventricular dysfunction. Elevated NT-proBNP has been associated with an increased risk of AF and thromboembolic events.[5]

Myocardial ischemia also independently affects atrial fibrosis. In patients with AF, an elevated troponin in the blood is associated with an independent risk of stroke or systemic embolism.[5] In such cases, troponin is likely an additional marker of vulnerable myocardium indicating ischemia, volume and pressure overload, or myocardial structural abnormalities.[5] With this vulnerable myocardium, therefore, AF can be precipitated acutely during states of increased cardiac output and demand, such as pneumonia, sepsis, hyperthyroidism, and alcohol intoxication, thereby not only increasing stroke risk acutely but also promoting further aberrant left atrial remodeling.

There is emerging evidence that elevated levels of inflammatory markers, namely interleukin-6 (IL-6) and C-reactive protein (CRP), can be associated with the presence and burden of AF, and in those with AF they may identify greater risk of cardiovascular morbidity and mortality.[5] These markers could reflect a prothrombotic state in AF, may reflect an inflammatory contribution to the development of aberrant atrial substrate, or not be causal at all.

There has been a shift in thinking regarding the manner in which AF leads to cardioembolic stroke.[4] The traditional model has been that the dysrhythmia of AF leads to uncoordinated atrial function, thereby promoting left atrial stasis of blood that can lead to thrombus formation with eventual embolization to the brain. However, this century-old hypothesis incompletely captures the pathogenesis of embolic stroke in AF. The findings from trials of rate and rhythm control in paroxysmal AF have not demonstrated a reduced stroke risk and suggests that there may be another mediator of thromboembolism that is related to AF but that is not necessarily AF itself.[7] There is an emerging appreciation that an abnormal left atrial substrate (endothelial dysfunction, fibrosis, left atrial dilatation, and left atrial appendage dysfunction) may be associated with cardioembolic stroke pathogenesis independent of AF.[7] It is more likely that an aberrant left atrial substrate—atrial cardiopathy—is both sufficient to cause cardioembolic stroke and necessary for AF to arise. When AF arises, superimposed on an aberrant atrial substrate, there is an even greater risk of cardiogenic embolism. A newly proposed model of left atrial cardiopathy and AF in the pathogenesis of cardioembolic stroke is summarized in Fig. 5-1.

Risk Stratification

The average annual risk of stroke in individuals with AF is 5 percent and is heavily dependent on age and the presence of additional risk factors. The most important predictor of stroke risk in patients with AF is a history of thromboembolism (i.e., previous TIA, stroke, or systemic arterial embolism). Other independent risk factors for stroke in patients with AF are increasing age, hypertension, congestive heart failure, diabetes mellitus, female sex, systolic hypertension, and left ventricular dysfunction.

There are two commonly used clinical tools to predict the risk of stroke in patients with AF based on the presence of additional risk factors. These are the CHADS_2 score (*C*ongestive heart failure,

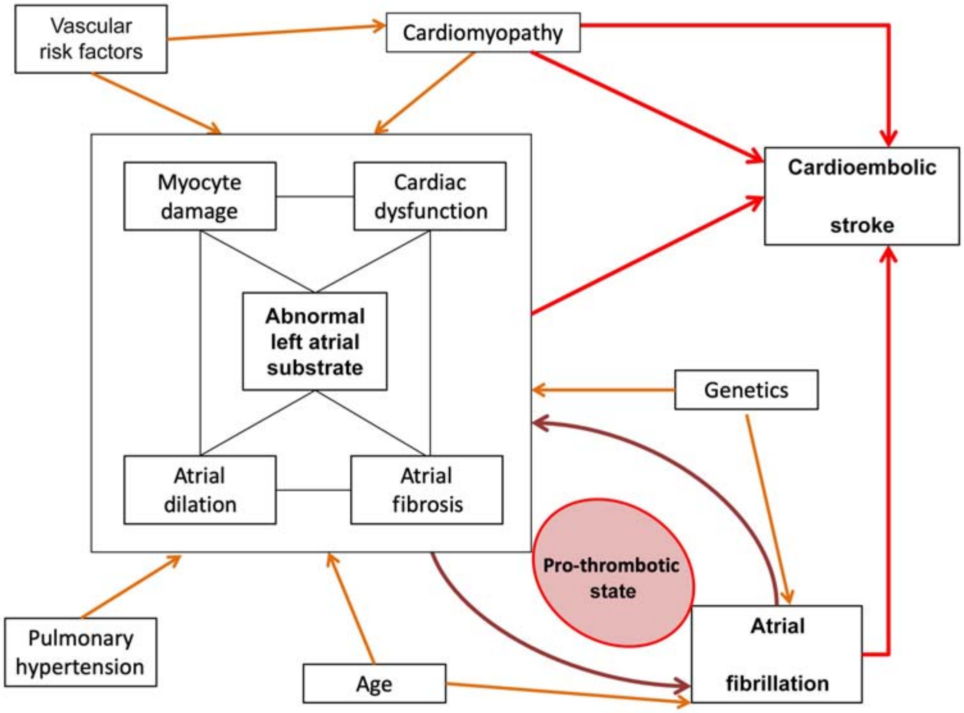

FIGURE 5-1 ■ Model of left atrial myopathy and atrial fibrillation as mechanisms of cardioembolic stroke.

*H*ypertension, *A*ge ≥75 years of age, *D*iabetes, *S*troke or TIA) and the CHA$_2$DS$_2$-VASc scale, which adds on points for *V*ascular disease (coronary artery disease or peripheral vascular disease), *A*ge ≥65 years of age or ≥75 years of age, and female *S*ex. The CHADS$_2$ scale ranges from 0 (low stroke risk, 1.9% per year) to 6 points (high stroke risk, 18.2% per year). The CHA$_2$DS$_2$-VASc scale is particularly helpful in discerning risk in those who score 0 or 1 on CHADS$_2$, and helps guide treatment decisions in these cases.

Another clinical risk factor associated with AF and independently associated with ischemic stroke is obstructive sleep apnea. During sleep, apneic episodes induce hypoxemia and sympathetic stimulation, which can induce tachycardia and nocturnal surges of hypertension, all of which can exacerbate AF.[7]

There is interest in exploring biomarkers to help improve stroke risk prediction beyond the clinical CHADS scores. The duration and burden of AF are also important contributors to stroke risk in AF. There is a greater risk of stroke in those with persistent and permanent AF compared to paroxysmal AF. Despite this, current guidelines regarding treatment decisions have not incorporated AF burden in the determination of stroke risk in AF. Furthermore, non-AF arrhythmias may be suggestive of an abnormal atrial substrate. Frequent atrial ectopy (premature atrial beats) is associated with AF. Both frequent atrial ectopy and paroxysmal supraventricular tachycardia are associated with stroke risk independent of AF.[7]

Echocardiographic features have been used for risk stratification in patients with AF. Left atrial enlargement, especially a diameter exceeding 45 mm or a left atrial volume index of 32 mL/m^2 or more can potentiate a greater risk of stroke and systemic embolism.[7] These markers are probably indicators of stasis and endothelial dysfunction.[7] Furthermore, the left atrial appendage (LAA) is a common and known source of emboli in patients with AF as it is a low-pressure and highly trabeculated sac vulnerable to thrombus formation (Fig. 5-2).[7] The presence of LAA thrombus, best visualized with TEE, predicts an increased risk of stroke. LAA function can also be assessed on TEE and is emerging as a biomarker of stroke risk in AF. LAA flow velocity is reduced in AF and a velocity of <0.2 m/sec or spontaneous echo contrast on TEE is associated with an increased risk of thrombus formation and embolic events in AF.[7] Spontaneous echo contrast or a “smoke-like” appearance on TEE represents stasis of blood in the atrium, and its presence may be a marker of increased stroke risk. There are also associations between stroke risk and LAA

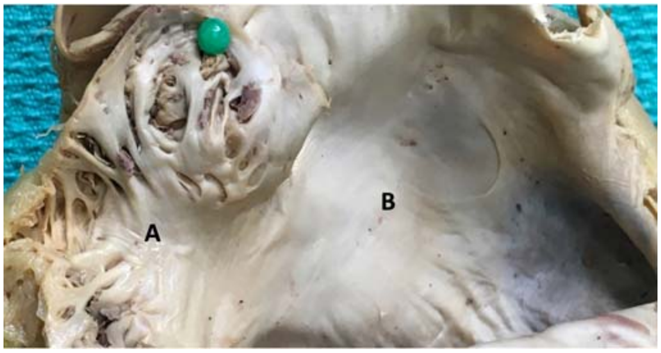

FIGURE 5-2 ■ Gross anatomic view of *A*, left atrial appendage (LAA) and *B*, left atrium (LA). The high density of trabeculations in the LAA contrasts with the smooth surface of the remaining left atrium. During states of low flow, the greater surface area conferred by the density of trabeculations in the LAA can predispose to thrombus formation. (With permission of the Department of Anatomy and Physiology, University of Toronto, and courtesy of Barbara (Dee) Ballyk, PhD, of the Division of Anatomy and Department of Surgery, University of Toronto, Toronto, Canada.)

morphology, with certain configurations portending a greater stroke risk. There are four known morphologies of the LAA: "chicken wing," "cactus," "windsock," and "cauliflower."[7] The chicken-wing morphology, compared to the other three variant morphologies, has the lowest risk of embolism. The cactus, windsock, and cauliflower morphologies may confer a greater stroke risk as they have lower LAA blood-flow velocities than the chicken-wing morphology. Furthermore large orifice area, ≥3 LAA lobes, and increased LAA trabeculations independently increase stroke risk in AF.[7] Cardiac MRI is emerging as a biomarker of stroke risk in AF as it can visualize and quantify atrial fibrosis, unlike echocardiography. Atrial late gadolinium enhancement on cardiac MRI is associated with ischemic stroke risk.[7]

Cardioversion

Cardioversion (electrical or pharmacologic) undertaken to convert AF back to sinus rhythm is associated with an increased risk of thromboembolism. Patients who have been in AF for 48 hours or more or in whom the duration of AF is unknown are at particular risk. In these individuals, anticoagulation should be started 3 weeks prior to and continued for 4 weeks after cardioversion.

Alternatively, TEE prior to cardioversion can be performed and if no left atrial or LAA thrombus is detected, cardioversion can occur as soon as the patient is anticoagulated. Even in these cases, anticoagulation should continue for at least 4 weeks.[8] If a left atrial thrombus is detected on TEE, anticoagulation is recommended for at least 3 weeks prior to cardioversion and may need to be continued for a longer duration afterward. The recommendations for cardioversion in atrial flutter are the same as for AF.[8]

Cardioversion within the previously acceptable 48-hour window from the time of AF onset may still be associated with a greater risk of cardioembolic stroke, in the vicinity of 0.7 to 1.1 percent.[8] Even a delay of 12 hours or more from time of AF onset to cardioversion is associated with a greater risk of stroke as well. Risk factors for stroke in these settings include female sex, heart failure, diabetes mellitus, and older age. Therefore, the 2019 American Heart Association guidelines suggest that heparin or direct non-vitamin K oral anticoagulants be started prior to cardioversion for those with AF or atrial flutter of less than 48 hours duration with a CHA_2DS_2-VASc score of ≥2 in men and ≥3 in women.[8] Anticoagulation should also be continued after cardioversion in these settings as well. For those with nonvalvular AF or atrial flutter for less than 48 hours, but with CHA_2DS_2-VASc scores of 0 in men and 1 in women, anticoagulation with heparin or direct non-vitamin K oral anticoagulants may be considered prior to cardioversion, without the need for postcardioversion anticoagulation.[8]

Chronic Sinoatrial Disorder (Sick Sinus Syndrome)

Sinoatrial disorder or sick sinus syndrome is due to dysfunction of the heart's sinoatrial (SA) node. This condition manifests as a mixture of bradyarrhythmia, tachyarrhythmia, and chronotropic incompetence. Patients may also have sinus arrest. As such, patients usually presents with syncope, lightheadedness, and exercise intolerance.

There is a higher rate of systemic emboli and AF in those with chronic sinoatrial disorder compared to those with atrioventricular block. Therefore, patients with chronic sinoatrial disorder should be screened closely for AF and, if detected, anticoagulation is usually initiated. In particular, patients with the "brady-tachy" form of the disorder are at higher risk of developing AF and stroke. Studies have not found any difference in stroke risk or mortality whether sinoatrial disorder is managed with single-lead atrial pacing (AAIR) or dual-chamber pacing (DDDR), but prior studies reported a decreased risk of AF with AAIR. Pacing helps with the symptoms of syncope and exercise intolerance and facilitates the detection of AF, but does not reduce stroke risk. Nearly 30 percent of those individuals will have AF at the time of their pacing insertion and by 7 years this increases to 60 percent. DDDR has been demonstrated to reduce the progression of atrial tachyarrhythmias to long-duration and permanent AF in those with sinoatrial disorder.

ATRIAL MYXOMA

Primary cardiac tumors—of which atrial myxomas and papillary fibroelastomas (PFE) are the most common—have a prevalence of 0.05 percent. Histologically, although both atrial myxoma and PFE are benign tumors, they have increased thrombogenic potential, often manifesting with cardioembolic stroke or systemic emboli. Embolic strokes arise either from tumor components or a dislodged thrombus. PFEs technically do not exist in the left atrium and affect the papilla of heart valves, but they are discussed here as they are of equal importance as rare causes of cardiogenic stroke.

Myxomas are more common in women than men and occur in the left atrium in more than 75 percent of cases. Rarely they can obstruct the mitral valve, causing valvular stenosis, which can manifest as exertional dyspnea. Nearly one-third of patients with myxomas have evidence of emboli, including silent brain infarcts. Management is often surgical, but there is a risk of recurrence after incomplete surgical resection. PFEs, while they mostly occur on the aortic and mitral valves, rarely cause valvular incompetence or stenosis. These tumors have fern-like projections from a central stalk and therefore have a large surface area upon which thrombus can form. Surgery is usually indicated for large or symptomatic tumors, whereas close monitoring may be employed for small or asymptomatic tumors.

Interatrial Septum: Paradoxical Embolus

A paradoxical embolus arises when a thrombus formed in the venous system passes into the arterial circulation through a right-to-left shunt such as a PFO, atrial septal defect, or ventriculoseptal defect. Incomplete closure of the foramen ovale in the first few days of life results in persistent PFO in approximately 25 percent of the population. In patients with cryptogenic stroke, a PFO is identified in 40 to 50 percent of cases. The risk of stroke recurrence with a PFO is about 1 to 2 percent per year.[1]

In patients with cryptogenic embolic stroke who are found to have a PFO, it is necessary to determine whether the PFO was responsible or just an innocent bystander given its high population prevalence. A comprehensive stroke work-up is recommended to exclude alternate causes. Factors that increase the likelihood that a PFO is pathogenic include Valsalva maneuver or increased abdominal pressure at the time of stroke onset, younger age and absence of traditional vascular risk factors, recent immobility (surgery; prolonged land or air travel), prior or concomitant venous thromboembolism such as DVT or pulmonary embolism, known hypercoagulable state, history of migraine with aura, pulmonary hypertension, sleep apnea, and stroke occurring during sleep. The probability of a PFO being the causal mechanism of a stroke event can be estimated using the Risk of Paradoxical Embolism (ROPE) score. Certain echocardiographic features of a PFO have been associated with a greater risk of stroke, such as large shunt/PFO size, a hypermobile atrial septum, and atrial septal aneurysm.

There are other fetal structures that can persist into adulthood and may have relevance in cryptogenic stroke. In utero, the right valve of the sinus venosus directs blood flow through the PFO. A Chiari network—a web-like network of fibers—and the Eustachian valve are fetal remnants of the right valve of the sinus venosus, located at the entry point of the inferior vena cava into the right atrium. Approximately 2 to 3 percent of adults have a persistent Chiari network. A Eustachian valve and a prominent Chiari network are common in patients with PFO. A prominent Chiari network is also seen fairly frequently in patients with cryptogenic stroke, and these individuals also tend to have a PFO or atrial septal aneurysm. Together PFOs, Chiari networks, and/or atrial septal aneurysms are associated with cardioembolic stroke. It is hypothesized that the presence of prominent fetal Chiari network and Eustachian valve can direct blood from the inferior vena cava preferentially toward a PFO and may facilitate paradoxical embolization.

Left Ventricle

ACUTE MYOCARDIAL INFARCTION

After myocardial infarction there is an increased risk of stroke that is highest within the first month and persists thereafter. Associated ST segment elevation on the ECG confers a greater risk of stroke than when the ST segment is not elevated. Predictors of stroke following myocardial infarction include advanced age, diabetes, hypertension, previous stroke or myocardial infarction, an anterior myocardial infarct, AF, and heart failure. Mechanisms of cardioembolic stroke in the context of myocardial infarction include (1) left ventricular hypokinesis or akinesis that predisposes to local stasis and formation of mural thrombus and (2) the development of AF, which occurs in up to 20 percent of patients following myocardial infarction.

There is a risk of left ventricular thrombus formation with acute infarction. Patients with large anterior myocardial infarcts associated with a left ventricular ejection fraction less than 40 percent and anterior wall motion abnormalities are at greatest risk of developing mural thrombus in the left ventricle. Left ventricular thrombus develops in about one-third of individuals during the first 2 weeks following an anterior myocardial infarct, posing an even greater risk of embolism. The risk of embolization though decreases after 3 months as thrombus becomes organized, fibrotic, and less mobile.[9]

The overall stroke risk following myocardial infarction has been reported to approximate 1 percent during the first month and about 2 percent at 1 year. This risk may be lower now with modern acute reperfusion interventions and use of anticoagulant therapy.[3] Percutaneous intervention for acute myocardial infarction also bears its own risk of stroke of approximately 0.1 percent.[3]

CARDIOMYOPATHIES

Cardiomyopathies are defined as a heterogeneous group of diseases of the myocardium associated with mechanical or electrical dysfunction (or both) that usually, but not invariably, exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes, frequently genetic. Specifically excluded are those diseases of the myocardium secondary to congenital or valvular heart disease, systemic hypertension, or atherosclerotic coronary disease. The cardiomyopathies are divided into two major groups based on predominant organ involvement. The primary cardiomyopathies are those solely or predominantly confined to heart muscle; genetic, mixed, and acquired forms are recognized. Both hypertrophic and dilated cardiomyopathies are considered primary diseases. Also included are the ion-channel disorders, in which there is a primary electrical disturbance without structural cardiac pathology. These disorders are considered later in relation to syncope.

Secondary cardiomyopathies involve skeletal or smooth muscle in addition to cardiac muscle. Neuromuscular or neurologic causes include Friedreich ataxia, Duchenne or Becker muscular dystrophy, Emery–Dreifuss muscular dystrophy, neurofibromatosis, and tuberous sclerosis. The secondary cardiomyopathy classification does not include infective processes, such as Chagas disease or infection with human immunodeficiency virus, which also cause cardiomyopathy.

In North America, the most common cardiomyopathy is hypertrophic cardiomyopathy, which is an autosomal-dominant disease affecting 1 in 500 persons. It is a major cause of sudden cardiac death in athletes but is compatible with survival until old age. Stroke risk in hypertrophic cardiomyopathy is elevated, with an annual incidence of 0.8 percent.

There are considerable geographic variations in the causes of cardiomyopathy. In Latin America, American trypanosomiasis (Chagas disease) is common. Cardioembolic stroke has been increasingly well documented as a complication, and most occur in the anterior circulation. In Chagas cardiomyopathy, the apical region of the left ventricle is the typical site for formation of thrombosis or aneurysm. Echocardiography reveals an apical aneurysm in one-third of patients and a mural thrombus in about 10 percent. Left ventricular diastolic dysfunction is present in nearly one-half of patients. The ECG is abnormal in two-thirds, including right bundle branch block, left anterior fascicular block, and AF.

Other regional variations include endomyocardial fibrosis restricted to the tropical regions of East, Central, and West Africa. Furthermore, the incidence of human immunodeficiency virus–associated cardiac disease, including cardiomyopathy, is increasing, in contrast to developed countries where the availability of antiretroviral therapy has reduced the incidence of myocarditis.

Patients with dilated cardiomyopathy have an increased incidence of embolic events including systemic embolism and stroke secondary to ventricular mural thrombi, and therefore anticoagulant therapy should be considered for secondary stroke prevention in select cases. Other neurologic manifestations of cardiomyopathies are considered later.

LEFT VENTRICULAR DYSFUNCTION

Patients with ischemic and nonischemic cardiomyopathies are at increased risk of stroke related to left ventricular dysfunction. Left ventricular dysfunction leading to systolic heart failure (also termed heart failure with reduced ejection fraction) is a risk factor for stroke. However, even in the absence of clinically overt heart failure or myocardial infarction, the presence of asymptomatic left ventricular systolic dysfunction is an independent risk factor for intracardiac thrombus formation and stroke.[3]

Congestive heart failure carries a two- to threefold increase in the relative risk of stroke. The mechanism underlying stroke in these cases is multifactorial, related to a hypercoagulable state, concomitant vascular risk factors, regional stasis, and the association between heart failure and AF.[3] Among patients enrolled into heart failure trials, the overall annual stroke risk ranges between 1.3 and 3.5 percent. The left ventricular ejection fraction was inversely associated with cardiovascular mortality up to a value of 45 percent in the Warfarin versus Aspirin in Reduced Ejection Fraction (WARCEF) trial.[10] An ejection fraction of less than 15 percent more than doubles the risk of stroke.[10] Other studies report an increased stroke risk with a left ventricular ejection fraction less than 35 percent.[9]

Valvular Diseases

MITRAL ANNULAR CALCIFICATION

Mitral annular calcification is a common process that arises due to chronic noninflammatory fibrous calcification of the mitral annulus. It is a low-risk potential source of calcific or thrombotic emboli to the cerebral and retinal circulations.[1] The Framingham study documented a doubling of stroke risk in those with mitral annular calcification compared to those without, but it is unclear whether this relationship is causal or a marker for other risk factors such as AF and generalized atherosclerotic disease, including carotid stenosis and calcified aortic arch plaque. Mobile plaques on the mitral annulus, however, do confer a greater risk of embolic potential.

MITRAL VALVE PROLAPSE

Mitral valve prolapse is the most frequent valvular disease in adults, with a prevalence of about 2 percent. In the Framingham cohort, no significant difference was found in the prevalence of stroke or TIA in those with or without it, but other studies have shown a modestly increased incidence of stroke in those with mitral valve prolapse. The estimated risk of stroke with it is 1 per 6000 patient years. The mechanism of stroke with mitral valve prolapse may be related to thrombi forming on the surface of redundant leaflet tissue.

MITRAL VALVE REGURGITATION

Mitral valve prolapse can also be associated with an elevated risk of thromboembolic complications in the presence of mitral valve thickening or mitral regurgitation. Mitral regurgitation can lead to progressive left atrial dilatation leading to the evolution of an aberrant atrial substrate and AF.

Mitral regurgitation can occur in the context of dilated cardiomyopathies, where displaced papillary muscles and annular dilatation impair leaflet coaptation. While there are primary causes of mitral regurgitation, it can also arise in the context of vascular risk factors manifesting as ischemic cardiac disease. Progressive mitral regurgitation begets further left ventricular dilatation and subsequently worsens the regurgitation. Unless AF arises in the context of mitral regurgitation, antithrombotic therapy has not been recommended for stroke prevention. However, with symptomatic regurgitation (heart failure, dyspnea, exercise intolerance), regurgitation volume ≥ 60 ml, left ventricular end-systolic diameter ≥ 40 mm, pulmonary artery systolic pressure >50 mmHg, or new-onset AF, patients may benefit from mitral valve surgery or repair.[8]

MITRAL VALVE STENOSIS AND RHEUMATIC HEART DISEASE

There is a well-established association between stroke and rheumatic heart disease, especially mitral stenosis, and particularly in the setting of AF and atrial thrombus. Rheumatic heart disease is a result of a delayed autoimmune reaction to a streptococcal infection, with molecular mimicry mediating an inflammatory reaction in cardiac valvular tissue. Systemically, patients with rheumatic fever can have arthritis and nephritis as well. Although the incidence of rheumatic heart disease has declined because of prompt antibiotic treatment, in some parts of the world it is an important cause of mitral stenosis, valvular AF, and stroke.

The term “valvular AF” has been used to refer to AF in the context of severe mitral stenosis or a mechanical valve. Guidelines recommend long-term warfarin (target $\text{INR} = 2.5 \pm 0.5$) for patients with rheumatic mitral valve disease who have a history of systemic embolism or who develop chronic or paroxysmal valvular AF.[11] It is also recommended, in the context of severe mitral stenosis, that warfarin be given to patients in normal sinus rhythm if the left atrial diameter is in excess of 5.5 cm, regardless of a history of AF or embolism.

AORTIC VALVE STENOSIS

Aortic valve stenosis or calcification is a minor-risk potential cardiac source of stroke.[1] Aortic valve stenosis can arise secondary to degenerative calcification and rheumatic or congenital pathologies and is associated with aging and vascular risk factors. Systemic embolism in patients with aortic valve disease is uncommon in the absence of AF or other risk factors. Severe and symptomatic aortic valve stenosis is an indication for percutaneous valvuloplasty or valve replacement.

LAMBL EXCRESCENCES

Lambl excrescences are rare fine, mobile, frond-like extensions of cardiac valves that occur at sites of valve closure and arise as a result of endothelial damage with wear and tear. Their appearance on echocardiography may evoke a differential diagnosis that includes vegetations, metastases, fibroelastoma, myxoma, or thrombi. TEE is the best modality with which to visualize them. They are mostly asymptomatic, but their location on and subsequent detachment from aortic or mitral valves can manifest as a cardioembolic stroke. They should be considered in cases of cryptogenic stroke.

PROSTHETIC HEART VALVES

Valvular heart disease necessitating surgical or endovascular valve replacement is fairly common. The risk of thromboembolism in patients with mechanical heart valves is dependent on several factors—the adequacy of anticoagulation, characteristics of the valve (type and location of valve, number of valves), and patient-related risk factors such as AF and others. In general, thromboembolic complications are more common with mechanical valves than bioprosthetic (tissue) valves, more common with mitral than aortic valve replacement, and more common with older- than newer-generation valves. Mechanical valves confer about a 4 percent annual risk of stroke, whereas bioprosthetic valves confer a much lower stroke risk.[3] Anticoagulation with warfarin reduces the annual risk of stroke to 0.8 percent with mechanical aortic valves and 1.3 percent with mechanical mitral valves.[3] Lifelong vitamin K antagonist therapy, such as with warfarin, is recommended for all patients with mechanical valves, and strict INR control is essential for stroke prevention. Published guidelines should be consulted for specific treatment recommendations because INR targets differ for certain valves or patient characteristics, and some guidelines recommend the addition of aspirin. The efficacy of warfarin depends on maintaining a stable therapeutic INR, and this can be challenging because the INR can fluctuate due to illness, drug interactions, diet, and medication adherence. Prosthetic heart valves are also an independent risk factor for infective endocarditis, a major risk cause of cardioembolic stroke.

Endocarditis

INFECTIVE ENDOCARDITIS

Infective endocarditis, discussed in detail in Chapter 6, refers to a bacterial or fungal infection of the endocardium or heart valves. Risk factors for its development include an immune-compromised state (diabetes mellitus, corticosteroid use), injection drug use, invasive procedures, and rheumatologic conditions such as psoriasis. The most common bacteria are Staphylococci, accounting for 60 to 80 percent of cases, but other organisms, such as *Candida*, gram-negative bacilli, and HACEK organisms (*Haemophilus parainfluenza, H. aphrophilus, H. parahrophilus, H. influenza, Actinobacillus actinomycetemcomitans, Cardiobacter hominins, Eikenella, Kingella kingae*) have been implicated as well. Regardless of the pathogen, left-sided endocarditis, affecting the mitral or aortic valves, confers a high risk of embolic stroke. Embolic cerebral ischemic lesions occur in 50 to 80 percent of cases as detected by MRI. Abscesses and mycotic aneurysms with subarachnoid hemorrhage occur in up to 10 percent of cases.

Given the risk of mycotic aneurysm formation and subarachnoid hemorrhage, the administration of acute thrombolytic therapy and anticoagulation may adversely affect outcomes. All febrile patients presenting with acute stroke symptoms should be evaluated urgently for signs of infective endocarditis by clinical examination, echocardiography, and blood cultures. It is prudent to exclude infective endocarditis before administering thrombolytic agents.

MARANTIC (NONBACTERIAL THROMBOTIC) ENDOCARDITIS

Marantic or nonbacterial endocarditis is characterized by sterile fibrin and platelet aggregates or vegetations on heart valves. Compared to infective endocarditis, these vegetations are more friable and prone to embolization, with an incidence of cerebral ischemia of 33 percent compared to 19 percent. There is no associated bacteremia or destruction of heart valves. Marantic endocarditis is not the same as “culture-negative” IE, which can occur in the context of prior antibiotic administration or infection with fastidious bacteria or nonbacterial pathogens. Marantic endocarditis is thought to arise after endothelial cell injury in the context of a hypercoagulable state. Many well-described conditions may be responsible, including antiphospholipid antibody syndrome, systemic lupus erythematosus (SLE), rheumatoid arthritis, and disseminated malignancy. Echocardiography reveals marantic endocarditis in upwards of 19 percent of metastatic adenocarcinomas, the most common originating from the pancreas and lung.

Clinically, marantic endocarditis can manifest as new cardiac symptoms with progressive dyspnea on exertion, pedal edema, exercise intolerance, constitutional symptoms, and signs of systemic rheumatologic disease, coupled with clinical manifestations of embolization including focal neurologic deficits, flank pain, an acute abdomen, or painful ischemic extremities. The diagnostic work-up in suspected cases includes serial blood cultures to exclude infective endocarditis, TEE to evaluate the mitral and aortic valves, imaging studies to look for occult malignancy, and blood tests for rheumatologic conditions, lupus anticoagulant, and anticardiolipin and anti-B_2-glycoprotein 1 antibodies. Treatment involves unfractionated or low-molecular-weight heparin or warfarin. Those with antiphospholipid antibody syndrome should receive life-long anticoagulation. Embolic stroke secondary to marantic endocarditis in the context of disseminated malignancy is associated with a poor prognosis.

MANAGEMENT OF CARDIOGENIC BRAIN EMBOLISM

Emergency Reperfusion Treatment

THROMBOLYSIS

The administration of intravenous alteplase (tPA) at 0.9 mg/kg within the first 4.5 hours of stroke onset improves functional outcomes and is guideline-recommended for eligible patients with acute ischemic stroke. Patients receiving intravenous tPA have an increased odds of reduced disability and of recovery with no disability at 3 to 6 months after their stroke, but the effectiveness of tPA is time sensitive. According to a 2014 meta-analysis of nine trials of intravenous tPA, the number of patients needed to treat (NNT) for one additional patient to recover without disability is 10 when intravenous tPA is administered within the first 3 hours of stroke onset, and 19 when administered between 3 and 4.5 hours after onset. In contrast, the NNT for one additional fatal intracranial hemorrhage is 40 to 50. Strict eligibility criteria have been established to minimize the risk of hemorrhage. Tenecteplase, another tissue plasminogen activator, is an emerging treatment being investigated for acute ischemic stroke that appears to be as effective as alteplase and may have a lower risk of bleeding.[2,11] Recent trials suggest that intravenous tPA can be effective beyond 4.5 hours in carefully selected patients who have potentially salvageable tissue as defined by CT perfusion studies or MRI.

Endovascular Therapy

Modern endovascular therapy has revolutionized acute stroke treatment and outcomes. Cardioembolic strokes, which often cause large proximal embolic intracranial or extracranial large-artery occlusions, may be amenable to emergency removal by mechanical thrombectomy or direct intra-arterial thrombolysis. The effectiveness of endovascular therapy for improving outcomes after large-vessel occlusions in the anterior circulation has now been firmly established by five randomized trials published in 2015. A pooled analysis of these trials (HERMES collaboration) demonstrates that endovascular therapy within 6 hours of onset doubles the odds of functional recovery without disability.[12]

The advent of CT perfusion imaging permits a more refined selection of patients who may benefit from endovascular therapy for up to 24 hours after stroke onset. A sizable "mismatch" lesion pattern on CT perfusion indicates potentially salvageable tissue. The DEFUSE-3 and DAWN trials established the effectiveness and safety of endovascular therapy for up to 16 or 24 hours after onset, respectively, for highly selected stroke patients with a favorable neuroimaging profile.[11] Mechanical thrombectomy is now recommended for carefully selected patients with acute ischemic stroke who are within 6 to 24 hours of their last known normal time, have a large-vessel occlusion in the anterior circulation, and satisfy DAWN or DEFUSE-3 eligibility criteria.[11]

Stroke Prevention

Anticoagulant Therapy for Atrial Fibrillation

Anticoagulant therapy is highly beneficial for stroke prevention in individuals with AF, reducing the risk of stroke by about two-thirds (Table 5-3).[13–15] Without anticoagulation, individuals with AF have an average annual risk of stroke of 4.5 percent in the absence of a past history of stroke, and 12 percent in those with a previous stroke. With warfarin, there is a 64 percent reduction in the stroke risk. For primary stroke prevention, the absolute stroke risk reduction (ARR) with warfarin is 2.7 percent (NNT, 37), and for secondary prevention the ARR is 8.4 percent (NNT, 12).[14] Ischemic strokes occurring in patients taking warfarin are less severe on average than in those not taking warfarin, with an inverse relationship observed between INR level and stroke severity.

Antiplatelet agents are far less effective than warfarin at reducing the risk of stroke in patients with AF. Aspirin (75 to 1200 mg daily), is associated with a 19 percent relative risk reduction of stroke compared with placebo or no treatment, and has an ARR of 0.8 percent (NNT, 125) for primary prevention and of 2.5 percent (NNT, 40) for secondary stroke prevention.[14] Warfarin as compared with antiplatelet agents is associated with a 37 percent relative reduction in stroke risk.[14] Aspirin's benefit in these patients may be to prevent nondisabling stroke that is not of cardioembolic origin. Therefore, guidelines

TABLE 5-3 ■ Efficacy of Warfarin for Stroke Prevention in Atrial Fibrillation

		Primary Prevention			Secondary Prevention		
	RRR (%)	Annual Stroke Risk (%)	ARR (%)	NNT	Annual Stroke Risk (%)	ARR (%)	NNT
No treatment		4.5			12		
Aspirin vs. placebo or no treatment	19		0.8	125		2.5	40
Warfarin vs. placebo or no treatment	64		2.7	37		8.4	12
Warfarin vs. aspirin	38		0.7	142		7.0	14
		All Stroke Prevention*					
	RRR (%)		ARR (%)	NNT			
DOAC vs. warfarin*	19		0.3	332			

ARR, Absolute risk reduction; RRR, relative risk reduction; DOAC, direct non-vitamin K oral anticoagulants.

*This meta-analysis by Ruff and colleagues did not distinguish between primary and secondary stroke prevention.[15]

Adapted from previously published meta-analyses (Hart RG, Pearce LA, Aguilar MI: Meta-analysis: antithrombotic therapy to prevent stroke in patients who have nonvalvular atrial fibrillation. Ann Intern Med 146:857, 2007[14] and Ruff CT, Giugliano RP, Braunwald E, et al: Comparison of the efficacy and safety of new oral anticoagulants with warfarin in patients with atrial fibrillation: a meta-analysis of randomised trials. Lancet 383:955, 2014[15]).

strongly recommend anticoagulant therapy rather than aspirin for stroke prevention in eligible individuals with AF. The risk of intracranial hemorrhage is doubled with warfarin compared to aspirin, although the absolute risk increase is 0.2 percent.[14] However, the outcome measure—stroke—in this meta-analysis represented a combination of intracranial hemorrhage and ischemic stroke. Therefore, the reported risk reductions above account for the increased risk of intracranial hemorrhage on warfarin. Compared with placebo, warfarin also reduces all-cause mortality by 26 percent.[14] Warfarin, however, is a difficult medication for patients because of the requirement for INR monitoring, drug and food interactions, fluctuations in INR, and bleeding risks.

Until 2009, warfarin and other vitamin K antagonists were the only type of oral anticoagulation available.[15] The arrival of the direct non-vitamin K oral anticoagulants as an alternative to vitamin K antagonists has represented a major advance in stroke prevention and these agents have now become the preferred anticoagulant treatment for patients with nonvalvular AF. The non-vitamin K oral anticoagulants either directly inhibit thrombin (dabigatran) or factor Xa (apixaban, edoxaban, rivaroxaban).[8] In contrast to warfarin, these drugs have a rapid onset of action, short half-life, fewer drug interactions, lack of food interactions, and do not require INR monitoring.[15] Regular follow-up of patients receiving such therapy is important to review their clinical status, assess and reinforce medication adherence, check blood pressure and renal function, screen for any bleeding concerns or drug interactions, and ensure that dosing is correct. An excellent practical guidance document has been published.[13] Direct non-vitamin K oral anticoagulants are contraindicated in patients with mechanical heart valves and are not recommended in renal failure.

There have been four pivotal phase III randomized trials evaluating the four non-vitamin K oral anticoagulants compared to warfarin in patients with nonvalvular AF. Overall, they are at least as effective if not slightly more effective than warfarin for stroke prevention, have similar or lower rates of major bleeding complications, and have a lower incidence of intracranial hemorrhage. In a meta-analysis by Ruff and co-workers comprising 71,683 patients, non-vitamin K oral anticoagulant therapy was associated with a 19 percent reduction in stroke or systemic embolic events compared with warfarin, mainly driven by a reduction in hemorrhagic stroke.[15] Specific antidotes have been developed and are entering clinical practice. Idarucizumab is a monoclonal antibody fragment that binds to dabigatran and rapidly normalizes hemostasis, and andexanet alfa is a recombinant coagulation factor Xa that can reverse the effects of rivaroxaban and apixaban.

TREATMENT DECISIONS

All types of AF (paroxysmal, persistent, or permanent) should be considered for anticoagulant therapy, unless contraindicated. AF occurring in the postoperative setting following cardiac surgery is fairly common and usually self-limited. Anticoagulation is reasonable if AF persists for more than 48 hours in this setting, but it may not need to be continued on a long-term basis if sinus rhythm is restored. Ongoing studies aim to better define the role of anticoagulation in such patients and it remains necessary to individualize management strategies for specific patients. Risk stratification is essential to determine optimal treatment.

The choice of a vitamin K antagonist or a direct non-vitamin K oral anticoagulant may be guided by a variety of factors including valvular heart disease, patient comorbidities such as kidney disease, concurrent medications, patient-specific bleeding risks, compliance, patient preferences, and cost. Risk stratification for bleeding can be estimated using the HAS-BLED or other scores, which take into account hypertension, renal disease, liver disease, past history of stroke, previous major bleeding episodes, unstable INR, age >65 years, alcohol use, and medications that increase bleeding risk.[13]

Many schemes have been devised for identifying patients with AF at high, moderate, or low risk for stroke. High-risk factors are previous stroke, TIA, or systemic embolism; mitral stenosis; and prosthetic heart valves. Patients at high-risk should be placed on an anticoagulant. Moderate-risk factors include age older than 75 years; hypertension; heart failure; left ventricular ejection fraction less than 35 percent; and diabetes. The $CHADS_2$ and CHA_2DS_2-VASc scores are commonly used to estimate an individual's risk of stroke and practical online tools are publicly available (e.g., www.sparctool.com). Current recommendations from the American Heart Association are that those with nonvalvular AF and a CHA_2DS_2-VASc score greater than 2 in men or 3 in women should be treated with an oral anticoagulant (level of evidence, A).[8]

The direct non-vitamin K oral anticoagulants are recommended over warfarin in eligible patients (level of evidence, A). Regardless of the CHA_2DS_2-VASc score, AF patients with a mechanical heart valve should only receive warfarin as non-vitamin K oral anticoagulants are contraindicated.[8] For patients prescribed warfarin, INR requires regular monitoring, usually on a monthly basis.[8] For those with a CHA_2DS_2-VASc score of 0 in men or 1 in women, it is reasonable to omit anticoagulant therapy (level of evidence, B).[8] Aspirin alone (81 to 325 mg) is considered sufficient for patients without any additional risk factors. Canadian guidelines currently recommend anticoagulant therapy for all individuals with AF who are aged 65 or older, unless contraindications exist. For patients with AF and a CHA_2DS_2-VASc score of 1 in men or 2 in women, anticoagulation may be considered (level of evidence, C). For patients who cannot take long-term anticoagulant therapy, an alternative is a LAA occlusion procedure, which has comparable efficacy to warfarin without the long-term bleeding risks.[2,8,13]

ACUTE MYOCARDIAL INFARCTION

For secondary stroke prevention after a myocardial infarct, current guidelines from the American Heart Association recommend treatment with vitamin K antagonists for patients who have an ischemic stroke or TIA in the context of an acute anterior infarct with an elevated ST segment and anterior or apical akinesis or dyskinesis defined by echocardiography.[9] In those with acute infarct complicated by left ventricular mural thrombus or either anterior or apical wall motional abnormalities and a left ventricular ejection fraction of less than 40 percent, there is an even stronger recommendation for anticoagulant therapy. For patients who are intolerant of vitamin K antagonists, treatment with low-molecular-weight heparin or a direct non-vitamin K oral anticoagulant can be considered.[9]

CARDIOMYOPATHY AND LEFT VENTRICULAR DYSFUNCTION

In patients with ischemic stroke or TIA who have either left atrial or left ventricular thrombus, anticoagulant therapy with vitamin K antagonist is recommended for at least 3 months (level of evidence, C).[9] In the WARCEF randomized trial of 2305 patients with heart failure (left ventricular function $\leq 35\%$) and in sinus rhythm, warfarin reduced the risk of ischemic stroke but the benefit was offset by an increase in major bleeding.[10] In a meta-analysis of patients with congestive heart failure with reduced ejection fraction, there was a small absolute reduction in the risk of ischemic stroke in those treated with warfarin rather than antiplatelet therapy, but this was accompanied by an increased risk of major hemorrhage (mostly intracranial) and was not associated with any accompanying reduction in death, myocardial infarction, or hospitalization due to heart failure. In the COMMANDER HF trial of patients with reduced left ventricular ejection fraction (40%) in sinus rhythm, rivaroxaban at a dose of 2.5 mg twice daily was not associated with a significantly lower rate of the composite outcome of death, myocardial infarction, or stroke compared with placebo, although stroke events were reduced.

PATENT FORAMEN OVALE

The treatment options for secondary stroke prevention after a presumed PFO-related ischemic stroke are: (1) percutaneous PFO device closure plus long-term antiplatelet monotherapy; (2) anticoagulant therapy; or (3) antiplatelet therapy alone. Six randomized controlled trials have compared PFO closure with medical therapy. There is strong evidence that PFO closure is more effective than antiplatelet therapy alone.[16,17] Guidelines recommend PFO closure for secondary stroke prevention in patients aged 18 to 60 years (up to age 65 years in one guideline), but careful patient selection is essential. PFO closure should only be recommended for patients with an embolic stroke event for which there is a high probability of a causal role for the PFO and a comprehensive etiologic work-up has excluded other causes. PFO closure is not recommended for primary stroke prevention.

In an analysis by Saver and colleagues, the NNT with PFO closure to prevent one recurrent ischemic stroke over 5 years is 24 overall; NNT was 18 for moderate to large shunts, and 13 for PFOs associated with an atrial septal aneurysm.[16] According to a 2018 meta-analysis and guideline, for every 1000 patients treated, there will be 100 recurrent strokes over 5 years with antiplatelet therapy alone, 29 with anticoagulant therapy, and 13 with PFO closure.[17] PFO closure is associated with a 3.6 percent incidence of procedural complications plus a 3 percent increase in the risk of developing AF (transient in about half the cases). Long-term anticoagulant therapy is associated with increased bleeding risks.[17]

For patients who do not undergo PFO closure, either antiplatelet or anticoagulant therapy is reasonable. Anticoagulant therapy is probably better, although the evidence for this recommendation is weak because randomized trial data are limited.[17]

Clinicians should help patients understand the benefits and risks of each of the treatment options using a shared decision-making approach and taking into account patient values and preferences. Useful patient decision aids are available (https://app.magicapp.org/app#/guideline/2649).[17]

SYNCOPE

Syncope is a transient loss of consciousness associated with an inability to maintain postural tone and with rapid spontaneous recovery.[18] It is due to generalized cerebral hypoperfusion in the context of cardiac, neurologic, vasovagal, hypovolemic, or psychogenic causes. Syncope is discussed in detail in Chapter 8, but is considered here with regard to its occurrence in patients with acquired cardiac disease and arrhythmias.

Clinical Manifestations

The clinical spectrum of abnormalities that occur with generalized cerebral hypoperfusion is broad, ranging from nonspecific "dizziness" to a variety of disturbances including paresthesias, visual alterations, loss of consciousness, and sometimes even convulsive movements. Syncope and seizure can therefore be difficult to differentiate clinically. Patients with syncope often report feeling distant, dazed, or as if they are "fading out" before losing consciousness. Motor activity is common, with generalized tonic contraction of axial muscles followed or accompanied by irregular nonrhythmic jerking of the extremities; generalized rigidity without clonic activity; or irregular facial movement or eyelid flutter without tonic activity. Myoclonic activity, head turns, oral automatisms, and writhing movements also occur rarely in syncope. Upward deviation of the eyes is common. During recovery, tonic flexion of the trunk may occur and patients may be dazed or confused for up to 30 seconds after restoration of the circulation. Typically though, there is an abrupt restoration of consciousness and cognition, in contrast to generalized seizures.

Certain clinical features can help to differentiate seizure from syncope, as summarized in Table 5-4. Syncope is especially common in the elderly, who show a high recurrence rate. Of the many causes of syncope, it is important to identify those of cardiac origin because mortality is significantly increased in this group of patients.

Cardiac Etiologies

Table 5-5 highlights the historical features distinguishing cardiac and noncardiac causes of syncope.[18] Cardiac causes can relate to arrhythmias, structural abnormalities, or both.

STRUCTURAL HEART DISEASE

Syncope can occur in patients with known heart disease. The most common valvular cause of syncope is aortic stenosis, which can cause syncope and dyspnea on exertion. In aortic stenosis, hemodynamic compromise mediates syncope due to an inability to sustain cardiac output across a fixed area of critical stenosis. Aortic valve replacement or repair is recommended in these individuals.[18]

Obstruction of the left ventricular outflow tract can also cause syncope. One cause is hypertrophic cardiomyopathy if the outflow tract comes to be obstructed, leading to syncope by one of two mechanisms. Exertional syncope may occur because of the obstructed outflow, or syncope may relate to left ventricular dilatation and heart failure predisposing to malignant arrhythmias and sudden cardiac death.[18] In addition to common structural causes, aortic tract outflow stenosis or intermittent obstruction to outflow may occur, for example, by a mobile thrombus or tumor in the left atrium or ventricle.

A rare cause of cardiac syncope is cardiac sarcoidosis, in which a number of mechanisms may be operative. Macro-reentrant arrhythmias surrounding granulomas are the most common form of ventricular arrhythmia in this context, but cardiac myocyte inflammation can compromise left

TABLE 5-4 ■ Clinical Features to Differentiate Generalized Seizures from Syncope

	Seizures	Syncope
Patient characteristics	Past history of seizures History of head trauma History of febrile seizures History of developmental delay	Severe anemia or gastrointestinal bleeding Cardiac disease Autonomic neuropathy Medications (eg., antihypertensives)
Before the event	Stereotyped prodrome May have speech arrest, sense of impending doom, epigastric sensation, sensory aura, and/or automatisms	May not have a prodrome If prodrome present, usually of lightheadedness or diaphoresis There may be situational triggers
During the event	Loss of consciousness Lasts seconds to minutes May have forced lateral eye or head deviation; repetitive stereotyped movements; or rhythmic clonic activity Incontinence is common	Loss of consciousness Lasts seconds (if patient falls flat) Nonrhythmic movements Incontinence may occur
After the event	Prolonged postictal confusion and behavioral disturbances (minutes or hours) Lateral tongue laceration	Rapid recovery to cognitive baseline within seconds
Neurologic findings	Focal neurologic deficit (Todd paresis) may persist after the episode	No focal neurologic deficits
Investigations	EEG may demonstrate epileptiform activity*	Hypotension and bradycardia may occur during tilt-table testing ECG and Holter abnormalities may suggest arrhythmia Structural cardiac disease may be found on echocardiography

*EEG, electroencephalogram. An EEG is not routinely ordered in the work-up of syncope unless there are accompanying neurologic features to suggest seizure.

TABLE 5-5 ■ Features Associated with Cardiac and Noncardiac Causes of Syncope

Cardiac	Noncardiac
Age > 60 years	Younger age
Male	No known cardiac disease
Presence of cardiac disease (ischemic, structural, prior arrhythmias, or reduced left ventricular ejection fraction)	Positional (from supine/sitting to standing)
Syncope on exertion	Presence of prodrome: nausea, vomiting, feeling warmth
Syncope in supine position	Triggers: dehydration, stress, distressing stimulus, medical environment, cough, laugh, micturition, defecation, deglutition
Low number of syncopal episodes	Frequent recurrence with similar characteristics
Abnormal cardiac examination	
Family history of inheritable conditions	
Family history of sudden cardiac death before 50 years of age	

Adapted from the 2017 American College of Cardiology and American Heart Association Guidelines on the evaluation and management of patients with syncope.[18]

ventricular function, affect the electrical automaticity of myocytes, and predispose to arrhythmia such as ventricular fibrillation.[18] Furthermore, varying degrees of atrioventricular conduction blocks are common in cardiac sarcoidosis.[18] The best method for evaluation of sarcoid is by cardiac MRI; the syncope is best managed with implantable cardiac defibrillators.[18]

Other rare and acquired cardiomyopathies (infiltrative, mitochondrial, and infectious etiologies) are associated with cardiogenic stroke and in some instances can present with syncope as well. There are a group of patients with syncope and a structurally normal heart who pose a particular diagnostic challenge and raise the possibility of additional disorders of the conducting tissues, including channelopathies.

ARRHYTHMIAS: CONDUCTION ABNORMALITIES

Bradyarrhythmias are commonly due to sinus node dysfunction (sick sinus syndrome) or AV nodal conduction diseases. Ischemic cardiomyopathy can cause second- and third-degree atrioventricular conduction blocks that can cause bradyarrhythmias and syncope, and rare infiltrative diseases such as cardiac amyloidosis and sarcoid can do so as well.[18] Stokes–Adams attacks are sudden, brief (10 to 30 seconds) episodes of loss of consciousness, sometimes accompanied by motor activity, that are typically caused by complete third-degree atrioventricular block, which can be seen on the ECG during an attack. Heart rate during an episode is markedly slow. Although coronary artery disease is a common etiology in older individuals, young individuals with congenital heart block may also experience attacks.

Supraventricular tachycardia seldom causes syncope, except in elderly subjects or in young persons with an extremely rapid tachycardia. A relatively common disorder predisposing to paroxysmal supraventricular tachycardia is Wolff–Parkinson–White syndrome. This occurs in the context of an accessory electrical pathway leading to a supraventricular tachycardia, which is usually sporadic with a prevalence of up to 1 in 1,000 persons.[18] AF may develop, and "dizziness," syncope, and, rarely, sudden death may occur. The characteristic ECG hallmarks are a short PR interval and a slowly rising prolonged QRS complex. Management may involve accessory pathway ablation.

Patients with a ventricular arrhythmia (fibrillation or tachycardia) experience syncope after 9 seconds regardless of whether the arrhythmia is sustained. The arrhythmia can be monomorphic or polymorphic. When a patient reports light-headedness with palpitations, ventricular tachycardia must be considered as a possible etiology.[18] Prolonged QT syndrome is considered in the next section.

ARRHYTHMIAS: CHANNELOPATHIES

Channelopathies are a major cause of cardiac-related syncope in young people and are associated with a family history of sudden cardiac death.[18] The possibility of a channelopathy must be considered in a young person with exertional syncope. There are 16 genotypes of long QT syndrome (LQTS) all of which are hereditary channelopathies, with more than 60 percent of cases associated with a loss-of-function mutation in either *KCNQ1* (LQTS type 1) or *KCNH2* (LQTS type 2) potassium channel genes. Exertion or emotion may trigger syncopal events. The characteristic feature is a prolonged QT interval (corrected for heart rate) ≥ 500 msec on a standard ECG. The disorder predisposes to polymorphic ventricular tachycardia, which, in turn, predisposes to syncope and sudden death.[18] More commonly, long QT syndrome occurs as an acquired nongenetic disorder in the context of drugs known to prolong the QT interval. In contrast, a short QT interval syndrome is another genetic condition characterized by palpitations, syncope, and sudden cardiac death with a $\text{QTc} \leq 349$ msec that predisposes to ventricular fibrillation.

Another channelopathy is catecholaminergic polymorphic ventricular tachycardia, which is characterized by catecholamine-induced bidirectional or polymorphic ventricular tachycardia. Approximately 60 percent of patients have a mutation in the cardiac ryanodine receptor (*RyR2*; autosomal dominant) or cardiac calsequestrin gene (*CASQ2*; autosomal recessive).[18] The prevalence is around 0.1 per 1,000. The disorder usually presents in the first or second decade of life with stress-induced syncope. Both this disorder and LQTS-type 1 are best evaluated by cardiac stress test with concurrent ECG recording as they are adrenergically mediated arrhythmias.[18]

Another genetic disease characterized by an increased risk of sudden cardiac death and syncope is Brugada syndrome, which also can produce malignant arrhythmias. Approximately 30 percent of patients have a mutation in *SCN51*, which encodes for cardiac sodium channels. Mutations in *SCN51* alter the function of the channel, ultimately reducing sodium influx into cardiac myocytes and leading to ventricular arrhythmias. It has a higher prevalence in males and in those from Asian countries compared to North America or Northern

Europe. This condition is synonymous with sudden unexplained nocturnal death syndrome (SUNDS). The baseline ECG may be abnormal and show ST elevation in leads V1 and V2, together with a right bundle branch block pattern. This ECG pattern may be concealed and require unmasking by the use of sodium channel blockers.

Evaluation of syncope requires attention to family history including unexplained sudden deaths, age of onset, note of apparent epileptic disorders, relation of events to exertion and distress, and effects of postural change. In the presence of an apparently normal heart, evaluation of the standard ECG, prolonged ECG monitoring, or exercise stress tests may reveal a cause.

CARDIOMYOPATHIES WITH ASSOCIATED NEUROLOGIC MANIFESTATIONS

Cardiomyopathies are mechanical or electrical diseases of the myocardium not caused by valvular heart disease, systemic hypertension, or atherosclerotic coronary disease. They can be inherited or acquired. Many classification systems exist and one phenotypic system classifies cardiomyopathies as (1) dilated, (2) restrictive, (3) hypertrophic, (4) left ventricular noncompaction, and (5) arrhythmogenic right ventricular cardiomyopathy.[19] Most cardiomyopathies are genetic, but secondary etiologies include infectious, infiltrative, inflammatory, nutritional, metabolic, and toxic causes.

While syncope and cardioembolic stroke can occur in the context of ventricular dysfunction from either inherited or acquired cardiomyopathy, the different causes of cardiomyopathy are associated with unique neurologic symptoms ranging from seizures to ataxia to peripheral neuropathy. Recognizing these neurologic manifestations in the presence of clinical and echocardiographic evidence of a cardiomyopathy may help guide clinicians in the differential diagnosis and diagnostic work-up.[19]

CONCLUDING COMMENTS

The relationship between infection of the heart valves and arterial embolization was first recognized by Rudolf Virchow in the mid-1800s and the classic clinical triad of fever, heart murmur, and hemiplegia was described 30 years later by Osler in his Gulstonian Lectures of 1885. Despite an increasing prevalence in recent decades of prosthetic valve and device-related infective endocarditis (IE),[1] the proportion of patients with IE and neurologic manifestations has remained relatively constant. Neurologic complications are frequent and are often associated with increased morbidity and mortality in IE. Although the key to treating neurologic complications is appropriate antibiotic therapy, the presence of neurologic manifestations often alters the medical or surgical treatment of IE.

EPIDEMIOLOGY OF NEUROLOGIC COMPLICATIONS

Neurologic events have long been recognized as frequent and severe complications of IE. Large prospective cohort studies, including the International Collaboration on Endocarditis, and the European Infective Endocarditis Registry provide evidence regarding IE and its various complications.[2–5] The overall frequency of neurologic complications of IE has remained relatively constant at approximately 15 to 30 percent (Table 6-1), and clinically silent cerebral embolism on presentation may occur in nearly half of these cases.[2] Nevertheless, due to the high overall incidence of stroke in the general population, IE is an unusual cause of stroke. Neurologic complications of IE can be divided into three major types:

NR, not reported.
*Includes transient ischemic attack.
†Reporting does not distinguish cases with potentially more than one cerebral event so estimates may be inflated. Ischemic stroke includes cerebral embolism on admission, and cerebral embolism/TIA/stroke in follow-up. Hemorrhage includes hemorrhagic stroke on admission and follow-up and cerebral hemorrhage in follow-up.

ischemic stroke, hemorrhagic stroke, and direct cerebral infection. Ischemic stroke is by far the most common, accounting for 50 to 75 percent of all neurologic complications. Primary hemorrhage, usually intraparenchymal or subarachnoid, is less common, reported in less than 10 percent of patients. Mycotic aneurysms are reported in less than 2 percent of cases in most cohort studies, although studies that include angiography for all patients report a much higher proportion.[6] Cerebral infections may manifest, without previous clinical evidence of ischemic or hemorrhagic stroke, in less than 10 percent of cases; typical infectious complications include cerebritis, meningitis, and micro- or macroabscesses. Other neurologic symptoms, including seizures, headache, mental status changes, and neuropsychologic abnormalities, sometimes occur but are usually secondary to one of the three major complications. Rarely, endocarditis has been associated with spinal cord infarction or abscess, discitis or spondylitis (4.7% in one series), retinal ischemia, and ischemic cranial and peripheral neuropathies.[2]

PATHOPHYSIOLOGY OF NEUROLOGIC COMPLICATIONS

Almost all the neurologic complications of IE have embolization as their primary cause (Fig. 6-1). Although cerebral emboli are probably not more common than extracerebral emboli, they are more often symptomatic and thus typically reported more frequently; they are also associated with an increased morbidity and mortality compared to other systemic emboli. In general, cerebral emboli most often affect the middle cerebral artery (MCA) territory and may be septic or nonseptic. In patients without neurologic symptoms, MRI shows cerebral lesions in at least 50 percent of cases, and the majority of these are ischemic.[7] Therefore, neuroimaging should be considered in all patients with IE, regardless of neurologic symptoms. Septic emboli may also lead to hemorrhagic stroke through the development of arteritis or mycotic (infectious) aneurysm; cerebral micro- or macroabscess (Fig. 6-2), usually via seeding of ischemic tissue; and cerebritis or meningitis by seeding the meninges.

Most primary intracerebral hemorrhages in IE result from septic embolism followed by septic necrosis and rupture of the vessel wall. Less commonly, they result from rupture of mycotic aneurysms.[2,3] Intracerebral hemorrhage may also occur owing to a secondary hemorrhage into an ischemic infarct (Fig. 6-3).

Mycotic aneurysm formation has been related to (1) septic embolization to the arterial lumen or the vasa vasorum; (2) direct extension from an infection outside the vessel wall; (3) bacteremia causing direct infection of the intima; or (4) direct contamination during surgery or trauma.[8] Mycotic aneurysms are usually small, located at distal arterial bifurcations rather than the circle of Willis, and can be single or multiple. Branches of the MCA are the most common location for mycotic aneurysms (Fig. 6-4).

Brain macroabscesses account for less than 1 percent of all neurologic complications of IE and may occur secondary to ischemic infarction from a septic embolus or from extension of infection from adjacent arteritis or mycotic aneurysm. Brain microabscesses are more common than macroabscesses, are often associated with *Staphylococcus aureus* infections, and usually occur in cases with multiple ischemic infarctions from distal migration

FIGURE 6-1 ■ Embolization to various cerebral structures is responsible for most of the neurologic complications of IE. Emboli that lodge in the lumen of cerebral vessels may lead to ischemic stroke and can lead to arteritis or mycotic aneurysm formation with resultant vessel rupture and cerebral hemorrhage. Emboli to the meninges may produce meningitis, and emboli to the brain parenchyma, especially when associated with cerebral ischemia, may result in meningoencephalitis or abscess. (From Solenski NJ, Haley EC Jr: Neurologic complications of infective endocarditis. p. 331. In Roos KL (ed): Central Nervous System Infectious Diseases and Therapy. Marcel Dekker, New York, 1997, with permission. Granted via Copyright Clearance Center.)

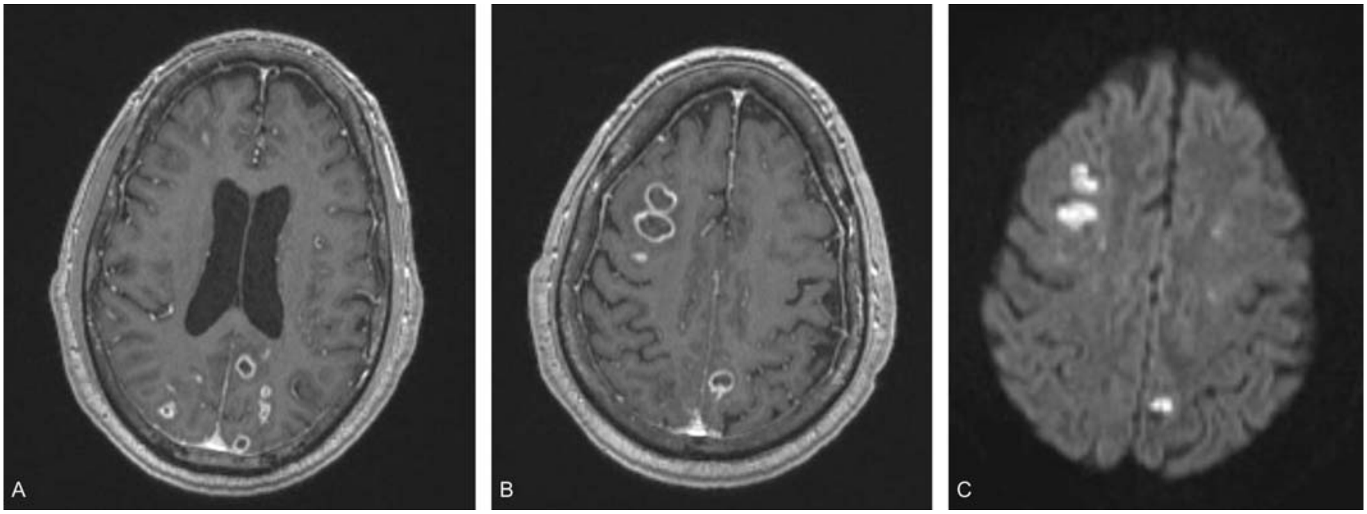

FIGURE 6-2 ■ This patient presented with fever, new cardiac murmur, mental status changes, and right hemiparesis. *A* and *B*, Contrast-enhanced axial T1-weighted magnetic resonance imaging (MRI) shows multiple ring-enhancing lesions suggesting septic microembolization. *C*, Axial diffusion-weighted imaging (DWI) sequences show restricted diffusion associated with the lesions.

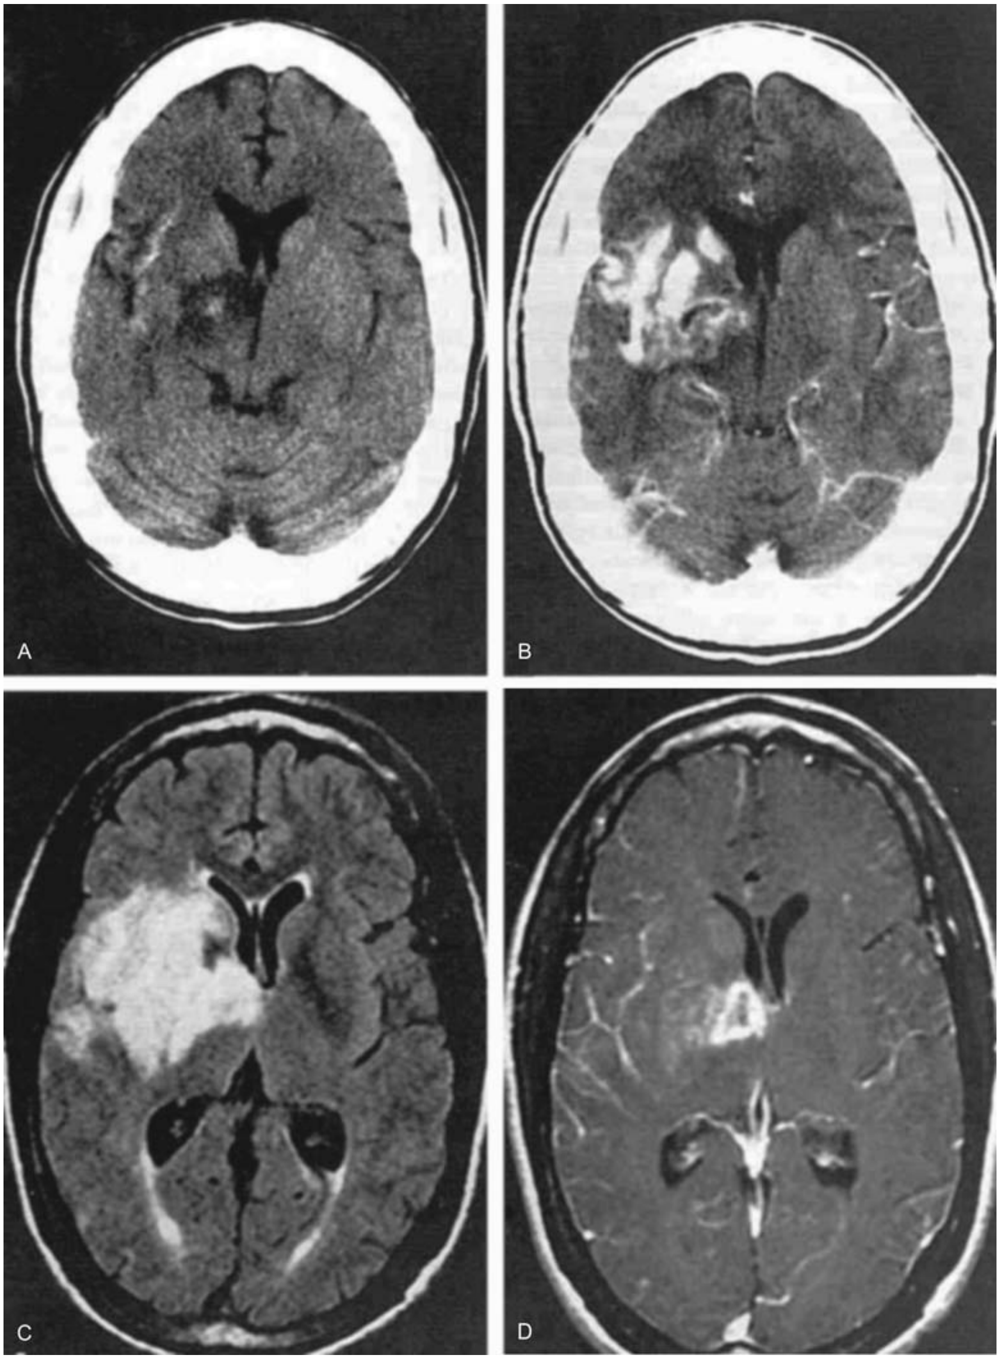

FIGURE 6-3 ■ This patient presented with left hemiparesis and mitral valve endocarditis. *A*, Noncontrast head CT showed a focal low-density lesion in the right internal capsule and lentiform nucleus with a central area of hemorrhage (increased density) and cortical hemorrhage in the insula. *B*, With contrast, large confluent areas of enhancement representing leaky blood–brain barrier can be seen in the right caudate and lentiform nuclei, the insula, and the temporal cortex. *C*, Fluid-attenuated inversion recovery (FLAIR) MRI 2 days after the head CT showed diffuse increased signal in the regions of CT enhancement and the right thalamus. *D*, Following gadolinium administration, ring-like enhancement in the area of a previous infarct can be seen, representing possible secondary infection. This pattern is sometimes referred to as a "septic infarction." This enhancement pattern resolved with antibiotic treatment and without development of a macroabscess.

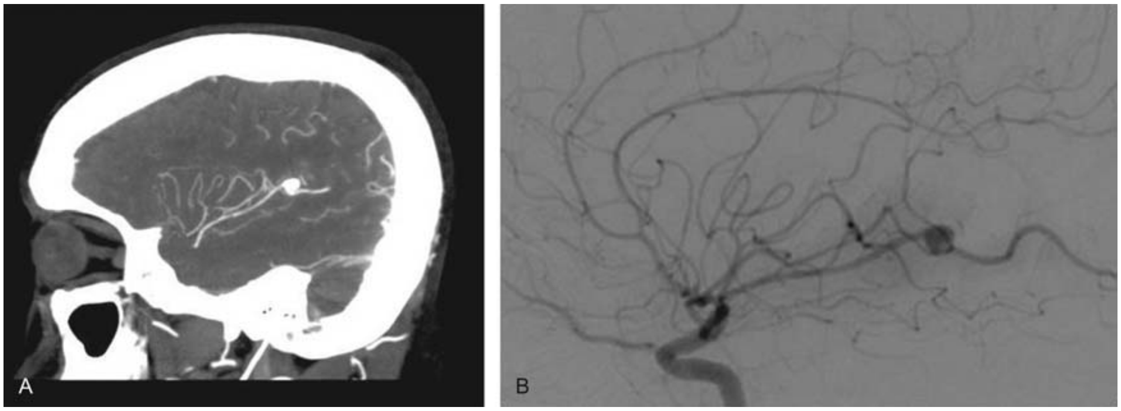

FIGURE 6-4 ■ This patient presented with fever, new systolic murmur, sudden headache, and altered mental status without focal neurologic deficits. Noncontrast head CT showed a small subarachnoid hemorrhage (not shown). Sagittal CT angiogram, *A* demonstrated a mycotic aneurysm in the distal MCA, confirmed by conventional angiography, *B*. This aneurysm enlarged despite adequate antibiotic therapy, and the patient subsequently underwent successful clipping.

of septic embolic fragments. Meningoencephalitis is usually a result of direct embolization to meningeal vessels, with subsequent parenchymal or cerebrospinal fluid (CSF) invasion of the infecting organism. Aseptic meningitis may also occur with subarachnoid hemorrhage due to a necrotic arteritis or ruptured mycotic aneurysm.

RISK FACTORS FOR NEUROLOGIC COMPLICATIONS

A variety of clinical and laboratory features have been associated with an increased risk of embolism or neurologic complications from IE (Table 6-2).[9–11]

Site of Infection

Neurologic complications are more common with left-sided IE than with right-sided valve involvement, although embolization to any organ may be more common with right-sided endocarditis.[2,3,5] Cerebral embolization in right-sided endocarditis may occur through a patent foramen ovale or a pulmonary arteriovenous fistula. Most reports comparing native and prosthetic valve endocarditis indicate no significant difference in the proportion of patients with neurologic complications. Among those with prosthetic valve endocarditis, however, mechanical valves may be associated with complications more often than bioprosthetic valves.

Infecting Organism

Streptococci, staphylococci, and enterococci are the three most prevalent infecting organisms. Both United States nationwide and multicenter European studies found *S. aureus* to be the most commonly identified organism, increasing in the United States from 38 percent in 1998 to 49 percent in 2009.[1,2] In one United States study, 53 percent of the *S. aureus* cases were meticillin-resistant. This changing resistance pattern is reflected in updated treatment guidelines.[9,10]

In most studies, *S. aureus* infection is independently associated with an increased risk of embolization;

TABLE 6-2 ■ **Suggested Risk Factors for Embolization in Infective Endocarditis**

Risk Factor	Proposed Mechanism
Mitral valve infection	Increased valve mobility and left-sided position predispose to cerebral embolization
"Virulent" organism	More rapid endothelial invasion leads to more friable, unstable valve surface
Acuteness of infection	More rapid endothelial invasion leads to more friable, unstable valve surface; acute infection is associated with hematologic factors that may promote thrombosis
Valvular vegetations	Increasing vegetation size and vegetation mobility may predispose to embolism
Hematologic factors	Increased endothelial cell activity, platelet aggregability, and antiphospholipid antibodies may be associated with increased risk of embolization

some authors have reported *Streptococcus bovis* and *Candida* species are also more likely to be associated with embolism.[1,2] It is unclear whether antibiotic susceptibility changes affect the risk of embolic complications, although infections that take longer to control might theoretically have an increased risk of embolization. The virulence of the organism, the availability of effective antimicrobial therapy, and the potential development of large, friable vegetations all contribute to the propensity for embolization.

Acuity of Infection

There is a higher risk of neurologic complications with acute endocarditis than with subacute endocarditis, probably relating to the specific typical etiologic agents noted in acute disease (*S. aureus* and β-hemolytic streptococci) and the potential for large vegetations or valve damage acutely. The risk of cerebral embolization is highest in the first week of infection. Once effective antibiotic therapy is started there is a steep decline in the rate of embolization to 15 percent in the first week and only 4 percent in the second week after antibiotics.[5]

Valvular Vegetations

Detection of valvular vegetations by either transthoracic (TTE) or transesophageal echocardiography (TEE) is a key step in diagnosing IE and also critical to patient management. Because of its increased sensitivity and ability to evaluate the more posteriorly located aortic valve, TEE appears to be cost-effective as the initial study when clinical suspicion of IE is high, but management algorithms often recommend TTE as the initial study because it can be obtained more quickly and it also shows other cardiac abnormalities important in medical and surgical decision-making.[9,10] Most studies have linked the presence of vegetations, especially increased vegetation size (often dichotomized at >10 mm), to an increased risk of embolization.[2,3,5,11,12] A meta-analysis of 21 cohort studies suggested that in addition to size greater than 10 mm, the presence of any vegetations, multiple or mobile vegetations, and vegetations on prosthetic valves were independently related to risk of embolism.[12] Current recommendations suggest that repeat echocardiography may be useful if clinical changes that suggest treatment failure occur during antibiotic therapy and that it should be performed urgently for unexplained progression of heart failure, new heart murmurs, or the development of atrioventricular block.[9,10]

Hematologic Risk Factors

Antiphospholipid antibodies have been associated with IE, and have also been reported to decrease after successful treatment of IE. A recent meta-analysis also found that elevated C-reactive protein was an independent risk for embolism among patients with IE.[11]

ISCHEMIC AND HEMORRHAGIC STROKE

Ischemic stroke secondary to embolization of friable valvular material is the most common neurologic complication of IE. Ischemic stroke is the presenting symptom of IE in up to 20 percent of cases and is most common in the acute stage of the infection, especially prior to or during the first week of therapy.[5] Because of this clustering of symptoms in the acute phase, transient focal neurologic symptoms in a febrile patient, especially in the presence of a regurgitant murmur, should always raise suspicion of IE.

Intracerebral hemorrhage in IE may be primary or secondary to ischemic stroke or other pharmacologic or hematologic conditions (Table 6-3). Of the primary hemorrhages, intraparenchymal and subarachnoid

TABLE 6-3 ■ Causes of Intracerebral Hemorrhage in Infective Endocarditis

- Primary Intracerebral Hemorrhage
    - Arterial rupture secondary to arteritis
    - Rupture of a mycotic aneurysm
- Secondary Intracerebral Hemorrhage
    - Hemorrhagic conversion of ischemic stroke
    - Anticoagulation
- Hematologic Disorder
    - Disseminated intravascular coagulopathy
    - Thrombocytopenia
    - Vitamin K deficiency
- Pre-existing central nervous system lesion (e.g., aneurysm, arteriovenous malformation)

hemorrhage are most common. In one series, only eight cases of subarachnoid hemorrhage occurred among 60 patients with IE and cerebral hemorrhage.[3] Mycotic aneurysms are infrequently reported in large cohort studies, but are estimated to be present in nearly one-third of patients with left-sided IE (26 of 81 consecutive patients with CT angiography, although 15 of the 26 were clinically asymptomatic).[6]

Other conditions that sometimes accompany IE may also predispose to bleeding, including disseminated intravascular coagulation, thrombocytopenia, and vitamin K deficiency. Although mycotic aneurysms are most commonly found in the intracranial vessels, rarely these aneurysms may involve the extracranial carotid, thoracic, or abdominal vessels.[8]

Clinical Presentation

In accordance with their embolic etiology, the majority of ischemic strokes involve the cortex rather than subcortical brain tissue, although finding multiple small emboli that are both cortical and subcortical in location is not uncommon (Fig. 6-5). Patients with multiple microemboli can present with nonlocalizing symptoms, including headache, diminished level of consciousness, encephalopathy, or psychosis (Fig. 6-5). Clinical worsening of ischemic stroke may result from a variety of mechanisms, including development of cerebral edema, recurrent embolization, secondary hemorrhage into the ischemic area, and development of cerebral abscesses. Cerebral edema may occur regardless of ischemic stroke mechanism, is more likely to be symptomatic in larger strokes and in younger patients, and is typically maximal between 3 and 5 days after stroke. Recurrent embolization should be suspected when new focal deficits develop; this complication is most likely to occur early in the course of treatment or when infection is uncontrolled.[5] Hemorrhagic transformation of an ischemic stroke may occur, and may theoretically be more likely in strokes caused by infective endocarditis due to the resulting arteritis. Hemorrhagic transformation of an ischemic stroke is often asymptomatic, as are cerebral microhemorrhages, although development of a large intra-infarct hematoma may be symptomatic. The term "septic infarction" has been used when, several days to weeks following an ischemic stroke, a cerebral abscess develops within the infarcted tissue.

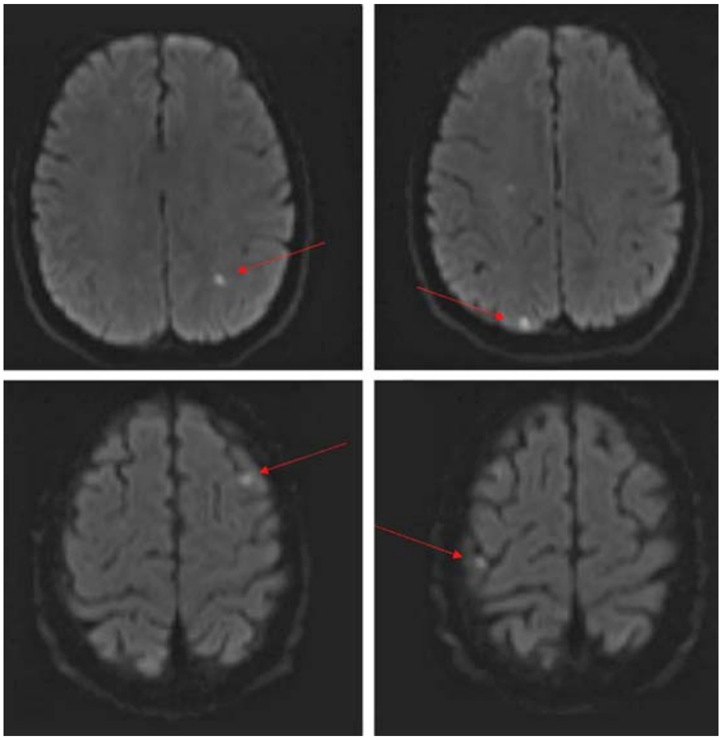

FIGURE 6-5 ■ This 36-year-old man presented with fever and headache and was found to have aortic valve enterococcal endocarditis. These diffusion-weighted MRI sequences illustrate the prototypical small, often asymptomatic embolic ischemic strokes that can occur with left-sided endocarditis.

As with ischemic stroke, intracerebral hemorrhage usually presents with focal neurologic disturbances, but nonlocalizing symptoms, such as headache and decreased level of consciousness, may also predominate. Seizures may occur at the onset of the hemorrhage or later in its course. When subarachnoid hemorrhage occurs, either from rupture of an arteritic vessel or from a mycotic aneurysm, meningismus may be a prominent feature. Headaches may be more diffuse and subacute than is typical with ruptured saccular aneurysms.

Seizures

Although seizures may occur in patients with IE from toxic or metabolic disturbances (e.g., hypoxia, antibiotic toxicity), most often seizures are secondary to ischemic or hemorrhagic stroke. A United States nationwide administrative data-based study of endocarditis hospitalizations from 1998 to 2009 reported 3.8 percent of all cases experienced seizures during the hospitalization, likely an underestimate of clinical seizure frequency.[1] Seizures that are secondary to stroke are usually focal in nature, with or without secondary generalization, whereas seizures due to metabolic or toxic factors are more often primarily generalized. The development of seizures during antibiotic treatment may signify clinical worsening from recurrent stroke, hemorrhagic transformation, or abscess formation. Therefore, the new onset of seizures in a patient with IE should always prompt an urgent neuroimaging study. Rarely, seizures are secondary to antibiotic therapy, with imipenem and fourth-generation cephalosporins most frequently associated with seizures.

Evaluation of Patients

Brain Imaging

All patients with acute focal neurologic deficits should undergo either a noncontrast computed tomography (CT) scan of the head or brain magnetic resonance imaging (MRI). Noncontrast CT may be done more quickly than MRI and is most useful for acutely ruling out hemorrhage or mass effect. If IE is known or suspected, head CT with and without contrast may have additional benefit as areas of increased contrast enhancement allow possible cerebral abscesses or mycotic aneurysms to be distinguished from areas of ischemia. However, brain MRI is the most sensitive modality for detecting the multiplicity of neurologic lesions seen in IE, especially small, multiple emboli (Figs. 6-2 and 6-5).[7] MRI findings have been categorized into four patterns: (1) embolic infarction; (2) multiple patchy infarctions (nonenhancing); (3) small nodular or ring-enhancing white matter lesions (probably microabscesses); and (4) hemorrhagic infarctions (intracerebral or subarachnoid). Multiple cerebral microbleeds, detected best on MRI, occur in up to 60 percent of patients and have also been described as a feature strongly associated with the presence of IE.[9] Hemorrhagic transformation of ischemic infarcts is most often patchy and may follow the contour of the gyri but may also appear as a homogeneous hematoma within an infarct (Fig. 6-3). A clue to the presence of an underlying mycotic aneurysm may be a focal area of cortical enhancement adjacent to an area of hemorrhage.

Vascular Imaging

Based on evidence that subarachnoid hemorrhage can occur without preceding symptoms in more than 50 percent of patients with mycotic aneurysm, some have advocated that all patients with IE should undergo noninvasive vascular imaging with MR angiography (MRA) or CT angiography (CTA) for aneurysm screening. Guidelines suggest screening for mycotic aneurysms in patients with endocarditis and neurologic deficits, including severe headache, erythrocytes or xanthochromia in the CSF, confusion, seizure, or focal neurologic signs.[9,10]

Patients with intracranial hemorrhage are more likely to have mycotic aneurysms than patients with ischemic stroke (22% vs. 1% in one series).[13] Although mycotic aneurysms tend to be small and—unlike saccular aneurysms—occur distally rather than at more proximal arterial branch points, CTA is emerging as a reasonable choice for initial screening, with one series demonstrating that 26 of 81 patients screened with CTA had a mycotic aneurysm, and angiographic findings changed the treatment plan in 21 of these patients.[6]

Patients with ischemic or hemorrhagic stroke who require long-term anticoagulation for mechanical valves or treatment of systemic thromboembolism may also benefit from repeat noninvasive angiography to exclude a mycotic aneurysm, even if initial studies performed at the time of presentation are negative. Patients with known mycotic aneurysms require serial monitoring of aneurysm size to ensure adequate response to therapy; CTA and MRA are likely adequate for this purpose.

Cerebrospinal Fluid Examination

CSF examination was once part of the standard evaluation of patients with IE and neurologic symptoms, but it does not often change management decisions for patients today. The interpretation of CSF findings in IE with acute stroke is complicated by the tendency for patients with stroke unrelated to endocarditis also to have mild to moderate increases in CSF white blood cells, red blood cells, or protein concentration. For these reasons, CSF examination does not usually aid in the diagnosis or management of patients with neurologic symptoms and IE.

Echocardiography

The diagnosis of IE depends on the documentation of a responsible organism on serial blood cultures and, in part, on the presence of valvular abnormalities on echocardiography. Echocardiography is also important in assessing valvular function and excluding conditions such as valve thrombosis or abscess formation that would change clinical management. TEE is more sensitive to mitral and aortic valve pathology and has been reported to change patient management in as many as one-third of cases. Most guidelines recommend TTE as the initial screening study because it can typically be obtained more quickly, but also recommend that TEE be performed to rule out other local cardiac complications.[9,10] Whether serial echocardiography provides data that reliably predict the risk of subsequent stroke or otherwise influence neurologic management is not known.

TREATMENT OF ISCHEMIC STROKE

Antibiotic Therapy

The cornerstone of treatment of IE is appropriate antibiotic therapy directed at the infecting organism. Numerous studies have shown that the risk of either initial or recurrent thromboembolism decreases sharply after the first few days of adequate antibiotic therapy, with one study of almost 1,500 patients demonstrating a risk of 4 percent after the second week of antibiotic therapy.[5] It is therefore critical to ensure that antibiotics are begun promptly and empirically, immediately after drawing initial blood for cultures (preferably three sets from separate sites) in febrile patients with stroke in whom IE is being considered. As effective long-term antimicrobial therapy will be required, the isolation and susceptibility testing of the pathogen are of critical importance. Involvement of a specialist in infectious diseases is recommended, as host defense is essentially ineffective in endocarditis; thus bactericidal antibiotics are more effective than bacteriostatic antibiotics.[9] IE related to infections of implantable cardiac devices is increasing.[1] In this setting, device removal is also typically required in addition to antibiotic therapy. Thorough discussion of a current approach to diagnosis and antimicrobial treatment in various clinical scenarios can be found in the American and European guideline statements, including the appropriate conditions for which antibiotic prophylaxis for the prevention of IE should be considered.[9,10]

Thrombolysis

Acute use of tissue plasminogen activator in patients with ischemic stroke and IE is generally felt to be inadvisable due to an increased bleeding risk. Although there are no large cohort studies, a case series and systematic review that included 40 published cases found a significantly higher post-treatment intracerebral hemorrhage rate among those treated with thrombolysis compared to those treated with endovascular therapy (63% vs. 18%).[14] This report found similar rates of good outcome and mortality in those treated with endovascular treatment, suggesting that clot retrieval may be emerging as the preferred therapy for patients with IE and acute, clinically severe cerebral embolism.

Antiplatelet and Anticoagulant Therapy

The use of antithrombotic therapy (antiplatelet and anticoagulant medication) is controversial in patients with IE, and guidelines recommend these management decisions be made in the setting of a multidisciplinary team.[9,10] Although some studies have suggested that antiplatelet therapy may reduce vegetation size and embolic events, both the European Society of Cardiology and the American Heart Association/American College of Cardiology guidelines for management of IE conclude that data do not support routine initiation of antiplatelet medications, and recommend interruption of antiplatelet therapy if the patient has major bleeding.[9,10]

Anticoagulation in patients with IE remains a controversial and complicated topic. Hemorrhagic complications are clearly more common in anticoagulated patients, but patients with mechanical prosthetic valves may require long-term anticoagulation, and the decision as to whether and for how long to withhold anticoagulants in these patients is complex, depending on the type of valve involved.

ANTICOAGULATION IN NATIVE VALVE ENDOCARDITIS

There is an increased risk of hemorrhagic complications in patients with native valve endocarditis and ischemic stroke who are treated with anticoagulation, and the risk of recurrent embolism is low in those patients receiving appropriate antibiotic therapy. Accordingly, there appears to be no benefit for stroke risk reduction to routinely anticoagulate these patients. An important consideration is whether, prior to the development of endocarditis, these patients were being anticoagulated for a specific indication such as clotting disorders, atrial fibrillation, or pulmonary embolism. In these cases, a review of MRI sequences, looking for occult hemorrhage and vascular lesions, should be part of a risk-to-benefit analysis before anticoagulants are stopped. When anticoagulation is deemed to be necessary, switching from oral to intravenous medications is recommended for optimal control of anticoagulation.[9,10] Whether lower-level anticoagulation (e.g., for prevention of deep venous thrombosis) is safe in patients with stroke and IE is unknown. Because other strategies, such as the use of sequential compression devices, may be equally efficacious, a conservative approach is to use these nonpharmacologic methods primarily.

ANTICOAGULATION IN PROSTHETIC VALVE ENDOCARDITIS

Patients with bioprosthetic valves typically do not receive long-term anticoagulant therapy, thus the same approach as outlined for native valve endocarditis is recommended. Patients with mechanical valve endocarditis and stroke, however, present more difficult management dilemmas.

If a patient with a mechanical valve is receiving long-term anticoagulant therapy and develops a cerebral embolus as a complication of IE, the decision as to whether to continue anticoagulation or temporarily withhold it depends on several factors. Because larger ischemic strokes, especially those secondary to emboli, may be more likely to develop secondary hemorrhagic complications, some authors favor temporarily withholding anticoagulation for several days up to 2 weeks, especially when *S. aureus* is the infecting organism. In general, recommendations favor reinstituting anticoagulation as quickly as possible after the ischemic stroke and following multidisciplinary discussion.[9,10] Patients with intracerebral or subarachnoid hemorrhage and a mechanical valve represent an extremely complex situation in which individual patient clinical, infectious, and valve characteristics must be weighed. In general, anticoagulation is withheld for some period of time and, when reinstated, use of unfractionated or low-molecular-weight heparin is recommended.[9,10] In this situation, determination of the type of mechanical valve and consultation with a multidisciplinary team concerning the risk of valve thrombosis will help guide the decision.

Surgical Treatment

Valve replacement is not recommended therapy for preventing initial or recurrent stroke. Typically, surgery is recommended for patients with severe or refractory congestive heart failure, perivalvular abscess, unstable valve prosthesis, recurrent embolism, infection with a pathogen resistant to effective antimicrobial agents, persistent vegetations greater than 10 mm, or an inability to clear the infection.[9,10] If surgery is required, the timing of the procedure in the setting of stroke is controversial and typically decided on a case-by-case basis. In ischemic stroke, recent cohort studies have suggested that early surgery (within 1 week) is not associated with increased mortality at 6 months or 1 year compared to delayed surgery (greater than 2 weeks). The 2015 American Heart Association guidelines provide multiple recommendations for when early surgery may be considered, including for patients with recurrent emboli.[10] Several risk scores, including the Society of Thoracic Surgeons and De Feo scores, have been developed and may be useful to help identify appropriate surgical candidates.[9,10]

TREATMENT OF HEMORRHAGIC STROKE

Intraparenchymal Hemorrhage

The mainstay of treatment for either primary or secondary intracerebral hemorrhage in patients with IE is the same as that for cerebral emboli: effective treatment of the underlying infectious organism. This is especially true for patients with pyogenic arteritis but is also critical for the treatment of mycotic aneurysms. Some patients with intracerebral hemorrhage and progressive neurologic deterioration, either from expanding hematoma or from edema, may benefit from surgical evacuation of the clot, but no firm guidelines exist. Patients with mechanical valves often will have their anticoagulant discontinued temporarily or converted to an intravenous form as noted earlier. All patients with IE and hemorrhage should have close neurologic monitoring in an intensive care setting since deterioration from recurrent hemorrhage or edema is not uncommon.

Mycotic Aneurysms

The natural history of mycotic aneurysms appears to be that approximately one-third resolve completely with 6 to 8 weeks of antibiotic treatment. The remaining two-thirds are relatively equally divided into those that increase, decrease, or are unchanged.[8] Because of their propensity to resolve with antibiotic therapy, the evaluation and treatment of mycotic aneurysms is highly individualized. Aspects of care that remain unclear are the choice of imaging technique, what frequency of serial angiography is necessary to follow mycotic aneurysms, and the indications and methods of treatment. These complex considerations and a suggested clinical management algorithm are detailed in the 2016 AHA Scientific Statement on mycotic aneurysms and other vascular infections.[8] In general, if an aneurysm enlarges, surgical treatment to prevent rupture is suggested. The need for ongoing or subsequent long-term anticoagulation is another factor that may suggest the need for angiographic surveillance and surgical treatment. Since mycotic aneurysms may persist after adequate antibiotic treatment and since new aneurysms can appear, it is reasonable to repeat angiography, typically with noninvasive techniques, at the conclusion of antibiotic therapy (usually 4 to 6 weeks). Late hemorrhage from a ruptured mycotic aneurysm in patients who have completed adequate antibiotic therapy is rare, therefore continued surveillance of a stable aneurysm following antibiotic treatment is probably unnecessary.

Once an aneurysm is discovered, controversy also exists regarding treatment. Asymptomatic aneurysms are often treated medically, with surgical intervention reserved for those that enlarge or have leaked.[8] Although symptomatic aneurysms may also resolve with antibiotic treatment, most authors favor surgical treatment of any ruptured mycotic aneurysm in addition to antibiotic therapy. This recommendation is usually based on the risk of recurrent bleeding and the need for subsequent cardiovascular surgery or anticoagulation. Aneurysm accessibility and number are other features that influence the decision for surgical treatment. Single aneurysms in a peripheral location are more likely to be treated surgically, with those in more eloquent areas treated with endovascular therapy.[8]

CEREBRAL INFECTION

Cerebral infection, most commonly abscess or meningitis, occurs in less than 10 percent of patients with endocarditis and neurologic complications (Table 6-1). These infections most typically occur after cerebral embolism. Infection arising without clinical evidence of prior embolization is unusual. Encephalitis has also been reported, although the usual pathology in these cases is multiple emboli with microabscess formation.

Meningitis accounts for approximately 5 percent of all neurologic manifestations of IE and is more common with either *S. aureus* or *Streptococcus pneumoniae* infections. When meningitis is associated with involvement of the cerebral cortex, evidenced by gyral enhancement on MRI, the terms “cerebritis” and “meningoencephalitis” are used. Rarely, cerebritis leads to the development of a parameningeal abscess in the cerebral cortex. Meningitis typically results from septic emboli to the meningeal vessels with subsequent CSF colonization. Less commonly, meningitis is nonseptic, resulting from sterile inflammation of the meninges due to blood products or circulating immune complexes released into the CSF.

Cerebral abscesses are rare, with small “microabscesses,” often defined as abscesses smaller than 1 cm, being more common than “macroabscesses.” Cerebral abscesses usually develop as the result of septic emboli and are not necessarily preceded by clinical symptoms. Radiographically, infarction-related abscesses are usually small and multiple and may demonstrate areas of nodular or ring-like enhancement (see Fig. 6-2).

Clinical Presentation

Although the clinical diagnosis of meningitis is infrequent in IE, symptoms of meningitis, including meningismus, headache, encephalopathy, cranial neuropathies, seizures, and increased intracranial pressure may occur. These symptoms may be subtle, especially in the elderly, and when associated with fever, elevated peripheral white blood cell count, and regurgitant murmur should prompt an urgent evaluation for IE.

Evaluation

All patients with known or suspected IE and neurologic symptoms, whether focal or nonfocal, should undergo imaging with noncontrast head CT prior to lumbar puncture because multiple embolic strokes, intracerebral hemorrhage, and abscess may all cause significant compartmental increases in intracranial pressure, thus increasing the risk of cerebral herniation. Lumbar puncture should not be performed in any patient with a focal lesion and evidence of mass effect on neuroimaging studies. Because patients with endocarditis have a propensity toward hematologic abnormalities, coagulation tests and a platelet count are important prior to lumbar puncture. In general, lumbar puncture is infrequently performed if the organism is known and the patient is stable, as CSF findings are unlikely to change antibiotic therapy.

Treatment of Cerebral Infection

As for any type of CNS infection, the goal of treatment is adequate antibiotic therapy to which the infecting organism is sensitive with good CSF penetration. Both microabscesses and macroabscesses usually respond to antibiotic treatment, although macroabscesses may occasionally produce significant mass effect and thus require stereotactic aspiration or surgical drainage.

OTHER NEUROLOGIC COMPLICATIONS

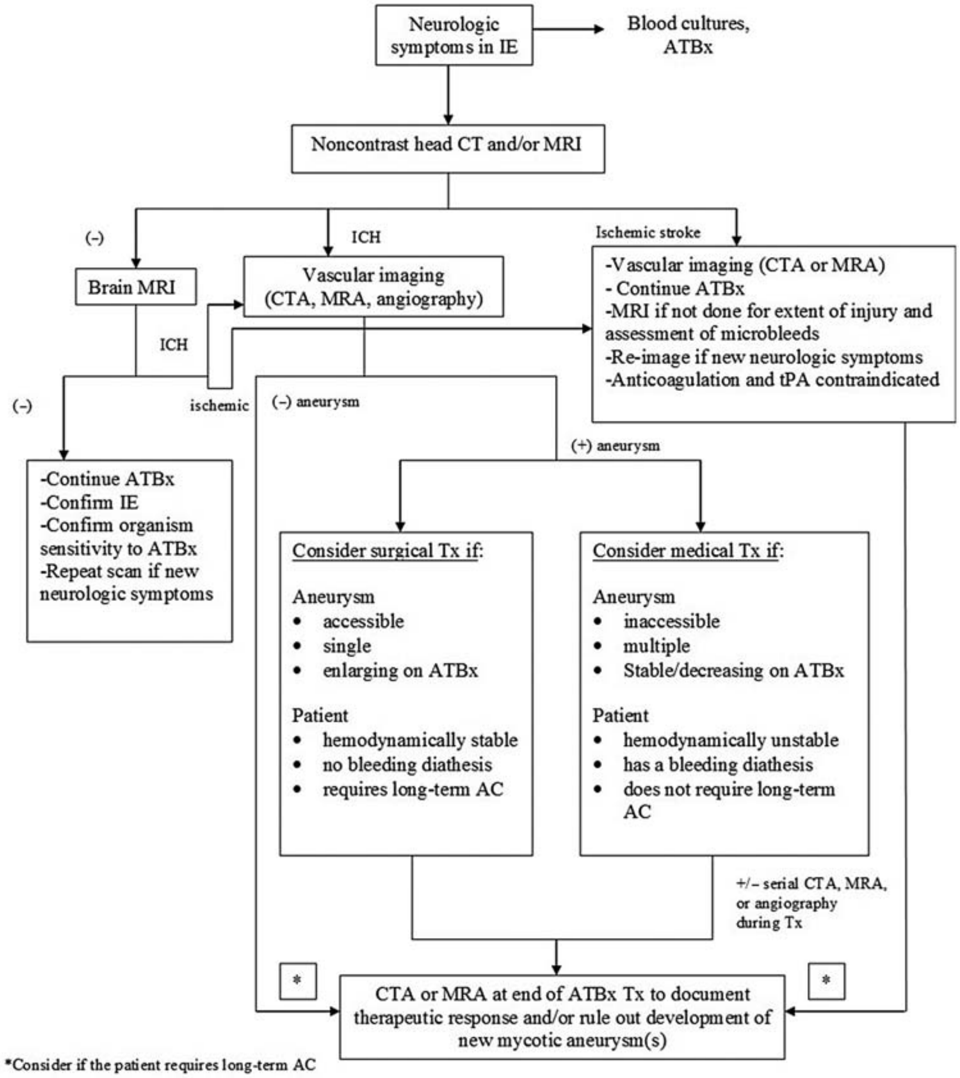
Other extracerebral neurologic complications may rarely occur. Although cerebral and systemic emboli appear to occur with similar frequency, cerebral neurologic complications predominate clinically over extracerebral neurologic complications, probably because the brain receives more blood flow than peripheral neurologic tissues and because cerebral complications are more likely to be symptomatic. Mononeuropathy or mononeuritis multiplex has been reported in patients with IE, and both peripheral and cranial nerves may be involved. Discitis or spondylitis, occasionally with associated epidural abscess or osteomyelitis, may be more common with *S. aureus* infection. Other rare sites of embolization include the spinal cord itself and the retina.

SUGGESTED MANAGEMENT ALGORITHM

The management of neurologic complications of IE is not standardized and substantial variations in care may be necessary based on individual patient characteristics. Nonetheless, it is helpful to consider a treatment algorithm that includes pathways for the major neurologic manifestations of the disease (Fig. 6-6). The two keys to managing patients, regardless of neurologic complications, are: (1) a high level of suspicion of the possibility of IE and (2) prompt initiation of appropriate antibiotic therapy after obtaining multiple sets of blood cultures.

PROGNOSIS

Overall, patients with IE have high mortality, with short-term mortality estimated at 20 percent and long-term mortality at 37 percent based on a meta-analysis of 25 observational studies and 22,382 patients.[15] Among patients with IE, short-term mortality is increased in those with neurologic complications compared to those without them.[2,4,16] Mortality is higher in infections with more virulent organisms, with some studies showing an association between *S. aureus* infection and mortality, and others reporting increased mortality as vegetation size increases.[9,10,12] Intracerebral hemorrhage appears to confer added risk, with reported mortality of 40 to 90 percent. Although rare, rupture of a mycotic aneurysm is associated with even higher mortality.



Neurologic symptoms in IE
Blood cultures, ATBx
Noncontrast head CT and/or MRI
(-)
ICH
Ischemic stroke
Brain MRI
Vascular imaging (CTA, MRA, angiography)
-Vascular imaging (CTA or MRA)
- Continue ATBx
-MRI if not done for extent of injury and assessment of microbleeds
-Re-image if new neurologic symptoms
-Anticoagulation and tPA contraindicated
ICH

*
CTA or MRA at end of ATBx Tx to document therapeutic response and/or rule out development of new mycotic aneurysm(s)
*Consider if the patient requires long-term AC

FIGURE 6-6 ■ Suggested management algorithm for patients with focal neurologic deficits and known or suspected IE. Factors favoring either surgical or medical treatment of mycotic aneurysms are presented, but management of these cases is highly individualized. Repeat angiography at the conclusion of medical therapy is suggested for all patients with known mycotic aneurysms and may be considered either for patients with intracerebral hemorrhage and a negative initial angiogram or for patients with ischemic stroke who require long-term anticoagulation. ATBx, antibiotics; CTA, Computed tomography angiography; ICH, intracerebral hemorrhage; LP, lumbar puncture; MRA, magnetic resonance angiography; Tx, treatment.

Longer-term mortality following IE may be less related to neurologic events, although some studies do find an association between neurologic complications and 1-year mortality.[16] Other studies suggest that age and other medical comorbidities including cancer, renal disease, and heart failure are more associated with mortality at 1 year.[3,4] The risk of recurrent neurologic events, either embolic or hemorrhagic, is low, with one study reporting 9 percent of patients having recurrent emboli (either cerebral or systemic).[5] Elimination of recurrent events appears to depend more on effective antibiotic treatment than on any other specific therapy.

CONCLUDING COMMENTS

Although IE has evolved somewhat with regard to prevalence, site, and susceptibility of infecting organisms, the proportion of patients with neurologic manifestations and the type of neurologic complications remain remarkably consistent. Most neurologic complications are caused by embolization of friable valvular material resulting in either ischemic or hemorrhagic stroke. A high index of suspicion for IE as the cause of stroke is critical, and some of the common treatments for acute stroke, such as thrombolysis, are often contraindicated in patients with IE and ischemic stroke. Although many clinical decisions in patients with neurologic manifestations of IE must be individualized, it is clear that the cornerstone of prevention and treatment of all neurologic complications is rapid delivery of appropriate antibiotic therapy.

Blood pressure was first measured in 1707 by an English divinity student, Stephan Hales, using a glass tube attached directly into the arteries of animals. Methods of measurement improved slowly over the next 200 years, with Nikolai Korotkoff describing the modern cuff-and-stethoscope technique in 1905. At the turn of the twentieth century, Theodore Janeway recognized that hypertension was an indicator of poor prognosis, including mortality from stroke in the years that followed the development of hypertension. A tolerable oral agent to treat hypertension was not available until 1957, when chlorothiazide was shown to reduce blood pressure in patients with essential hypertension.

Both acute hypertension and chronic hypertension produce neurologic disease. Acute hypertension is associated with hypertensive encephalopathy, a relatively uncommon presentation since the widespread identification and treatment of hypertension. Chronic hypertension is associated with stroke, which is its most important neurologic complication. All stroke subtypes are linked to hypertension, including ischemic infarction, intraparenchymal hemorrhage, and aneurysmal subarachnoid hemorrhage. Chronic hypertension is also associated with dementia.

EPIDEMIOLOGY

Both systolic and diastolic blood pressures are distributed approximately normally in the population. For convenience, physicians have defined pathologic states such as hypertension based on specific blood pressure thresholds. Most recently, hypertension has been defined as a systolic blood pressure >130 mmHg or diastolic >80 mmHg. Thus defined, hypertension is common, affecting approximately 116 million adults in the United States in 2016; its prevalence is projected to increase by 60 percent and affect 1.54 billion adults worldwide by 2025.[1,2]

Despite the frequent division of blood pressure into diagnostic categories such as hypertension and

Aminoff's Neurology and General Medicine, Sixth Edition.

normotension, there is no obvious threshold at which higher blood pressure begins affecting the risk of complications, and even patients with diastolic blood pressures of 80 to 90 mmHg are at increased risk of stroke compared with those with blood pressures of 70 to 80 mmHg (Fig. 7-1). Reflecting an awareness of the continuous risk associated with blood pressure, normal blood pressure has been defined as a systolic <120 mmHg and diastolic <80 mmHg and blood pressures of 120 to 129 mmHg systolic and <80 mmHg diastolic have been termed "elevated blood pressure."[3]

Related to the concept of thresholds for defining hypertension and normotension is the question of what the optimal blood pressure targets for treatment should be. The recent Systolic Blood Pressure Intervention Trial (SPRINT) was terminated early after demonstrating fewer cardiovascular events with an intensive blood pressure target (systolic blood pressure <120 mmHg) compared to a standard blood pressure target (systolic <140 mmHg).[4] Note that patients with a history of stroke (or diabetes) were specifically *excluded* from this study, and hypotension, syncope, electrolyte abnormalities, and acute kidney injury or failure were more common with intensive treatment. Also, the automated oscillometric blood pressure measurements used in the study are 5 to 10 mmHg lower than routine clinic measurements. How well these results obtained in a population of patients with higher cardiovascular risk generalize to patients with neurologic diseases, frailty, or a history of stroke or cerebrovascular diseases is uncertain.

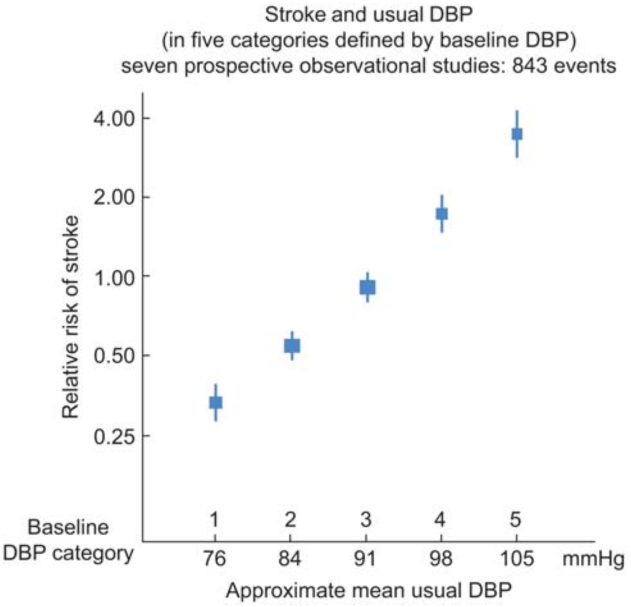

FIGURE 7-1 ■ Relative risks of stroke. Estimates of the usual diastolic blood pressure (DBP) in each baseline DBP category are taken from mean DBP values 4 years after baseline in the Framingham study. Solid squares represent disease risks in each category relative to risk in the whole study population; sizes of squares are proportional to the number of events in each DBP category; and 95 percent confidence intervals for estimates of relative risk are denoted by vertical lines. PATHOPHYSIOLOGY

In the brain, the primary pathophysiologic process of hypertension is related to increases in vasomotor tone and peripheral arterial resistance. Acute elevation in blood pressure results in constriction of small arteries in the brain in a compensatory response termed *autoregulation*, leading to blood flow to the brain being maintained at a relatively constant level over a range of pressures. At high pressures, vasoconstriction is thought to be protective by reducing pressure at smaller, more distal vessels. Acute severe hypertension overwhelms normal autoregulation at a mean arterial pressure of approximately 150 mmHg, with increased cerebral blood flow occurring above this pressure threshold. Vasoconstriction in acute hypertension is patchy, and some small vessels are exposed to high pressures, which may lead to endothelial injury and focal breakdown of the blood–brain barrier. Acute hypertensive encephalopathy is a fulminant presentation of this process. Fibrinoid necrosis of small vessels may also occur, lowering the threshold for future ischemic and hemorrhagic events.

Chronic hypertension results in cerebral vascular remodeling. The media hypertrophies, and the lumen becomes narrowed. These changes are protective, with reduction in wall tension and shifting of the autoregulation curve to allow compensation at higher blood pressures. However, vascular remodeling is accompanied by endothelial dysfunction, with impaired relaxation and poor compensation for hypoperfusion. The result is greater susceptibility to ischemic injury due to reduced collateral flow.

Hypertension also predisposes to atherosclerosis. Hypertension is proinflammatory and is accompanied by increased plasma oxygen free radicals. Free radicals induce vascular smooth muscle cell proliferation and may oxidize low-density lipoproteins, which in turn promotes macrophage activation and monocyte extravasation. Angiotensin II is elevated in many hypertensive patients and may play a direct role in atherogenesis independent of its effects on blood pressure. It directly stimulates smooth muscle cell growth, hypertrophy, and lipoxygenase activity, with resultant inflammation and low-density lipoprotein oxidation, thus accelerating atherosclerosis.

EVALUATION AND TREATMENT

The gold standard of blood pressure measurement has been auscultation using a mercury sphygmomanometer with the patient in the seated position after a 5-minute rest and with the patient's feet resting on the floor and the arm supported at heart level during the measurement. Accurate readings depend on the use of an appropriate-sized cuff with the bladder covering at least 80 percent of the arm. The classification of blood pressure into specific diagnostic categories had been based on the average of two or more readings on each of two or more office visits.

However, automated oscillometric blood pressure devices are common in the clinic and the home, and ambulatory devices that measure blood pressure at frequent intervals over the course of the day and night during normal activities are also available. Since these devices can take multiple consecutive readings and measurements can be made unattended or at home to reduce the white coat effect, data from clinic and out-of-office readings can be integrated to formally establish the diagnosis of hypertension as well. Different methods of blood pressure measurement may yield results that are systematically different, so careful attention to the specific method used to measure blood pressure when interpreting the results of recent clinical trials is vital.

A complete history and physical examination with basic laboratory measurements are essential to evaluate for identifiable causes of hypertension and assess risk. Several patient characteristics may suggest an identifiable cause of hypertension including young age, severe hypertension, hypertension that is refractory to multiple interventions, and physical or laboratory findings suggestive of endocrinologic disorders, such as truncal obesity or hypokalemia. Abdominal bruits or decreased femoral pulses may also be an indicator of renovascular disease or coarctation of the aorta. Discrepant readings between each arm raise the concern for subclavian stenosis and peripheral arterial disease.

Lifestyle modification is recommended as an initial therapy for patients with blood pressure of 120/80 mmHg or higher. Effective lifestyle interventions include weight loss, limiting alcohol intake, aerobic physical activity, adequate potassium intake, dietary salt restriction, and comprehensive dietary regimens such as the Dietary Approaches to Stop Hypertension (DASH) eating plan. The addition of pharmacologic treatment with one or more antihypertensives is justified when baseline atherosclerotic cardiovascular risk is high such as with established cardiovascular disease or stroke, diabetes, chronic kidney disease, or advanced age (>65) and when blood pressure readings at initial presentation are particularly high.

The reductions in cardiovascular risk that result from pharmacologic treatment of blood pressure have more to do with the degree of blood pressure reduction achieved than the particular antihypertensive agent used. Monotherapy with thiazides or related diuretics, calcium-channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II receptor blockers (ARBs) is reasonable subject to certain considerations for defined subpopulations (e.g., ACE-inhibitor or ARB with chronic kidney disease) and an individual patient's experience with tolerability and side effects. For patients with blood pressure that is well above goal at initial presentation, starting two first-line agents may be warranted from the outset, though regardless of the initial approach, a systematic approach to dose escalation and combination therapy is essential to achieve adequate blood pressure control as evidenced by the results of comprehensive hypertension management programs.[5]

There are many benefits to treating hypertension, including a reduction in myocardial infarction, congestive heart failure, retinopathy, renal failure, and overall mortality. The focus of the remainder of this chapter is on specific neurologic complications of hypertension and the unique aspects of treatment that they necessitate.

STROKE

Of all the identified modifiable risk factors for stroke, hypertension appears to be the most important, owing to its high prevalence and its strong association with elevated stroke risk. Based on epidemiologic data, approximately 50 percent of strokes could be prevented if hypertension were eliminated (Table 7-1). Studies have shown that even small reductions in blood pressure with active treatment (e.g., a reduction of even 5 mmHg diastolic) can result in large (~40%) reductions in stroke risk. The benefits of blood pressure reduction on stroke risk extend similarly to the elderly with isolated elevations in systolic blood pressure. Studies of patients aged 60 years or more have demonstrated similar reductions in stroke with reductions in systolic blood pressure and the best available data suggest that benefits of treating blood pressure in the oldest old (>85 years) are comparable to those seen in younger individuals.

In much of the developed world, improvements in hypertension awareness, increased use of antihypertensive medications, and better blood pressure control at a population level have largely paralleled a steady decline in the age-adjusted burden of disease from stroke. However, on a global scale, hypertension remains the leading risk factor for death worldwide and the developing world continues to bear a disproportionate, substantial, and increasing burden of disease from stroke (Fig. 7-2).

Hypertension contributes to each of the major intermediate causes of both ischemic and hemorrhagic stroke including carotid stenosis, intracranial atherosclerosis, small-vessel arteriosclerosis, and the development of both macroscopic and microscopic aneurysms. Each of these conditions is considered separately in this chapter.

In the acute phase of cerebral ischemia, hypertension may play a compensatory role in maintaining cerebral perfusion to viable but threatened areas of the brain. Loss of normal cerebral autoregulation has been demonstrated in areas of ischemic brain. When autoregulation is lost, blood flow to the brain becomes directly proportional to mean arterial pressure and therefore, in theory, pharmacologic increases in blood pressure could have salutatory effects in preserving hypoperfused regions of the brain. In some studies, rapid pharmacologic reductions in blood pressure have predicted worse outcomes, and there are numerous anecdotal reports of the recrudescence of stroke symptoms after a decrease in blood pressure. Therefore, withholding or reducing pharmacologic treatments of blood pressure in acute ischemic stroke seems reasonable unless the blood pressure exceeds 220/120 mmHg or acute end-organ injury or administration of thrombolytics necessitates setting a lower goal.

In the chronic phase, there is overwhelming evidence to support the use of pharmacologic interventions to lower blood pressure for secondary stroke prevention. Studies of combination therapy with ACE-inhibitors and thiazide diuretics in patients with a history of stroke have found greater reductions in the relative risk of recurrent stroke compared to ACE-inhibitors alone, largely owing to greater reductions in blood pressure that are achieved with combination therapy. Although therapy with renin-angiotensin system antagonists and diuretics may provide especially strong benefits for stroke prevention, particularly when compared with β-blockers, once again, the degree of hypertension control that is achieved is usually the best predictor of protection against recurrent stroke. Therefore, response to therapy and other comorbidities, such as heart failure, diabetes, asthma, and arrhythmia, should be considered when deciding on an appropriate antihypertensive drug regimen. Although the acute physiologic response to stroke can induce a

TABLE 7-1 ■ Estimated Impact of Modifiable Risk Factors on Stroke in the United States*

Risk Factor	Percentage Exposed	Relative Risk	Population-Attributable Risk (%)	Projected Number of Strokes Preventable
Hypertension	56	2.7	49	370,000
Cigarette smoking	27	1.5	12	92,000
Atrial fibrillation	4	3.6	9	71,000
Heavy alcohol consumption	7	1.7	5	35,000

*Relative risks are from the Framingham study. Population-attributable risk is the expected decrease in stroke rates if the risk factor were eliminated. Projected number of strokes preventable is based on an estimated 750,000 strokes per year.

FIGURE 7-2 ■ Age-standardized stroke incidence by country, for both sexes, 2016. (Reprinted with permission from GBD 2016 Stroke Collaborators: Global, regional, and national burden of stroke, 1990–2016: a systematic analysis for the Global Burden of Disease Study 2016. Lancet 18:439, 2019.)

short-term hypertensive reaction that may necessitate a de-escalation of antihypertensive therapy in certain patients, the general approach of initiating antihypertensive therapy before hospital discharge may improve patient adherence and blood pressure control during the crucial transition in care to the outpatient setting and over the longer term.

CEREBRAL ANEURYSMS

Cerebral aneurysms are focal dilatations of blood vessels. Subarachnoid hemorrhage, an important form of hemorrhagic stroke, occurs when a cerebral aneurysm ruptures (Fig. 7-3). Hypertension is associated with cerebral aneurysm formation and with subarachnoid hemorrhage. Hypertension is more commonly listed as a secondary diagnosis in patients admitted with unruptured aneurysms compared to hospitalized patients more generally, and studies suggest that hypertension may confer a nearly threefold higher risk of subarachnoid hemorrhage compared to nonhypertensive controls.

The cause of the development and rupture of cerebral aneurysms is multifactorial. Epidemiologic studies have identified several environmental risk factors for subarachnoid hemorrhage other than hypertension. Cigarette smoking doubles the risk of subarachnoid hemorrhage, perhaps by increasing the release of proteolytic enzymes that affect blood-vessel integrity. Heavy alcohol consumption increases subarachnoid hemorrhage risk perhaps due to alcohol-induced hypertension, relative anticoagulation, or increased cerebral blood flow. Oral contraceptives are associated with a small but significant excess risk of subarachnoid hemorrhage.

Genetic factors are also important to aneurysm formation and subarachnoid hemorrhage. The risk of subarachnoid hemorrhage is much greater in patients with an affected first-degree relative, and the prevalence of unruptured aneurysms is probably at least twice as high when a family history of aneurysm is present. Females are nearly twice as likely as males to have an aneurysm or to present with subarachnoid hemorrhage. African Americans have twice the rate of subarachnoid hemorrhage as whites. Polycystic kidney disease, Ehlers–Danlos syndrome type 4, and α_1-antitrypsin deficiency are also associated with increased risk.

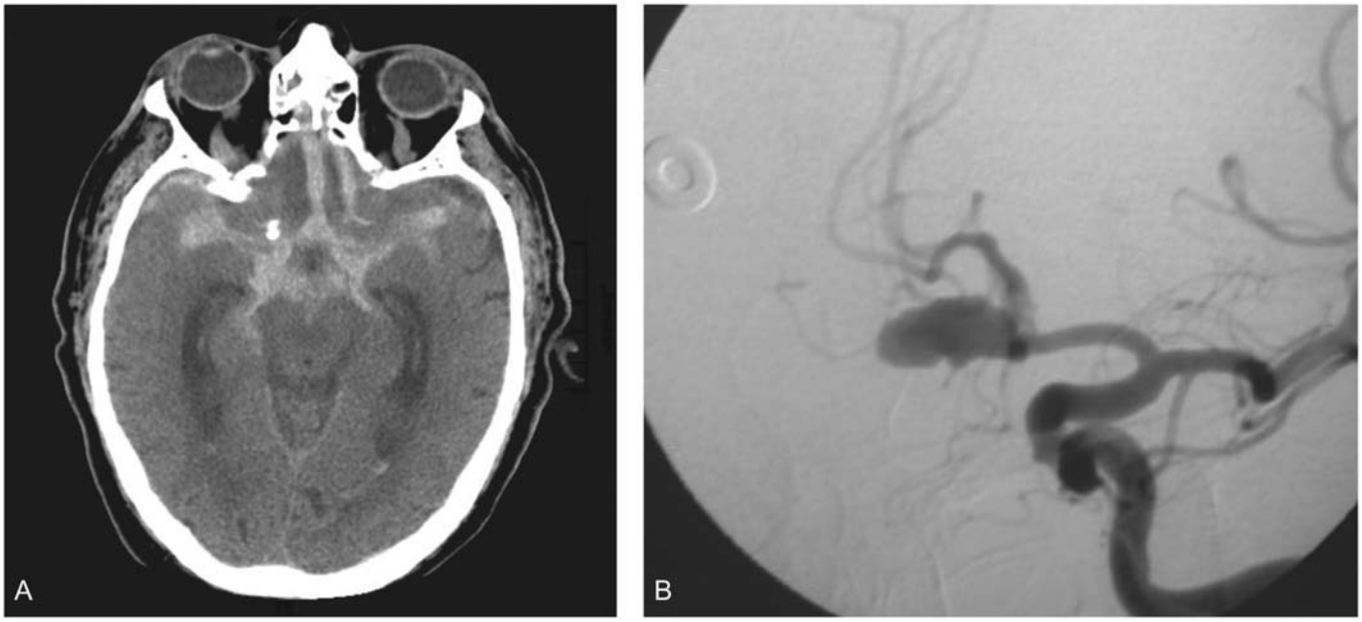

FIGURE 7-3 ■ A ruptured anterior communicating artery aneurysm producing acute subarachnoid hemorrhage. *A*, Head computed tomography (CT) shows a large amount of blood at the base of the brain and a small amount of intraventricular blood. *B*, Angiogram reveals a complex saccular aneurysm.

Unruptured Cerebral Aneurysms

Estimates of the prevalence of unruptured aneurysms vary widely but seem to cluster around an overall prevalence of about 3 percent. The vast majority of aneurysms are less than 10 mm in diameter, and most are less than 6 mm. Cerebral aneurysms are being detected more frequently as imaging technology improves and as imaging studies are used more frequently.

Unruptured aneurysms are often asymptomatic and discovered incidentally in the work-up for an unrelated problem. Some aneurysms produce symptoms by compressing neighboring structures. Presentation with a new cranial neuropathy is considered a worrisome sign of imminent rupture and often prompts urgent treatment. New headaches are also a presenting sign of unruptured aneurysm. Although migraine may simply represent an unrelated occurrence that prompts head imaging, some headaches may be due to the aneurysm itself. A sudden, severe "thunderclap" headache may herald rapid aneurysm growth or a small leak without evidence of overt subarachnoid hemorrhage.

Catheter angiography remains the gold standard for detecting aneurysms and for characterizing the morphology and anatomy of these lesions for planning treatment. Head computed tomography (CT) does not reliably detect unruptured aneurysms, though CT angiography and magnetic resonance (MR) angiography are capable of detecting many aneurysms, particularly those that are larger than 3 mm.

The prognosis of unruptured aneurysms, as reflected in the rate of rupture, is a subject of controversy, although most small aneurysms appear to be at very low risk of rupture. The size of the aneurysm (≥7 mm in maximum diameter) and location at the basilar tip or posterior communicating artery are independent predictors of hemorrhage. For patients with no history of subarachnoid hemorrhage, the annual risk of hemorrhage for small aneurysms (less than 7 mm in diameter) in the anterior circulation is essentially close to 0 percent and about 0.5 percent when the aneurysm is located in the posterior circulation.

The standard of care for treatment of aneurysms had historically been surgical clipping, in which a metal clip is placed over the neck of the aneurysm, thereby isolating it from the circulation. However, coil embolization, which involves packing platinum coils into an aneurysm through a microcatheter with an angiographic endovascular procedure, appears to be a generally safer approach when technically feasible, although coiled aneurysms can sometimes require retreatment in early follow-up.

Whether a given aneurysm requires treatment depends on the anticipated rupture rate and procedural risks. For asymptomatic aneurysms smaller than 7 mm with no history of subarachnoid hemorrhage, treatment may not be justified, particularly when in the anterior circulation, given the risks of surgery or endovascular therapy. Treatment of unruptured aneurysms appears to be cost-effective from a societal perspective when they are larger or symptomatic or when there is a history of subarachnoid hemorrhage from a different aneurysm. Controlling or eliminating risk factors, such as hypertension, smoking, and alcohol abuse, may reduce rupture rates, but this has not been systematically established.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage accounts for approximately 5 percent of all strokes, but it tends to occur at a younger age than other stroke subtypes, with median age at death typically in the 50s to 60s for subarachnoid hemorrhage, as compared to 70s for intracerebral hemorrhage, and 80s for ischemic stroke. Subarachnoid hemorrhage accounts for nearly one-third of the years of potential life lost before age 65 due to stroke. Case fatality rates have been improving, but 10 to 20 percent remain disabled and dependent at follow-up.

Presentation with subarachnoid hemorrhage generally involves the sudden onset of severe headache, sometimes accompanied by neck pain. Alteration of consciousness occurs in a minority of patients, but it may be severe enough to produce coma or sudden death outside the hospital. Head CT often shows blood surrounding the base of the brain. Intraventricular and intraparenchymal hemorrhage may be present and can provide clues as to the location of the ruptured aneurysm. Lumbar puncture may rarely show signs of hemorrhage when there is no evidence of it on head CT. Blood in the spinal fluid that does not clear is suggestive of acute subarachnoid hemorrhage. Xanthochromia is present in nearly all cases and may persist for more than 3 weeks, but its appearance can be delayed by more than 12 hours in 10 percent of cases. Angiography is required to characterize the aneurysm and to plan treatment.

Prognosis depends on the ability to treat the underlying aneurysm and on the patient's condition at presentation. Recurrent hemorrhage occurs in more than 4 percent of untreated patients during the first day and then in 1 to 2 percent per day for the next 2 weeks; re-rupture is associated with even greater fatality and morbidity than primary rupture. Regardless of treatment and recurrent hemorrhage, the level of consciousness at presentation is the major predictor of mortality (Table 7-2). The World Federation of Neurological Surgeons developed a Universal Subarachnoid Hemorrhage Grading Scale, similar to the older Hunt and Hess scale, which has been widely adopted but offers little advantage over determinations based on level of consciousness alone.

To reduce the risk of recurrent hemorrhage, ruptured aneurysms should be identified rapidly and repaired with surgical clipping or endovascular coil embolization as early as feasible. Hydrocephalus from obstruction of the cerebral aqueduct or the meninges by blood clot may require external ventricular drainage. Vasospasm is a common complication

that can produce delayed cerebral ischemia due to blood vessel constriction in areas exposed to subarachnoid blood. It becomes symptomatic in one-third of cases, usually 3 to 14 days after hemorrhage, and can result in cerebral infarction or death. Transcranial Doppler ultrasonography can detect vasospasm before it becomes symptomatic. Oral nimodipine, a calcium-channel antagonist, reduces poor outcomes from vasospasm and is generally given for the first 21 days after the initial bleed. Hypertension induced with pressors and maintaining adequate hydration with intravenous fluids may reduce the risk of infarction, but these measures have never been studied in trials. They should not be used in patients with untreated aneurysms because of the risk of precipitating further episodes of bleeding. Vasodilatation through angioplasty or intra-arterial verapamil can reverse angiographic vasospasm in many cases, but clinical benefits have not been definitely demonstrated.

INTRACEREBRAL HEMORRHAGE

Bleeding directly into the substance of the brain is termed *intraparenchymal* or *intracerebral hemorrhage* (Fig. 7-4). It may occur as a complication of ischemic stroke, termed *hemorrhagic conversion*, or as the primary injury without preceding ischemia. Hypertension is the most important identified risk factor for intracerebral hemorrhage. More than 70 percent of patients with intracerebral hemorrhage have a history of hypertension, and the risk of hemorrhagic stroke increases exponentially as systolic blood pressure increases.

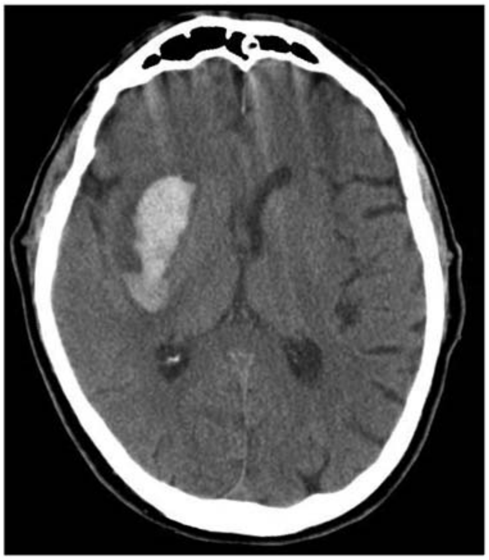

FIGURE 7-4 ■ Head CT of an acute basal ganglia intracerebral hemorrhage with mass effect compressing the ventricles.

Intracranial hemorrhage is responsible for 10 to 15 percent of all stroke deaths but for more than one-third of the years of life lost before age 65 due to the younger age distribution of intracerebral hemorrhage compared with other causes of stroke. Case fatality rates are high, with one-quarter to one-half of patients dead at 1 month and only about one-fifth of patients returning to independence at 6 months.

Other risk factors for intracerebral hemorrhage include age, race, substance abuse, anticoagulation, platelet dysfunction, and vascular and structural anomalies. Rates of intracerebral hemorrhage increase with age. African Americans have higher rates than whites, with larger differences at younger ages. Cocaine and amphetamine use are associated with increased risk, particularly acutely, possibly because of transient severe hypertension. Abnormalities in clotting may account for an increased incidence of intracerebral hemorrhage with heavy alcohol use. Excessive anticoagulation and antiplatelet therapy also increase the risk of intracerebral hemorrhage. Thrombolytic agents used for ischemic stroke and myocardial infarction cause intracerebral hemorrhage in some cases. It may also occur with severe thrombocytopenia and platelet dysfunction.

Intracerebral hemorrhage may result from and occur in brain tumors, such as glioblastoma multiforme and in metastatic melanoma, choriocarcinoma, renal cell carcinoma, and bronchogenic carcinoma. Cerebral amyloid angiopathy, a vasculopathy common in the elderly, is associated with lobar hemorrhages, often centered at the gray—white junction. Other punctate hemorrhages may be apparent on gradient-echo or susceptibility-weighted MR images (Fig. 7-5), supporting the diagnosis. Arteriovenous malformations, abnormal complexes of arteries and veins in brain parenchyma, account for about 5 percent of intracerebral hemorrhages. Cavernous malformations are dense collections of thin-walled vascular channels and appear to be the cause of intracerebral hemorrhage in about 5 percent of autopsies. They are not apparent on angiography but have a "popcorn"

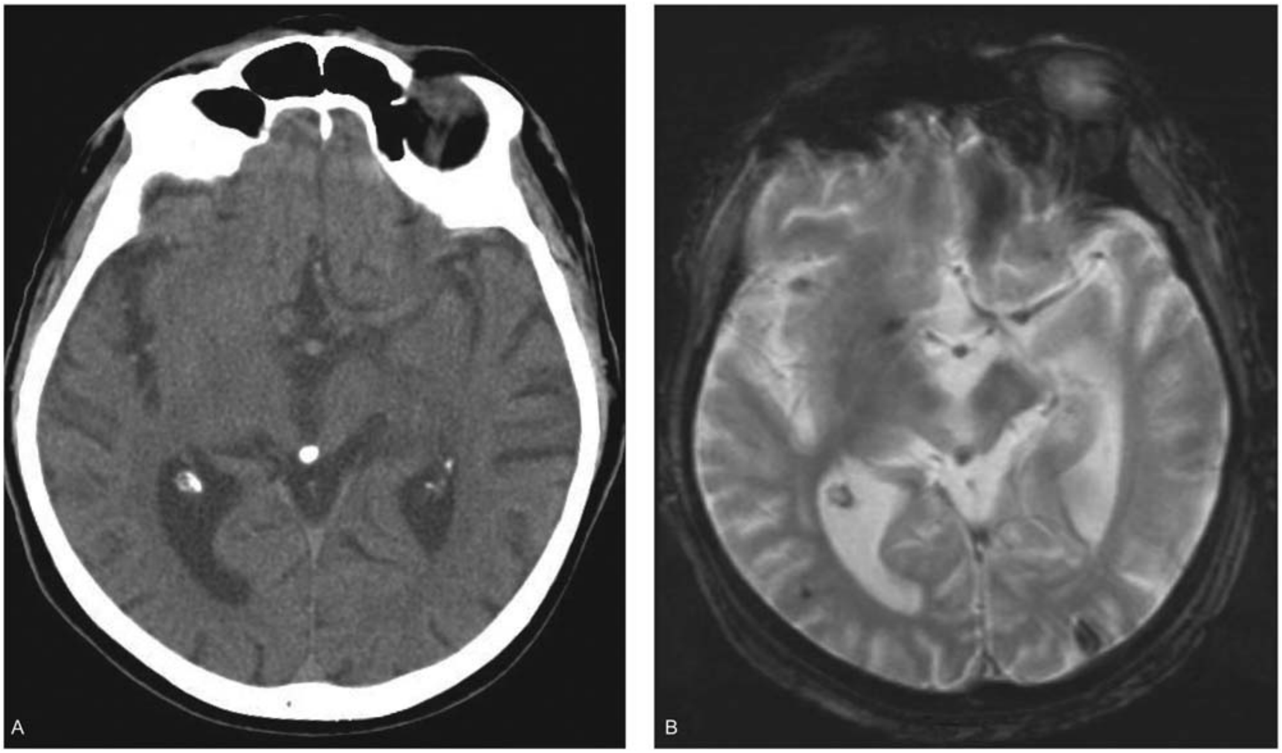

FIGURE 7-5 ■ Imaging findings of amyloid angiopathy, with no evidence of hemorrhage on CT, *A*, but multiple punctate areas of susceptibility at the gray–white junction on T2-weighted multiplanar gradient-recalled (MPGR) magnetic resonance imaging (MRI), *B*, suggesting prior hemorrhage.

appearance on MR images, with a hyperintense core surrounded by hypointense hemosiderin from previous small hemorrhages (Fig. 7-6). Aneurysms may produce intracerebral hemorrhages when blood is directed into the brain, but these rarely are mistaken for primary hypertensive hemorrhages.

Primary hypertensive intracerebral hemorrhage was thought to be caused by chronic vascular injury, resulting in formation of microscopic aneurysms, first characterized by Charcot and Bouchard in 1868. Advances in pathologic tissue preparation have raised doubts about the frequency and importance of microscopic aneurysms, which may actually represent complex vascular coils. More recently, fibrinoid necrosis of small arteries has been proposed as the initial step in intracerebral hemorrhage. Brain injury occurs because of compression of surrounding tissue and from the direct toxic effects of blood. Mass effect from the hematoma may lead to uncal, subfalcine, tonsillar, or transtentorial herniation, depending on location, and death may ensue.

Clinical presentation depends on the location and size of the hemorrhage (Table 7-3). Nearly all intracerebral hemorrhage is characterized by the sudden onset of neurologic deficits, progressing over minutes and accompanied by headache, often with alteration of consciousness. Deterioration due to surrounding edema, hydrocephalus, or continuing or recurrent hemorrhage often occurs within the first 24 hours but may be delayed by days.

Prognosis is multifactorial. Hemorrhage volume, most easily measured by halving the product of the length, width, and depth on axial head CT images, is a powerful predictor of mortality. Mortality is much greater in those with intraventricular extension of blood. Hydrocephalus due to intraventricular extension or cerebrospinal fluid (CSF) outflow obstruction also predicts in-hospital mortality. Lower Glasgow Coma Scale scores at presentation, advanced age, infratentorial location, and initial elevated blood pressure or pulse pressure are other independent predictors of mortality. Simple multivariable prediction models that integrate these factors have been developed and validated.

Urgent head CT is required in patients with suspected intracerebral hemorrhage. MRI is as sensitive as CT for detecting hemorrhage and is more

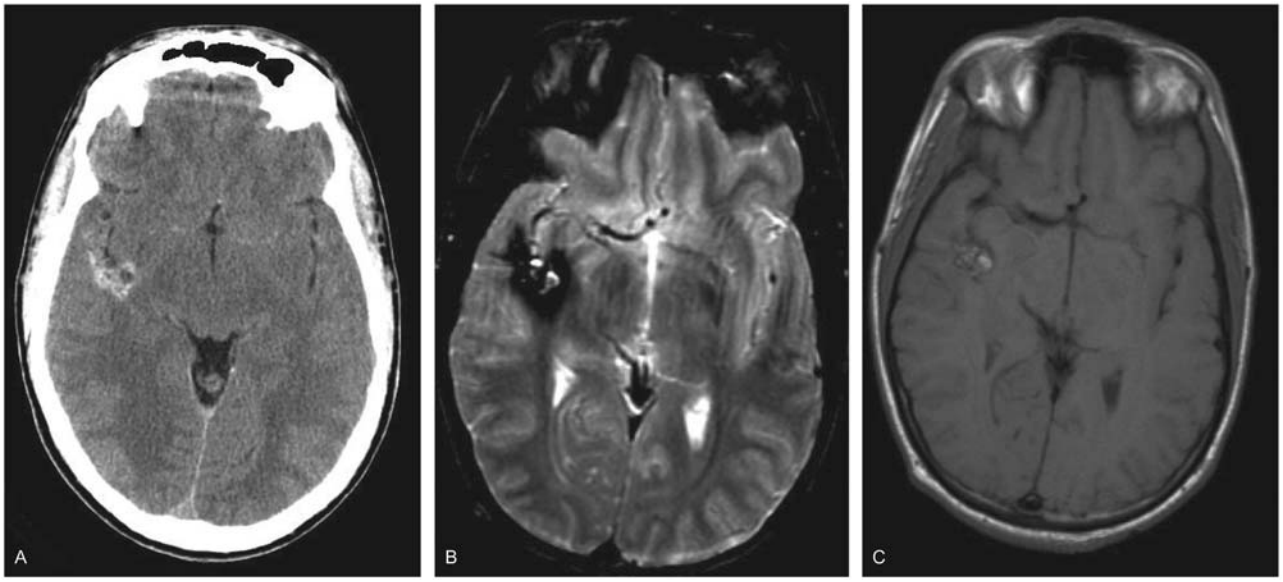

FIGURE 7-6 ■ A cavernous malformation with a small amount of acute, intracerebral hemorrhage surrounding it on head CT, *A*. T2-weighted brain MRI *B*, shows a lesion with a focal area of high signal intensity surrounded by a thick rim of hypointense hemosiderin. T1-weighted brain MRI *C*, showing the typical "popcorn" appearance. The high signal intensity represents methemoglobin.

TABLE 7-3 ■ **Clinical Presentation of Intracerebral Hemorrhage**

Location	Occurrence (%)	Clinical Signs	Nonhypertensive (%)	Mortality (%)
Putamen	28–42	Motor and sensory deficit; depressed consciousness	10	20
Thalamus	10–26	Sensory and motor deficit; depressed consciousness; homonymous hemianopia	10	40
Subcortical white matter (lobar)	19–30	Higher incidence of seizures; coma unlikely; other symptoms depend on involved lobe	65	20
Cerebellum	8–15	Ataxia, cranial neuropathies; ± depressed consciousness	15	Coma 75 Other 17
Brainstem	4–11	Coma, decerebrate posturing, pinpoint reactive pupils, cranial neuropathies	30	85

sensitive for detecting an underlying structural etiology, but the rapidity, availability, and ease of interpretation of CT favor its initial use. Contrast-enhanced head CT scan may show evidence of persistent hemorrhage at the time of presentation, the so-called "dot" or "spot" sign, which is associated with hematoma expansion and poorer prognosis. Vascular imaging is required whenever aneurysmal subarachnoid hemorrhage is possible, such as in cases with a large amount of subarachnoid blood, and should be considered for all patients without a clear etiology. Early MRI may be indicated if a structural etiology is suspected, but findings are often obscured by the hemorrhage in the acute phase. A scan delayed by 4 to 8 weeks may provide more useful information if urgent diagnosis is unnecessary. MRI is also useful in diagnosing cavernous malformations and may suggest cerebral amyloid angiopathy.

Treatment is generally supportive, although surgical intervention is indicated in rare cases. Severe hypertension is common after intracerebral hemorrhage, in part because it is a response to elevated intracranial pressure and brain injury. In patients with a systolic blood pressure of 150 to 220 mmHg, acute lowering of systolic blood pressure to 140 mmHg is probably safe. Current consensus guidelines suggest treating with antihypertensive medications for systolic blood pressure greater than 180 mmHg or mean arterial pressure greater than 130 mmHg, although studies to determine optimal blood pressure control after intracerebral hemorrhage suggest that targeting a systolic blood pressure of <160 or <140 mmHg is reasonable. Increased intracranial pressure may lead to coma and is treated with ventricular drainage, osmotherapy, or hyperventilation.

Surgical evacuation of primary intracerebral hemorrhages is commonly performed when there is posterior fossa hemorrhage with a risk of brainstem compression or when there is evolving neurologic deterioration in patients with lobar hemorrhages and other prognostic signs are favorable. For supratentorial intracerebral hemorrhages, studies have failed to establish a benefit of early surgical evacuation of the hematoma over a strategy of initial conservative treatment followed by surgical evacuation only if necessitated by neurologic deterioration, even among the subgroup of patients with lobar hemorrhage that are near the cortical surface. In practice though, patient selection and decisions on offering surgical interventions for supratentorial intracerebral hemorrhages are often individualized and variable. In recent years, there has been increasing interest in evaluating minimally invasive techniques for hematoma evacuation, although whether a definitive clinical benefit of these approaches will ultimately be demonstrated is unknown.

After the acute period, aggressive treatment of hypertension is indicated. In addition to reducing cardiovascular disease and ischemic stroke, treating hypertension substantially reduces the risk of intracerebral hemorrhage.

LACUNAR INFARCT

The term *lacune* was first introduced in 1843 by M. Durand-Fardel to describe small, subcortical areas lacking gray and white matter. These lesions were attributed to infarct and associated with particular clinical presentations by Marie and Ferrand more than 50 years later. In the 1950s, Miller Fisher reintroduced the term into modern neurology through his descriptions of the clinical and pathologic presentation which recognized the importance of hypertension as an etiology and a theory of pathogenesis that survives today.

Less than 2 cm in diameter, lacunes are small infarcts that result from occlusion of small penetrating branches arising from large arteries (Fig. 7-7). There is general agreement about the definition of lacune, but much argument about the interrelationship between lacunar infarcts, lacunar strokes (symptomatic lacunes), lacunar syndromes (symptom complexes often associated with lacunar strokes), and lacunar disease (lacunes due to intrinsic small-vessel changes). Arguments arise from imperfect correlations between these entities. First, not all lacunes produce lacunar strokes because some are silent. Second, lacunar syndromes are sometimes associated with large-vessel strokes. Third, lacunes are produced by intrinsic small-vessel disease and by other etiologies.

The majority of lacunes are located in the basal ganglia and thalamus, with the remainder in the internal capsule, pons, cerebellum, and subcortical white matter. Approximately 20 to 30 percent of ischemic strokes are due to lacunes. Lacunes are often found incidentally on MR scanning, particularly in older patients, and the vast majority of those with a lacune identified on imaging deny a history of stroke or transient ischemic attack (TIA). These “silent” lacunes are associated with impairment in cognitive and functional tasks, suggesting that the overall clinical burden of lacunes may be greater than previously suspected.

Hypertension is one of the most important risk factors for development of lacunes. However, the strength of the association may be no greater for lacunes than for other forms of ischemic stroke, and hypertension is not always present in lacunar disease. Elevation in the level of serum creatinine is independently associated with lacunar infarction, perhaps because it is a marker for chronic end-organ damage from hypertension in the small vessels of both the kidneys and the brain.

Diabetes mellitus is a risk factor for symptomatic lacunes, approximately doubling the risk. However, the influence of diabetes on lacunar stroke does not appear to differ from its effect on other ischemic stroke subtypes. This is also true for cigarette smoking, which doubles the risk of all ischemic strokes, including lacunes. Carotid artery stenosis is associated with an increased risk of lacunar stroke, with studies suggesting that the risk of a symptomatic lacune is doubled with carotid stenosis of 50 percent

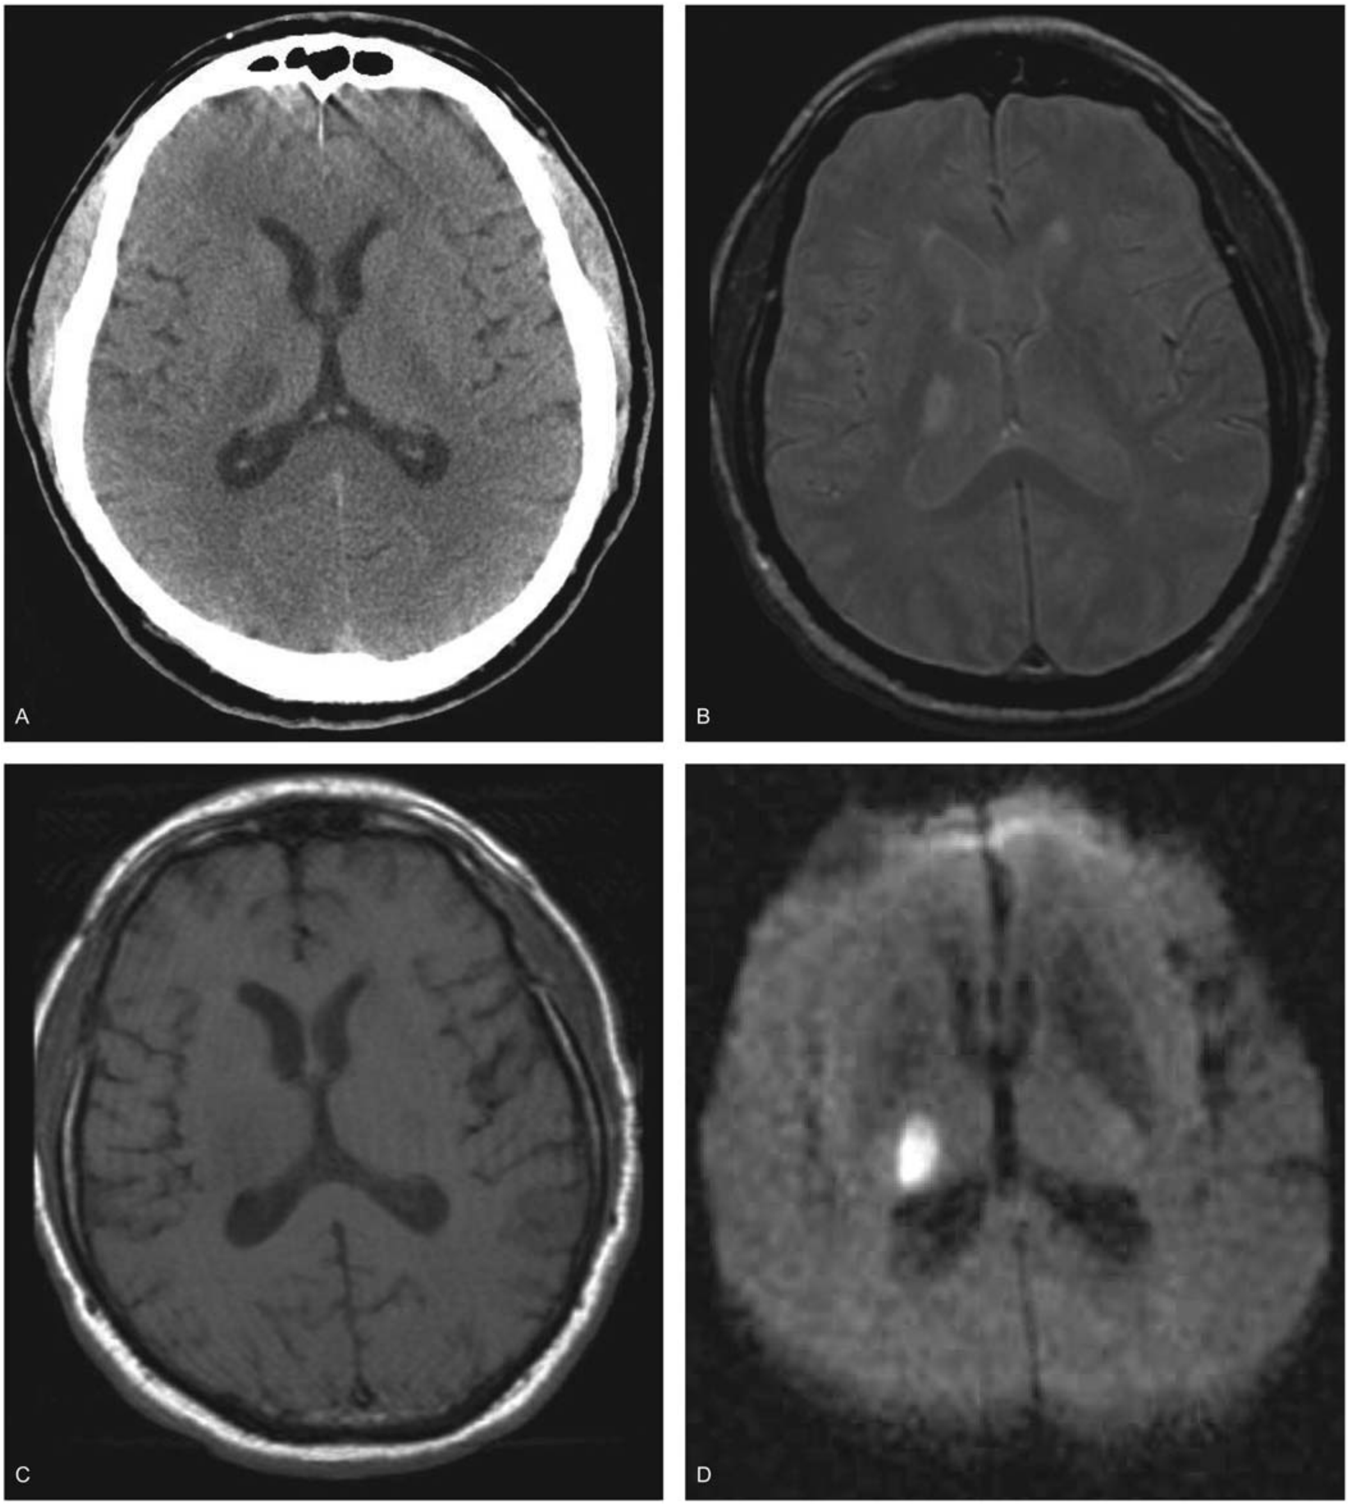

FIGURE 7-7 ■ An acute right thalamocapsular lacunar stroke producing a left sensorimotor syndrome. The lesion was hypodense on noncontrast head CT, *A*. With brain MRI, it was hyperintense on T2-weighted images, *B*, inconspicuous on T1-weighted images, *C*, and hyperintense on diffusion-weighted images, *D*.

or greater. Cardiac disease is less common in patients with lacunes than in those with other ischemic stroke types.

The etiology of lacunes has been argued over bitterly. Some have suggested that the vast majority of lacunes are due to changes within small penetrating vessels, primarily because of chronic hypertension, but others have argued that emboli to small vessels and intracranial atherosclerosis are responsible for a significant number of lesions. Fisher produced much of the data supporting an intrinsic small-vessel disease mechanism. He found degenerative changes in small vessels that he termed lipohyalinosis and fibrinoid degeneration, characterized by layers of connective tissue within the vascular media, obstructing the lumen. These changes were proximal to infarcts in some cases. Atherosclerosis at the origin appeared responsible for other infarcts. Fisher recognized that emboli may be responsible for some lacunes. Animal models have shown that particles may embolize to small penetrating arteries, producing lacunes. The etiology of lacunes is likely multifactorial. Intrinsic small-vessel disease may predominate, but emboli and intracranial atherosclerosis almost certainly account for a significant minority of cases.

Several classic presentations of lacunar strokes have been described, termed the *lacunar syndromes*. Pure motor hemiparesis is the most common, accounting for nearly half of cases. Motor functions involving face, arm, and leg are impaired, but other neurologic functions are spared. The appearance is different from that with cortical strokes, in which deficits in sensation or cognition often accompany motor changes. Pure motor hemiparesis is not always due to a lacune, with 10 to 20 percent of cases attributed to a cortical stroke. When a lacune is responsible, it is most often located in the posterior limb of the internal capsule or in the basis pontis, but any other site along the path of corticospinal fibers can produce the syndrome.

Sensorimotor syndrome is the second most common lacunar syndrome, accounting for about 20 percent of cases. Weakness and numbness are present in varying degrees, usually involving the face, arm, and leg. The syndrome is most commonly produced by a lacune involving the lateral thalamus and internal capsule, but some cases are not due to lacunes.

Ataxic hemiparesis accounts for about 15 percent of lacunar syndromes. In the affected limbs, pyramidal weakness is combined with elements normally attributed to cerebellar ataxia. Intention tremor, exaggerated rebound, and irregular rapid alternating movements are superimposed on ipsilateral weakness. The findings are highly suggestive of a lacunar stroke, with almost all of these cases attributable to lacunes. Infarct locations are identical to those that cause pure motor hemiparesis.

Among patients with lacunar syndromes, about 10 percent have a pure sensory stroke, characterized by impaired sensation without other accompanying neurologic deficits. When the face, arm, and leg are involved, the lesion is nearly always a lacune in the contralateral thalamus. A lesion in the medial lemniscus in the midbrain or rostral pons may occasionally produce an identical syndrome. Pain and dysesthesia in the affected region may accompany the lesion acutely or may be delayed by weeks to months.

Many other lacunar syndromes have been described, including clumsy-hand dysarthria, hemiballism, and pure motor hemiparesis combined with various eye movement abnormalities. Although lacunes occur more commonly in certain regions of the brain, they can occur anywhere, producing a multiplicity of potential syndromes. Even signs generally attributed to cortical lesions may be produced by lacunes, including aphasia, abulia, confusion, and neglect.

Prognosis for recovery after a lacunar stroke is generally more favorable than for ischemic strokes due to the occlusion of major vessels, although symptoms may occasionally worsen in the first few days after symptom onset. Recurrent stroke and mortality rates are also lower than for other stroke subtypes.

Diagnostic imaging has been recommended for all those presenting with lacunar syndromes. An immediate head CT scan will rule out hemorrhage as an etiology but may not distinguish lacunes from large-vessel infarctions. MRI provides more definitive confirmation, and MR or CT angiography may suggest intracranial atherosclerosis. For lacunar strokes in the internal carotid distribution, carotid artery imaging should be performed because a stenosis proximal to the lacune would generally be considered symptomatic.

Tissue plasminogen activator is effective in patients judged to have small-vessel occlusive strokes. In fact, absolute improvements in favorable outcomes may even be greater for small-vessel strokes than for large-vessel occlusive and cardioembolic strokes. Furthermore, the correlation between lacunar stroke and lacunar syndrome is so poor that a diagnosis of nonthrombotic small-vessel occlusion cannot be made with accuracy. Therefore, tissue plasminogen activator should still be administered for lacunar syndromes.

Aspirin reduces the risk of subsequent ischemic stroke, regardless of etiology. Clopidogrel and the combination of dipyridamole/aspirin are alternatives for secondary prevention in those who cannot tolerate aspirin, although the incremental improvement in efficacy compared to aspirin is small.[6] Long-term combination therapy with aspirin and clopidogrel is generally not recommended to prevent recurrent stroke owing to increased bleeding risks.[7,8] However, short-term combination therapy (21 days) with aspirin and clopidogrel can be helpful in the acute period compared to aspirin alone in patients with high-risk TIA or minor stroke.[9,10]

Long-term anticoagulation with warfarin is generally indicated in patients with ischemic stroke when atrial fibrillation is identified. Control of hypertension reduces subsequent ischemic stroke risk, and risk reduction may be even greater for lacunes. Treatment of isolated systolic hypertension in elderly patients may be particularly helpful to prevent lacunar stroke.

PERIVENTRICULAR WHITE MATTER DISEASE

With improvements in head imaging, changes in the white matter surrounding the lateral ventricles are frequently recognized in the elderly, a finding termed *leukoaraiosis*. Head CT shows a periventricular mantle of hypodensity, often most profound at the frontal and occipital horns, which is hyperintense on T2-weighted MRI (Fig. 7-8). Age is the most important risk factor, with nearly all of those older than 65 years showing at least some evidence of such change. Clinically, the changes are most frequently associated with insidious declines in cognitive and motor performance, particularly on tests that depend on reaction time and speed.

These white matter lesions have been related to several distinct pathologic processes, including hypoperfusion injury, cerebral amyloid angiopathy, dilated perivascular spaces, axonal loss, astrocytic gliosis, and loss of ependymal integrity with resulting cerebrospinal fluid extravasation. Lesions contiguous with the ventricles show fewer histologic and molecular markers of ischemia than lesions in the deep subcortical areas, where they resemble areas of "incomplete" infarction on pathologic examination. Loss of vasomotor reactivity and autoregulation due to small-vessel vasculopathy is hypothesized to be a frequent cause of the ischemic changes. Leukoaraiosis may be an important clinical indicator of end-organ injury from hypertension, integrating information about cumulative exposure to

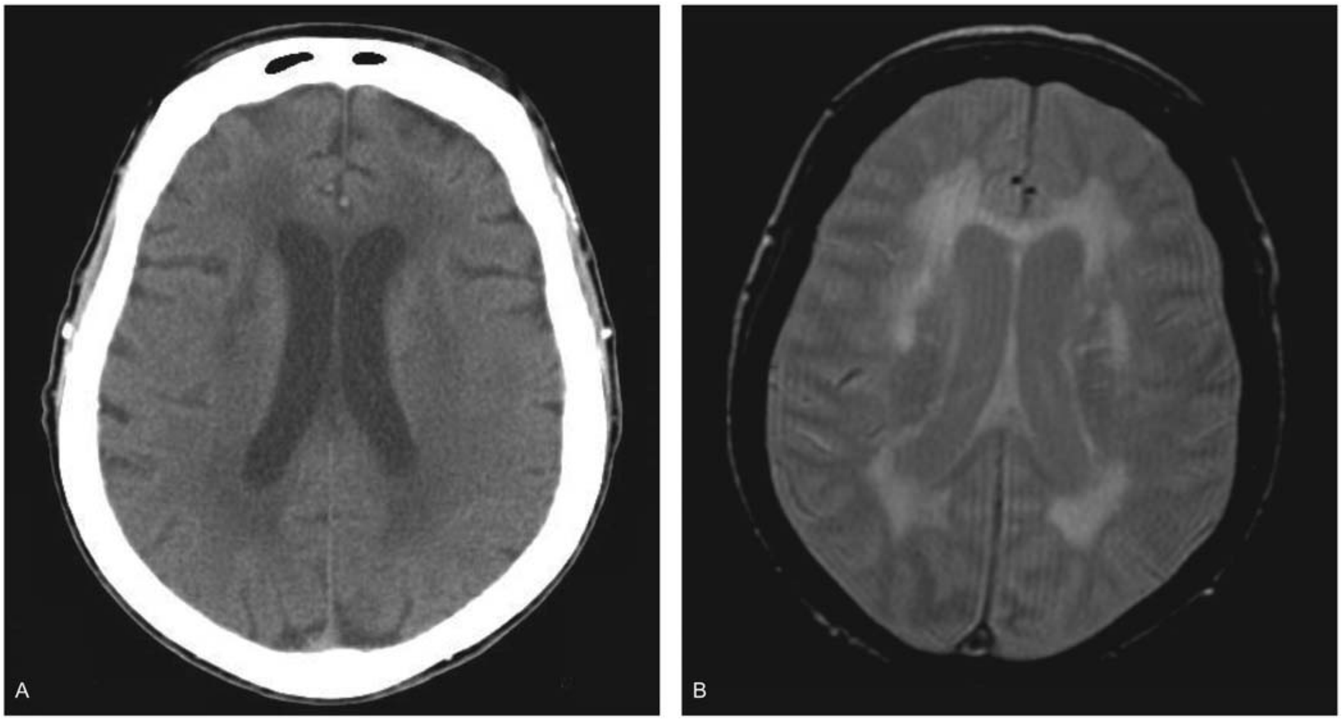

FIGURE 7-8 ▪ Imaging findings of periventricular white matter disease, with hypodensity on head CT, *A* and T2-weighted hyperintensities on brain MRI, *B*.

high blood pressure as well as susceptibility to injury. Individuals with white matter lesions in the brain are at high risk of incident stroke and other clinical cardiovascular events. White matter burden is also one of the strongest predictors of incident brain infarction defined by serial brain MRI.

CEREBRAL AUTOSOMAL-DOMINANT ARTERIOPATHY WITH SUBCORTICAL INFARCTS AND LEUKOENCEPHALOPATHY

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a dementing illness caused by mutations in the *NOTCH3* gene, which encodes a transmembrane receptor protein of unclear function and is characterized by a stepwise decline in cognitive and motor functions. Onset is early, beginning at 30 to 50 years of age, and it is often preceded by migraines with aura. Hypertension and diabetes are not associated. Head imaging shows multiple lacunes superimposed on periventricular white matter disease. Degeneration of vascular smooth muscle cells and granular deposits characterize vessels in the brain and in other regions. Involvement of the dermis allows confirmation by skin biopsy, although molecular genetic tests are available. No specific treatment is available.

CAROTID ARTERY STENOSIS

The first comprehensive description of carotid occlusion and stroke is attributed to Hunt, who in 1914 described a patient with decreased carotid pulsation contralateral to a hemiparesis. Autopsy confirmed a hemispheric infarct and showed patent intracranial vessels. With the advent of angiography and surgical exploration, internal carotid artery occlusion with recent thrombus was confirmed in the 1940s.

The precise contribution of internal carotid artery stenosis to the incidence of stroke is unclear because it is difficult to definitively attribute a stroke to the stenosis. Approximately 10 percent of ischemic strokes are due to internal carotid stenosis or occlusion and a substantial minority of the middle-aged population has some evidence of carotid plaque on ultrasonography. An asymptomatic carotid stenosis of more than 60 percent may be found in approximately 5 percent of 65-year-olds and this figure increases with age.

Hypertension is an important risk factor for carotid stenosis. Systolic hypertension is a powerful predictor of subsequent carotid stenosis, with the odds of carotid stenosis doubling with each 20-mmHg increase in systolic blood pressure. Systolic blood pressure is also a predictor of progression in patients with asymptomatic stenoses. Cigarette smoking, high serum cholesterol level, and increased homocysteine are other risk factors for carotid stenosis.

Internal carotid artery stenosis is produced by atherosclerosis just distal to the common carotid bifurcation. The pathophysiology of carotid artery stenosis is complex. Hypertension induces vascular remodeling, resulting in medial thickening, luminal narrowing, and impaired smooth muscle relaxation. These changes are concentrated in areas of nonlaminar flow, such as the common carotid bifurcation. Atherosclerotic plaques are thought to develop in these areas as a response to injury produced by hypertension, blood-flow abnormalities, lipids, and possibly infection. This initiating injury induces endothelial cell expression of cell adhesion molecules that mediate local extravasation of mononuclear cells, resulting in inflammation of vessel walls, with foamy, lipid-laden macrophages and T lymphocytes. Chronic injury leads to intimal hyperplasia and formation of complex plaques that may include a lipid core. When a plaque ruptures into the vessel lumen, thrombosis is induced, which may produce local occlusion, distal embolus, or, after organization, progressive luminal stenosis. Shear forces associated with a severe stenosis may induce platelet activation and thrombus formation without plaque rupture.

Clinically, symptomatic patients present with large-vessel ischemic strokes or TIAs in the distribution of the ophthalmic, middle, or anterior cerebral artery. Transient monocular blindness (amaurosis fugax), weakness, numbness, aphasia, or neglect may occur, depending on the affected region of the anterior circulation. Borderzone ischemia due to distal hypoperfusion in the anterior and middle cerebral artery territories presents with proximal upper and lower extremity weakness and numbness (i.e., "man-in-the-barrel" syndrome) and may indicate a critical stenosis or occlusion with inadequate collateral blood flow. Artery-to-artery emboli classically appear as cortical wedge-shaped infarcts, indistinguishable from emboli from other sources. Lacunar infarcts, often attributed to intrinsic small-vessel disease, probably represent embolic events from carotid artery stenoses in some instances because endarterectomy appears to reduce the risk of ipsilateral lacune.

A cervical bruit may be a sign of carotid stenosis, but it is absent in up to half of cases later confirmed to have stenosis exceeding 70 percent and is present in up to half of those without a severe stenosis. Therefore, carotid imaging studies are generally indicated for patients with anterior circulation ischemic strokes or transient ischemic attacks independent of a finding of a carotid bruit.

CT angiography, carotid Doppler ultrasonography, neck MR angiography, or catheter angiography is required for the determination of whether an internal carotid stenosis is present. CT angiography is often part of an initial emergency department for large-vessel occlusion stroke. Although CT angiography can reliably exclude the presence of significant carotid artery stenosis, it can sometimes overestimate the degree of stenosis, particularly when calcifications are present. In this setting, carotid Doppler ultrasonography can be a helpful second noninvasive study to confirm the degree of stenosis. MR angiography provides three-dimensional views and can be extended to include the intracranial vasculature. Catheter angiography is considered the gold standard but carries a small procedural risk. Therefore, it is generally preferable to obtain noninvasive imaging first and in most cases these noninvasive studies obviate the need for catheter angiography.

Aspirin has been shown to reduce risk of stroke and myocardial infarction in patients with ischemic stroke or TIA and carotid disease, with a risk reduction of about 10 to 20 percent. Some clinicians use anticoagulation with heparin to treat symptomatic carotid stenosis in the acute setting until a more definitive surgical or endovascular intervention can be applied, but there are no reliable data supporting this approach. Based on results in coronary artery disease, a process with similar pathophysiology, and on overall risk reduction of ischemic stroke, treatment with cholesterol-lowering agents may be of benefit even in those without hypercholesterolemia.

Urgent surgical removal of the obstructing plaque by endarterectomy is the established standard of therapy for symptomatic patients with carotid artery stenosis of at least 70 percent (Table 7-4). Endarterectomy also reduces recurrent stroke rates in patients (especially men) with symptomatic carotid stenoses of 50 to 69 percent, but the benefits of treatment are more modest and the consequences of procedural complications are even more important to consider since the baseline risk of recurrent stroke is lower than with stenosis greater than 70 percent. Endarterectomy is not beneficial in patients with stenosis less than 50 percent and is generally impractical in those with carotid artery occlusion, unless it is considered a part of an acute large-vessel occlusion stroke syndrome (e.g., with a concurrent ipsilateral MCA

TABLE 7-4 ■ Yearly Ipsilateral Stroke Rates with Carotid Artery Stenosis Based on 5-Year Follow-up

	Endarterectomy* (%)	Medical Therapy (%)	*P* Value	NNT 5-Year†

*Includes any perioperative stroke or death.

†NNT with surgery to prevent one ipsilateral stroke in 5 years.

‡Degree of stenosis converted to NASCET criteria (diameter at narrowest/diameter in most proximal normal internal carotid artery). End-point included perioperative death or major strokes and was calculated based on mean 6-year follow-up.

occlusion). The risk of stroke with medical therapy is greater in those with cerebral events than ocular events, with plaque surface irregularity consistent with ulceration, with a recent symptomatic event, and with greater degrees of stenosis. The risk of surgery is greater in females, in those with severe hypertension, and in those with peripheral vascular disease. These prognostic factors may be useful in fine-tuning patient selection for endarterectomy.

For patients with asymptomatic carotid artery stenosis, endarterectomy also prevents stroke when there is stenosis of at least 60 percent as assessed by carotid ultrasonography, but the benefits are more diffuse, and therefore current guidelines recommend consideration of endarterectomy for asymptomatic stenosis for patients with a surgical risk less than 3 percent and life expectancy of at least 5 years. Many of the pivotal studies for carotid stenosis were conducted decades ago, before the widespread use of statins for example, and the recurrent stroke risk with medical management seems to be improving over time. Therefore, it is unclear whether carotid revascularization interventions (carotid endarterectomy or carotid artery stenting) would still be favored when compared to modern medical regimens—a question that is being evaluated in the ongoing CREST-2 trial.[11]

Endovascular angioplasty and stenting is an alternative approach to treatment of carotid stenosis, and stenting has been shown to be not inferior to endarterectomy in patients with both symptomatic and asymptomatic stenoses who have comorbidities associated with high surgical risk during endarterectomy. A large-scale trial comparing endarterectomy and stenting in more representative patient populations showed similar long-term outcomes with both approaches; there was an increased risk of periprocedural stroke with endovascular stenting and a higher risk of myocardial infarction with endarterectomy, although these complications are not directly comparable given the relative ease of detecting a troponin elevation with a simple blood test as opposed to detecting a stroke that would likely have to be symptomatic to justify a confirmatory neuroimaging test.[12]

INTRACRANIAL ATHEROSCLEROSIS

Atherosclerosis involving the large intracranial vessels causes about 10 percent of ischemic strokes. African Americans, Hispanics, and Asians have a higher prevalence of intracranial atherosclerosis, and a relatively lower prevalence of extracranial carotid artery stenosis compared with Caucasians. Extracranial carotid atherosclerosis is associated with a higher prevalence of peripheral vascular and coronary artery disease, but intracranial atherosclerosis is not. Given racial and risk factor distribution differences, it seems appropriate to consider intracranial atherosclerosis an entity distinct from carotid artery disease rather than as an additional manifestation of widespread atherosclerotic changes.

Hypertension is an important risk factor for intracranial atherosclerosis, with a two- to threefold higher risk of disease in those with a history of hypertension. Smoking may be the most important risk factor, with a risk that steadily increases with the number of pack-years of smoking exposure. Diabetics have about three times the risk of developing intracranial atherosclerosis. Hypercholesterolemia also increases risk, but probably to a lesser degree. The relative contribution of these factors to intracranial atherosclerosis as opposed to other stroke subtypes is unclear. The distribution of known risk factors probably accounts for some of the racial differences.

There are intriguing differences in the pathophysiology of intracranial atherosclerosis and other forms of vascular disease. Intracranial arteries are less susceptible to hypercholesterolemia than are extracranial arteries, and atherosclerotic plaque rupture appears to be less common. Release of endothelial adhesion molecules is greater with intracranial atherosclerosis than in other ischemic stroke subtypes, suggesting that inflammation is particularly important in its pathogenesis.

Clinical presentation is characterized by large-vessel or penetrating artery ischemia. The middle cerebral artery is most commonly involved, followed in order by the basilar, intracranial internal carotid, anterior cerebral, and posterior cerebral arteries. Thrombosis at the site of the stenosis may lead to hypoperfusion in the entire distal territory or to artery-to-artery embolus indistinguishable from events caused by extracranial carotid artery stenosis or cardiac embolus. Basilar thrombosis may result from underlying atherosclerosis in the basilar or vertebral arteries or after cardiac embolus; it is a life-threatening, often delayed diagnosis characterized by coma, quadriplegia, and cranial nerve findings. Involvement of the origin of penetrating small vessels may produce lacunar infarctions. Presentation with TIA prior to infarction is more common with intracranial atherosclerosis than with other stroke subtypes.

Intracranial MR or CT angiography may reveal narrowing or occlusion of large vessels. Time-of-flight MR angiography is prone to artifacts and may suggest a stenosis where none is present; sensitivity is low for medium-sized and smaller vessels, although contrast-enhanced MR angiography can mitigate these issues. CT angiography offers a true luminal image but involves use of ionizing radiation. Transcranial Doppler ultrasonography shows increased blood flow velocities in large stenotic vessels. Its sensitivity and specificity are also low, so it may be most useful as an adjunct. Catheter angiography is the gold standard for establishing the diagnosis, but it is associated with a procedural stroke risk under 1 percent. Given the risk of angiography, it is justified only if results will alter treatment decisions.

Prognosis in symptomatic patients is poor but can be improved with aggressive medical therapy. Stenoses generally become more severe with time, but regression in some segments may occur. Studies have shown that the combined outcome of stroke, brain hemorrhage, or vascular death is similar with warfarin compared with high-dose aspirin, although bleeding risks are greater with warfarin. More recent studies comparing intracranial angioplasty stenting compared to an aggressive medical regimen including dual-antiplatelet therapy with aspirin and clopidogrel along with a statin, demonstrated a lower risk of stroke or death with aggressive medical management, which some speculate is due to improvements in medical therapy in recent years; as a result, stenting is not commonly recommended.[13]

Patients with intracranial atherosclerosis also have a theoretical risk of hypoperfusion distal to the stenosis when blood pressure is lowered. Since these lesions are less commonly corrected compared with those in the carotid artery, some physicians may be less aggressive about treating hypertension in these patients. There is currently no evidence to justify higher long-term blood pressure thresholds in patients with intracranial atherosclerosis or to support the belief that lower blood pressures could increase the risk of infarction distal to a stenosis. In fact, targeted blood pressure management was an important component of aggressive medical treatment in studies comparing it with angioplasty and stenting.

AORTIC ARCH ATHEROSCLEROSIS

The aortic arch can be a source of emboli to the brain. Ulcerated plaque in the aortic arch is more common in patients with ischemic stroke compared with control populations, and thickened aortic arches are identified more often on transesophageal echocardiograms in stroke patients than in control subjects. In those with no other identified etiology for stroke, a thickened aortic arch is present about 25 percent of the time. Aortic arch atherosclerosis is more strongly associated with peripheral vascular disease than with carotid stenosis. Epidemiologic studies have been small, and only cigarette smoking has been identified as an important risk factor. Hypertension, diabetes, and hypercholesterolemia may be risk factors, but this has not been confirmed.

Strokes and TIAs produced by aortic atherosclerosis are identical to those produced by cardiac sources of emboli. Large-vessel territories are generally affected, producing weakness and numbness in similar distributions often along with cortical signs, such as aphasia and neglect.

Atherosclerotic plaque in the aortic arch that is 4 mm thick or larger carries a particularly high risk of recurrent stroke, even after accounting for other risk factors. The relative efficacy of antiplatelet therapy compared to anticoagulation to prevent recurrent stroke in patients with aortic arch disease remains unclear.[14] Aortic endarterectomy has been performed in some patients who have failed medical therapy, but it has not been studied systematically.

CARDIAC EMBOLUS

Hypertension increases the risk of myocardial infarction and atrial fibrillation. These diseases are associated with increased stroke risk from cardiac embolus, as discussed in Chapter 5.

DEMENTIA

There is evidence from multiple cohort studies that cardiovascular risk factors, including hypertension, are risk factors for the development of dementia and cognitive impairment. The biologic basis for these associations remains unresolved. Although there are some data to support a direct association between hypertension and Alzheimer pathology, there is increasing recognition that most individuals with dementia have a combination of neurodegenerative and vascular pathology. The association between hypertension and dementia is likely to be mediated in part by the accumulation of subclinical vascular injury in the brain, including infarcts and leukoariosis, that results in the interruption of cognitive networks. Whether this process is simply additive to the cognitive effects of Alzheimer pathology or whether there is synergism between the two processes remains unresolved.

Whether treatment of hypertension will make a large impact on the occurrence of dementia outside of its established benefits for stroke prevention is unclear. Some studies have suggested that a calcium-channel blocker for primary prevention can substantially reduce the risk of dementia but other studies have not confirmed this finding. Some studies have suggested that active therapy with an ACE-inhibitor and diuretic can reduce the risk of dementia when used for secondary prevention, but these potential benefits are more difficult to establish for primary prevention.

Although it hardly seems necessary to define additional benefits of treating hypertension, the recognition that cognitive decline may be an important manifestation of end-organ injury from hypertension has important implications for testing new treatments for cerebrovascular disease, assessing risk of stroke, and encouraging adherence to treatment. If hypertension therapy is proven to prevent dementia among those without stroke, the cost–benefit ratio for more aggressive screening and therapy could also be substantially improved, an important issue given that the elderly, who are at highest risk of dementia, are also the least likely to have their hypertension adequately treated. Some have suggested that aggressive blood pressure reduction could worsen cognition, particularly among those with loss of cerebral autoregulation due to small-vessel arteriopathy. Therefore, the benefits of blood pressure therapy for cognition will need better definition in order to optimize treatment regimens.

HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy is one of several forms of posterior reversible encephalopathy syndrome (PRES), a syndrome also encompassing other etiologies, including renal failure, immunosuppressive therapy, and eclampsia.

The incidence of hypertensive encephalopathy is thought to have declined with greater use of antihypertensive medications. It tends to occur with a sudden elevation in blood pressure rather than with chronic hypertension. A number of medical conditions are known precipitants. Hyperadrenergic states may be responsible, including pheochromocytoma, tyramine ingestion with monoamine oxidase inhibitors, abrupt antihypertensive discontinuation, lower gastrointestinal irritation in paraplegic patients, and stimulant medications. Structural precipitants include aortic coarctation and renal artery stenosis. Acute or chronic renal failure is another cause, probably through volume overload in addition to hypertension, and human recombinant erythropoietin may be a precipitant. In patients in the postoperative period after endarterectomy, changes ipsilateral to the surgery may be identical to those seen with hypertensive encephalopathy, even in the absence of blood pressure elevation, probably because vessels compensate for chronic hypoperfusion distal to a severe stenosis and sudden return of blood flow produces relative hypertension.

Hypertensive encephalopathy is associated with vasogenic cerebral edema, particularly severe in the posterior regions of the cerebral hemispheres, which is sometimes sufficient to result in herniation. The pathophysiology linking hypertension and cerebral edema has been argued. At mean arterial pressures greater than 120 to 170 mmHg, cerebral blood flow increases linearly with blood pressure, and some have argued that this is the threshold for hypertensive encephalopathy, when a "breakthrough of autoregulation" occurs. Angiotensin II may contribute to the formation of edema by increasing cerebrovascular permeability through oxygen free radicals. A predilection toward involvement of the posterior hemispheres may be due to differential vascular innervation by the sympathetic nervous system.

Hypertensive encephalopathy is a neurologic emergency that can lead to death if untreated. Diagnosis may be delayed when the connection between acute neurologic dysfunction and hypertension is not obvious. High blood pressure may be attributed to an underlying neurologic condition or agitation rather than identified as the causative agent. Headache is a common early complaint,

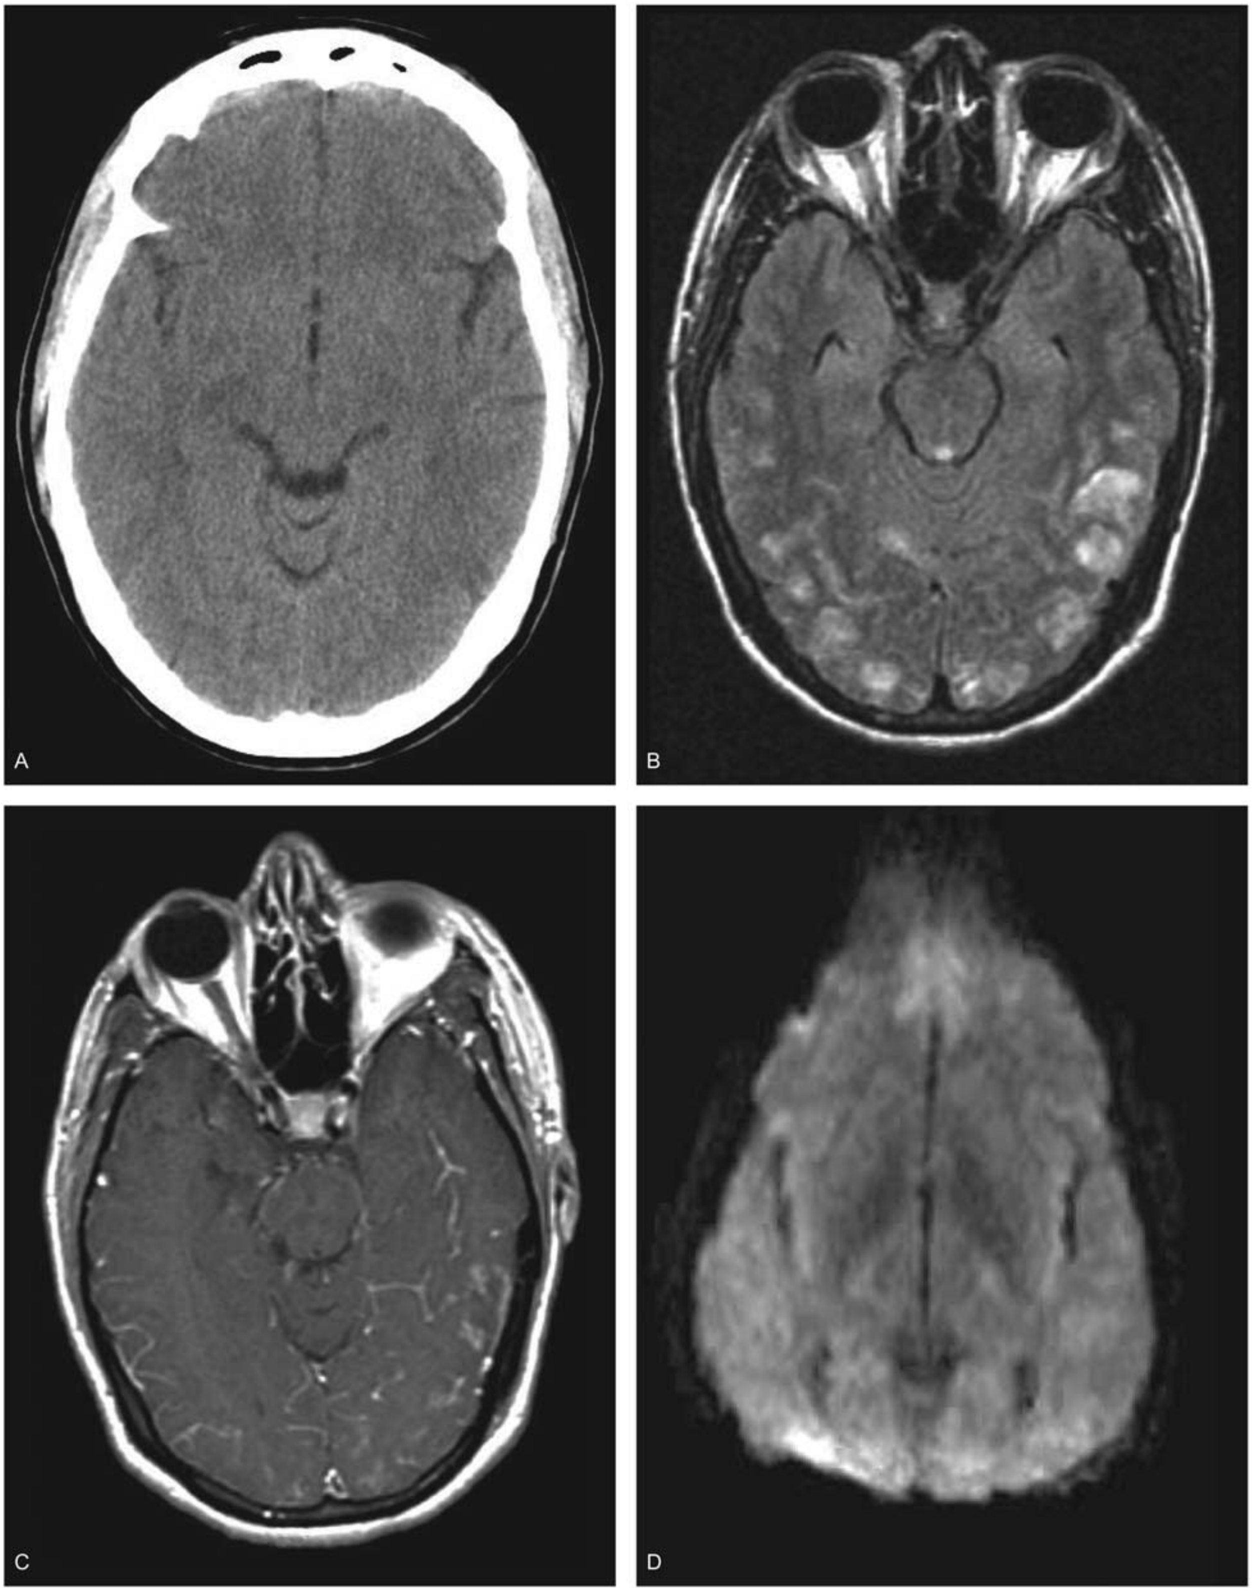

FIGURE 7-9 ■ A patient with eclampsia. Typical findings in hypertensive encephalopathy are identical and include normal or subtle hypodensity on head CT, *A*, subcortical hyperintensities on brain MRI fluid-attenuated inversion recovery (FLAIR) sequences, *B*, enhancement with gadolinium on T1-weighted images, *C*, and no abnormality on diffusion-weighted MRI, *D*.

sometimes accompanied by nausea and vomiting. Confusion with either agitation or lethargy may proceed to obtundation and coma if the process is untreated. Visual disturbance is frequent due to involvement of the retina and occipital lobes, with papilledema and subjective blurred vision, hemianopia, or cortical blindness. Other cortical deficits may occur, including neglect, aphasia, and weakness. Focal or generalized seizures may complicate the course.

Head imaging should be performed to exclude hemorrhage or a structural etiology for both the encephalopathy and the hypertension. Since increased intracranial pressure can result in severe hypertension, which may be required to maintain cerebral perfusion, an urgent study is necessary. Head CT may show hypodensity in subcortical white matter, often most obvious in the occipital lobes (Fig. 7-9). MRI findings may be dramatic, with multifocal T2-weighted hyperintensities particularly apparent in fluid-attenuated inversion recovery sequences. These changes are distinguished from infarcts by sparing of the cortex and absence of reduced diffusion, as expected with vasogenic edema. When cerebral edema is severe, lumbar puncture should be avoided.

Once a structural etiology has been excluded, treatment of hypertension must be initiated. Target blood pressures are tailored to individual patients, with the goal of returning patients to their recent baseline. For patients without a history of hypertension, normal blood pressure parameters are appropriate, but for those with chronic hypertension, an abrupt return to 140/90 mmHg may result in hypoperfusion owing to chronic vascular compensatory changes. Close observation and intravenous antihypertensives are generally indicated. Intravenous dihydropyridine calcium-channel blocking agents and ACE-inhibitors are effective and easy to titrate and may have less profound effects on cerebral vessels. The underlying cause of the hypertensive episode should be sought. Prognosis in treated patients is generally good. Neurologic deficits usually recover completely within 2 weeks.

ECLAMPSIA

Eclampsia can be considered a form of posterior reversible encephalopathy. Occurring during the second half of pregnancy or the puerperium, eclampsia presents with proteinuria and clinical and imaging manifestations identical to hypertensive encephalopathy. Hypertension may not be severe, so additional effects on brain endothelial cell permeability with evidence of generalized endothelial cell dysfunction with abnormal vascular reactivity are probably important. An underlying inflammatory response may be causative, but other potential etiologies have also been hypothesized.

Cerebral venous sinus thrombosis is another complication of pregnancy and delivery and can present with findings similar to those seen with eclampsia. MRI and venography are usually adequate to distinguish the two diseases, showing obstructed venous sinuses or ischemia with cytotoxic edema on diffusion-weighted sequences in cerebral venous sinus thrombosis.

Treatment includes delivery of the fetus and intravenous magnesium. Other antihypertensive medications and anticonvulsants can also be used. Prognosis is good if treatment is initiated quickly.

IMMUNOSUPPRESSION

Several immunosuppressive agents produce a posterior reversible encephalopathy identical to hypertensive encephalopathy. Cyclosporine is the classic example, and it may produce neurologic symptoms at therapeutic levels and without evident hypertension. Tacrolimus, interferon-α, cytarabine, and fludarabine are some of the other medications that have also been associated. An alteration in the permeability of cerebral endothelial cells has been postulated. Lowering blood pressure and discontinuing immunosuppression generally reverses the process.

- General Precautions in Dysautonomic Patients

When a healthy person stands up after being recumbent, approximately 500 ml of blood (or more) pools in the vessels of the legs and abdomen, causing a reduction in filling pressure of the right atrium and thus a decrease in cardiac output and systemic blood pressure. This leads to changes in baroreceptor activity and thus to changes in impulse traffic in the ninth and tenth cranial nerves. These changes affect the activity of the brainstem vasomotor center, which, in turn, influences the autonomic neurons in the intermediolateral cell columns of the thoracolumbar spinal cord, producing reflex peripheral vasoconstriction and an increase in force and rate of myocardial contraction (Figs. 8-1 and 8-2). Cardiopulmonary reflexes, subserved by vagal afferent fibers from mechanoreceptors in the heart and stretch receptors in the lungs, contribute to maintenance of the blood pressure, acting synergistically with the baroreceptor reflexes. The venoarteriolar axonal reflexes may also be important in limiting blood flow to the skin, muscle, and adipose tissues. Standing up also leads to release of norepinephrine. Venous return is aided during maintenance

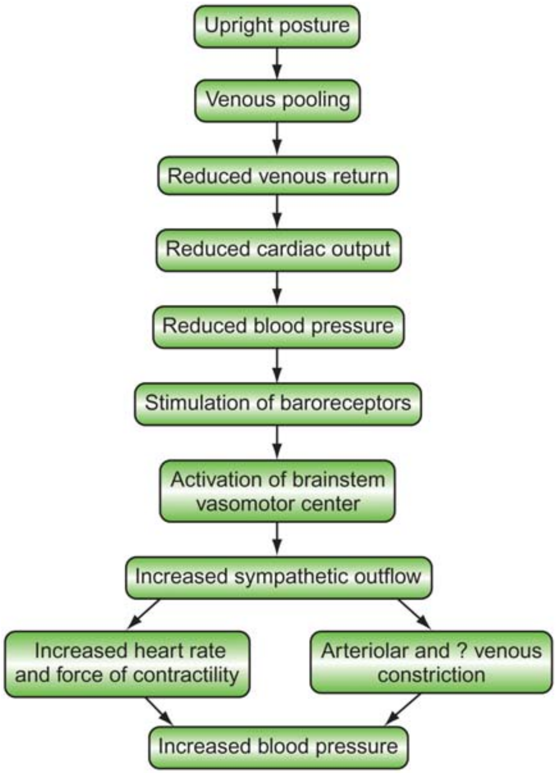
FIGURE 8-1 ■ Anatomy of the autonomic pathways involved in maintaining the blood pressure on standing.

of the upright posture by mechanical factors, such as the tone in the leg muscles and the pumping action of these muscles during walking, and by maneuvers that increase intra-abdominal pressure. This has important therapeutic implications (see p. 141). In addition, there is secretion of antidiuretic hormone (arginine vasopressin) and activation of the renin-angiotensin-aldosterone system, so that salt and water are conserved and blood volume increases. These, however, are typically longer-term rather than immediate control mechanisms.

Postural hypotension is defined as a decrease of at least 20 mmHg in systolic pressure or 10 mmHg in diastolic pressure within 3 minutes of standing. It occurs when there is a failure of the autoregulatory mechanisms that maintain the blood pressure on standing. It may therefore occur with any neurologic disorder that impairs baroreceptor function, disturbs the afferent input from these receptors, directly involves the brainstem vasomotor center or its central connections, or interrupts the sympathetic outflow pathway either centrally or peripherally. It may also occur with a number of non-neurologic disorders, and it is important to consider these disorders if patients are to be managed correctly. Postural hypotension is associated with an increased risk of falls and consequent morbidity and mortality, especially among the elderly.



Upright posture
Venous pooling
Reduced venous return
Reduced cardiac output
Reduced blood pressure
Stimulation of baroreceptors
Activation of brainstem vasomotor center
Increased sympathetic outflow
Increased heart rate and force of contractility
Arteriolar and ? venous constriction
Increased blood pressure

FIGURE 8-2 ■ Sequence of events that ensure maintenance of the blood pressure after adoption of the upright posture. Only the immediate cardiovascular changes are shown. As indicated in the text, a variety of other humoral mechanisms is also activated.

NON-NEUROLOGIC CAUSES OF POSTURAL HYPOTENSION

Cardiovascular Disorders

A variety of cardiac disorders may lead to postural hypotension or even syncope. Pathologic processes such as mitral valve prolapse, aortic stenosis, or hypertrophic cardiomyopathy may limit cardiac output. Cardiac outflow may also be blocked in rare instances by a thrombus or myxoma when the patient is in the upright position. Certain paroxysmal cardiac dysrhythmias (bradycardias or tachycardias) may occur with activity or on standing and produce episodic hypotension or syncope; however, disturbances of cardiac rhythm are common in asymptomatic elderly persons, and their presence must be interpreted with caution.

In patients with congestive heart failure, the heart rate and level of sympathetic tone may be such that compensatory adjustments cannot be made when the patient stands, and postural hypotension therefore results.

Alterations of Effective Blood Volume

Postural hypotension can occur because of loss of effective blood volume. Normal adults can withstand the loss of 500 ml of blood or bodily fluids with few if any symptoms, but greater volume depletion may occur acutely for a variety of reasons (e.g., hemorrhage or burns) and cause a postural drop in blood pressure. Hyponatremia and Addison disease may also lead to an absolute reduction in blood volume. Postural hypotension may occur owing to venous pooling in patients with severe varicose veins or congenital absence of venous valves or because of poor peripheral resistance and reduced muscle tone in patients with paralyzed limbs. Similarly, it may occur during the late stages of pregnancy owing to obstructed venous return by the gravid uterus. Marked vasodilatation, such as occurs in the heat or with the use of certain drugs or alcohol, sometimes causes postural hypotension.

Drugs

Numerous drugs may produce postural hypotension, including those given to treat neurologic disorders (e.g., dopamine agonists, levodopa, and selective monoamine oxidase B inhibitors) and psychiatric disturbances (e.g., tranquilizing, sedative, hypnotic, and antidepressant agents). Antihypertensive drugs, diuretics, phosphodiesterase inhibitors, and vasodilators commonly lead to postural hypotension as a side effect, as do α-blockers (e.g., tamsulosin). Insulin may cause nonhypoglycemic postural hypotension in diabetic patients with autonomic neuropathy, possibly because of vasodilatation and reduced venous return in the absence of functioning compensatory mechanisms or because of impaired baroreceptor responses to changes in arterial pressure. Iatrogenic and toxic autonomic neuropathy is considered later.

Endocrine and Metabolic Disorders

Autonomic neuropathy, with consequent postural hypotension, is a major and common complication of diabetes. Postural hypotension may be a feature of Addison disease, hypopituitarism, myxedema, thyrotoxicosis, pheochromocytoma, carcinoid syndrome, and hypokalemia. It may also occur with anorexia nervosa. Anemia may exacerbate or cause postural hypotension.

Inadequate Postural Adjustments

Prolonged bed rest may result in postural hypotension when patients first begin standing again, but this problem is self-limited. Its cause is poorly understood, but it may be multifactorial. Carotid baroreceptor function is impaired, cardiac vagal activity is reduced, blood pooling is increased in the legs because of greater venous compliance, the total circulating blood volume and central venous pressure are reduced, and the red cell mass may decline. Prolonged bed rest also leads to an increased incidence of cardiac dysrhythmias. In otherwise healthy subjects, vigorous exercise to the point of exhaustion may also cause a postural decline in blood pressure, possibly because of marked peripheral vasodilatation and venous pooling.

Age

Many patients older than 70 years have a decline in systolic pressure of 20 mmHg or more on standing, although in most instances this is asymptomatic. Several causes of reduced orthostatic tolerance with advancing age have been identified. Baroreflex sensitivity declines with age and certain adrenoreceptors exhibit reduced sensitivity. Loss of preganglionic neurons also occurs with age and becomes symptomatic when approximately 50 percent of the cells are lost. Diuretics (which are commonly taken by the elderly) reduce blood volume and may lead to postural hypotension. Finally, structural, mechanical, and functional changes in the vascular system,[1] such as loss of vascular elasticity and the occurrence of varicose veins, may be contributory, as may a reduction in the skeletal muscle mass. Prolonged bed rest, intercurrent illness, and adverse reactions to medication (especially antihypertensive drugs) may also be important.

Syncope is a common problem in the elderly. Often no precise explanation for it can be found, but postural hypotension is probably responsible in many instances. Nevertheless, it is best not to ascribe patients' symptoms to postural hypotension unless they can be reproduced by a demonstrable fall in blood pressure on standing. Many of the homeostatic mechanisms that maintain intravascular volume and blood pressure may be impaired with advancing age, as discussed earlier, so that syncope is more likely to occur. Indeed, in many elderly patients a number of factors can be found to account for syncope, and it is then difficult to determine which of these factors is responsible in any individual instance.

AUTONOMIC REGULATION OF THE HEART AND BLOOD VESSELS

The central nervous system (CNS) is important in regulating cardiovascular function. Various lower brainstem centers receive inputs from both the periphery and other central structures such as the cerebral cortex, temporal lobe, amygdala, hypothalamus, cerebellum, periaqueductal gray matter, and pontine nuclei. The nucleus tractus solitarius is the site of termination of baroreceptor, chemoreceptor, and cardiopulmonary afferent fibers; it connects with the nucleus ambiguus and dorsal nucleus of the vagus and with neurons in the lateral reticular formation that project to the cord in the bulbospinal pathway, thereby influencing the cardiovascular system.

The vagus nerve has a major role in regulating the heart rate responses to various maneuvers. The sympathetic nervous system is important in influencing vasomotor tone and peripheral vascular resistance, but the sympathetic outflow to different regions and structures is regulated separately. The sympathetic nervous system causes a vasoconstriction in response to the release of norepinephrine. The occurrence of vasodilatation in the limbs probably depends on reduced sympathetic activity, and, to a lesser extent, on axon reflexes and antidromic conduction, but some of the vessels in limb muscles are probably also supplied by sympathetic vasodilator cholinergic fibers.

Microneurographic studies in humans have shown that bursts of impulses occur rhythmically in sympathetic efferent vasomotor fibers to the skin and muscles and are time-locked to the pulse. This rhythmic activity depends on supraspinal mechanisms and is not seen below the level of a complete spinal cord transection. Such sympathetic impulse traffic to vessels in the limb muscles is markedly affected by baroreceptor activity, but not by brief mental stress, whereas the traffic in human cutaneous nerves is markedly increased by mental stress. High-pressure arterial baroreceptors are located primarily in the carotid sinus and aortic arch, from which afferent fibers pass to the brainstem in the glossopharyngeal and vagus nerves, respectively.

Sympathetic efferent activity is inhibited by an increase in the pressure in the carotid sinus and aortic arch, whereas a reduced pressure causes increased sympathetic activity and a peripheral vasoconstriction. The heart rate is also influenced by the baroreceptors and cardiopulmonary stretch receptors, so that a bradycardia occurs when the pressure is increased and a tachycardia when the blood pressure declines.

Change from recumbency to an erect posture causes blood to pool in the legs and lower abdomen. There is a slight fall in systolic blood pressure; this leads to baroreceptor activation, a peripheral vasoconstriction, and an increase in heart rate and contractile force. Compensatory changes in the splanchnic vasculature, constriction of venous beds, and activation of the renin-angiotensin system also occur.

The carotid baroreceptor reflexes seem to be more important in responding to the immediate changes in blood pressure that occur on standing, whereas the aortic baroreceptors assume a greater role with maintenance of the upright posture. The cardiopulmonary stretch receptors act synergistically with the baroreceptor reflexes. The venoarteriolar axon reflex, which is activated by venous distention in the legs and an associated increase in transmural venous pressure, is also important in ensuring an increase in limb vascular resistance with change to an erect posture. During activity, the baroreceptors are reset by an uncertain, probably neural, mechanism to allow the blood pressure to increase with exercise. Unmyelinated chemoreceptor afferent fibers from skeletal muscles are also activated, thereby increasing blood pressure and correcting any deficiency in muscle perfusion pressure during moderate to heavy exercise. In addition, activation of mechanically sensitive muscle receptors (muscle mechanoreflex) occurs, and these exercise pressor reflexes (peripheral neural reflexes originating in skeletal muscle) contribute significantly to cardiovascular regulation during exercise.[2] At the initiation of exercise, "central command" from higher brain centers leads to an immediate increase in heart rate and output as well as in blood pressure and respiration.

NEUROLOGIC CAUSES OF POSTURAL HYPOTENSION

Central Lesions

A variety of brainstem lesions can impair autonomic function and affect control of the blood pressure, including syringobulbia and posterior fossa tumors. Chiari malformation with tonsillar herniation may lead to syncopal episodes. Impairment in Wernicke encephalopathy may relate to central or peripheral involvement.

The extent to which cardiovascular reflex function is impaired in *Parkinson disease* is disputed. Many patients with Parkinson disease have postural hypotension from cardiac (especially left ventricular) and extracardiac sympathetic denervation. In such patients, responses to the Valsalva maneuver are also abnormal.[3] Other dysautonomic symptoms, such as disturbances of bladder or gastrointestinal function, and excessive salivation, are relatively common.

The findings in certain *other disorders with parkinsonian features* (e.g., multiple system atrophy, olivopontocerebellar atrophy, and striatonigral degeneration) are discussed later. Postural hypotension may also occur in diffuse Lewy body disease. Mild dysautonomic features may occur late in the course of progressive supranuclear palsy, but cardiovascular reflexes are usually preserved or show only minor abnormalities of dubious significance.

A variety of dysautonomic symptoms may occur in *Huntington disease*, but any abnormalities of blood pressure regulation are usually mild and subclinical, except when related to neuroleptic medication taken for chorea or behavioral disturbances. Postural hypotension or other disturbances of cardiovascular autonomic function occur occasionally in patients with *multiple sclerosis*, but disturbances of bladder and bowel function are much more common dysautonomic features of that disorder. *Wallenberg syndrome* or bilateral brainstem strokes may lead to bradycardia and hypotension that may exacerbate the underlying neurologic problem.

Spinal Injury

The autonomic consequences of spinal cord injuries depend on the level and severity of the lesion. In quadriplegic patients, the period of spinal shock that follows injury is associated with a dysautonomia in which the resting blood pressure and heart rate are typically low and postural hypotension is marked. This mandates that the patient be kept flat, without elevation of the head of the bed, and that any loss of blood volume be avoided or treated vigorously.

A few weeks after transection of the cervical cord, activity returns to the isolated spinal segment, but the brain is no longer able to control the sympathetic nervous system. Loss of regulation during postural change leads to orthostatic hypotension, whereas overactivity occurs if spinal sympathetic reflexes are activated and leads to the syndrome of *autonomic hyperreflexia*. This occurs with usually complete cervical or high thoracic lesions. It is characterized by episodic hypertension, bradycardia, headache, and hyperhidrosis above the level of the lesion, with pallor and piloerection distal to it. Anxiety, confusion, nasal congestion, and facial flushing may also occur. Treatment of this syndrome thus requires avoidance of stimuli that activate spinal sympathetic reflexes (e.g., a distended bladder), elevation of the head of the bed, and, if necessary, use of short-acting antihypertensive agents such as calcium-channel blockers. In general, spinal cord transection produces postural hypotension if the lesion is above about the T6 level. Intramedullary and extramedullary tumors, transverse myelitis, and syringomyelia involving the cord above T6 may also produce dysautonomia.

Root and Peripheral Nerve Lesions

HEREDITARY DISORDERS

Primary amyloidosis and familial amyloid polyneuropathy of Portuguese type (FAP type 1) are often accompanied by dysautonomia consequent to the loss of predominantly unmyelinated and small myelinated peripheral fibers and of cells in the intermediolateral columns of the spinal cord. Postural hypotension and impotence are early manifestations; episodic constipation and diarrhea, distal anhidrosis, impotence, urinary retention, and cardiac arrhythmias may also be conjoined. Tests of sympathetic and parasympathetic function are typically abnormal.

In Fabry disease, disturbed sweating, reduced saliva and tear production, impaired pupillary responses, and gastrointestinal symptoms are common, but postural hypotension does not usually occur, and postural cardiovascular reflexes are normal or only mildly abnormal.

Autonomic involvement may occur in a variety of other hereditary polyneuropathies and in acute porphyria. In familial dysautonomia, or Riley—Day syndrome, many parts of the nervous system are affected. Presentation during infancy may be with inability to suck, but episodic vomiting, recurrent pulmonary infections, hypertension, tachycardia, and diaphoresis occur, especially after 3 years of age. There may also be emotional outbursts, difficulty in swallowing, hypothermia or hyperthermia, poor flow of tears, postural hypotension, and syncope. Sensory abnormalities include impaired pain and temperature appreciation, and the tendon reflexes are depressed. The tongue is smooth and lacks fungiform papillae. Cardiac arrest may occur on tracheal intubation. Treatment is essentially supportive. Postural hypotension usually is not a feature of the other hereditary sensory and autonomic neuropathies, whereas sudomotor function is often markedly impaired.

Autonomic symptoms or signs may occur in patients with hereditary motor and sensory neuropathy type 1, and abnormal vascular reflex responses may be present. Postural hypotension is usually not a conspicuous feature of the disorder.

METABOLIC DISORDERS

Autonomic involvement is particularly frequent in diabetic neuropathy, although usually relatively mild in severity; indeed, diabetes is the most common cause of autonomic neuropathy in the more developed countries. Postural hypotension occurs in approximately 25 percent of patients with diabetic neuropathy. In addition to postural lightheadedness, the dysautonomia of diabetes may be manifest by impotence, postprandial bloating, early satiety, gastrointestinal motility disturbances, abnormalities of bladder control, and alterations of sweating. Cardiac vagal control is usually impaired early, before the development of postural hypotension; the quantitative sudomotor axon reflex test is commonly abnormal and indicates involvement of distal postganglionic sympathetic fibers.

Autonomic dysfunction with abnormal cardiovascular responses occurs in some patients with chronic renal failure on intermittent hemodialysis, but the site of autonomic involvement is unclear. Vitamin B_{12} deficiency may lead to autonomic neuropathy and postural hypotension that improves or resolves completely after vitamin supplementation.

The presence of autonomic neuropathy in patients with chronic alcoholism has been correlated with nutritional status. The cardiovascular responses to various maneuvers are abnormal, reflecting both sympathetic and parasympathetic involvement, but despite this there is often no excessive decline in blood pressure on standing,

INFECTIOUS, INFLAMMATORY, AND IMMUNE-MEDIATED DISORDERS

Postural hypotension may occur in patients with tabes dorsalis because of interruption of circulatory reflexes. Autonomic involvement, with impairment of sweating and cardiovascular responses, occurs in leprosy, sometimes without conspicuous features of peripheral nerve involvement, and also in patients with human immunodeficiency virus infection or Chagas disease.

Autonomic involvement in Guillain—Barré syndrome is usually mild, but paroxysmal cardiac arrhythmias or asystole or episodic hypertension may lead to a fatal outcome. Postural hypotension is common. It has a number of possible causes including inactivity and bed rest, baroreceptor deafferentation, efferent sympathetic denervation, hypovolemia, cardiac abnormalities, or some combination of these and other factors. The severity of autonomic involvement in Guillain—Barré syndrome is not related to the degree of sensory or motor disturbance, and a wide variety of autonomic abnormalities is found if patients are studied in detail. The hypertensive episodes may relate to catecholamine supersensitivity or denervation of baroreceptors. Treatment of Guillain—Barré syndrome is by supportive measures or with plasmapheresis or intravenous immunoglobulin therapy depending on disease severity. Patients with autonomic instability require close observation and management in an intensive care unit. Further aspects of treatment are given on p. 141. Curiously, postural hypotension is uncommon in chronic inflammatory demyelinating polyneuropathy, although mild impairment may be found in many patients on tests of autonomic function.

Autonomic neuropathy of acute or subacute onset, possibly on an autoimmune basis, sometimes occurs as a monophasic disorder in isolation or with associated sensory or motor involvement. It has occurred in the context of antecedent viral infections, malignancy, Hodgkin disease, infectious mononucleosis, ulcerative colitis, celiac disease, and certain connective tissue diseases. In approximately 50 percent of patients, high titers of ganglionic acetylcholine receptor (AChR) antibody are found. In patients with a paraneoplastic etiology, other autoantibodies may be present, including antineuronal nuclear antibody 1 (ANNA-1 or anti-Hu) or 2 (ANNA-2), Purkinje cell antibody 2 (PCA-2), collapsin response-mediator protein 5 antibody (CRMP5), and *N*-methyl-D-aspartate (NMDA) receptor antibody. The presence of such antibodies may suggest the likely site of an underlying primary tumor. Both sympathetic and parasympathetic fibers are usually involved, leading to marked postural hypotension accompanied by a fixed heart rate, anhidrosis or hypohidrosis, heat intolerance, sphincter disturbances, gastroparesis, ileus, and dryness of the eyes and mouth, but occasionally abnormalities are confined to postganglionic cholinergic neurons (acute cholinergic neuropathy), in which case postural hypotension does not occur. Pure adrenergic neuropathy has also been described. Autonomic function tests reflect the clinical findings. Nerve conduction study results are typically normal, but sensory abnormalities are sometimes found. Treatment is supportive; immunomodulating therapy may have a role in those with severe disease. Paraneoplastic dysautonomia may remit if the underlying malignancy is treated. The prognosis of patients with acute or subacute autonomic neuropathies is guarded: approximately one-third of patients do well, but the remainder either fail to improve or are left with a major residual deficit, including marked postural hypotension.

Symptoms of autonomic impairment, including postural hypotension, may also be a presenting feature of systemic autoimmune disorders.

IATROGENIC DISORDERS

Iatrogenic postural hypotension is common in the elderly and relates most often to the use of antihypertensive agents or diuretics. Iatrogenic polyneuropathies may be responsible in other instances, however. For example, postural hypotension may be conspicuous in patients with the neuropathy caused by perhexiline maleate, cisplatin, paclitaxel (Taxol), vinca alkaloids, or amiodarone.

Toxic Exposure

Autonomic dysfunction may result from occupational or other exposure to certain neurotoxins but does not usually lead to postural hypotension. Long-term occupational exposure to a mixture of organic solvents may cause subtle disturbances of peripheral parasympathetic nerves as well as sensorimotor peripheral neuropathies, as reflected by cardiovascular reflex studies, but reports of autonomic involvement in this context are few. Intentional inhalation of *n*-hexane or methyl-*n*-butyl-ketone for recreational purposes may lead to a rapidly progressive neuropathy with associated postural hypotension. Acrylamide neuropathy is usually accompanied by hyperhidrosis and cold, cyanotic extremities; experimental studies in animals reveal baroreceptor dysfunction, but the clinical significance of this in humans is unclear. A variety of autonomic symptoms (including tachycardia, hypertension, and disturbances of sweating) may occur with thallium, arsenic, or mercury poisoning, but postural hypotension is not usually a feature.

The rodenticide *N*-3-pyridylmethyl-*N*′-*p*-nitrophenyl urea (Vacor) has caused severe dysautonomia with disabling postural hypotension, as well as sensorimotor peripheral neuropathy and encephalopathic states. Symptoms reflecting autonomic dysfunction (anorexia, nausea, hyperhidrosis, and tachycardia) have been associated with cumulative exposure to moderate levels of pesticides, particularly organophosphate or organochlorine insecticides, regardless of recent exposure or history of poisoning[4] but whether postural hypotension occurs is unclear.

Primary Degeneration of the Autonomic Nervous System

Postural hypotension resulting from primary degeneration of the autonomic nervous system is well described. The postural hypotension is often exacerbated postprandially, and the normal circadian rhythm is reversed so that the blood pressure is highest at night and lowest in the morning. In addition, blood pressure typically declines with activity rather than increasing as in normal subjects. Other symptoms of dysautonomia in these patients include erectile dysfunction, disturbances of bladder and bowel function, impaired thermoregulatory sweating, and xerostomia. Two distinct groups of patients are now recognized. In one, primary or *pure autonomic failure* (PAF) leads to idiopathic orthostatic hypotension and other evidence of dysautonomia without peripheral neuropathy or CNS involvement. In the other, autonomic failure is associated with more widespread neurologic degeneration (i.e., with evidence of *multiple system atrophy* or MSA) such that there may be clinical features of parkinsonism or striatonigral degeneration (MSA-P), and often of more widespread neurologic lesions as well. A disorder similar to olivopontocerebellar atrophy may also occur (MSA-C). The autonomic deficit may precede the somatic neurologic one, or vice versa, but within a short period there is clinical evidence of both. Occasionally there is a family history of dysautonomia.

The time course and pattern of the dysautonomia reportedly differ between these two disorders, both of which are synucleinopathies. In PAF, syncope and sudomotor dysfunction may precede the onset of constipation, bladder dysfunction, or respiratory disturbances whereas in MSA, urinary complaints occur early and are then followed by abnormalities of sweating or by postural hypotension. Patients with PAF have a slower functional deterioration and a better prognosis. The ingestion of water temporarily increases the seated blood pressure by uncertain mechanisms in patients with chronic autonomic failure. This occurs earlier in PAF than MSA, perhaps reflecting differing lesion sites in these two disorders.

Most patients with PAF have imaging and neuropathologic evidence of cardiac sympathetic denervation, whereas such innervation generally is intact in MSA because there is loss of central rather than peripheral autonomic neurons.[3] In patients of both groups, plasma renin activity is usually subnormal. There are, however, a number of reported pharmacologic differences between them. Patients with PAF have low plasma norepinephrine levels when lying down, and these levels fail to increase appropriately on standing; they also have a lower threshold for the pressor response to infused norepinephrine. The increase in plasma norepinephrine level in response to tyramine (see p. 138) is significantly less than in normal subjects or patients with MSA.[5] Extensive cell loss occurs in the intermediolateral cell columns of the thoracic cord, and the autonomic dysfunction has been attributed primarily to loss of these preganglionic sympathetic neurons. However, the pharmacologic studies described previously indicate that loss of postganglionic noradrenergic neurons also occurs, and norepinephrine may be depleted from sympathetic nerve endings.

By contrast, in MSA, in which lesions are situated at multiple sites in the CNS, circulating norepinephrine levels are normal, suggesting that peripheral sympathetic neurons are intact, but plasma norepinephrine fails to increase appropriately with standing, implying that these neurons have not been activated.[5] There is also an exaggerated pressor response to infused norepinephrine, but only patients with idiopathic orthostatic hypotension show a shift to the left in their dose—response curve, reflecting true adrenergic receptor supersensitivity.[5]

Central catecholamine deficiency in these disorders is reflected by the levels in the cerebrospinal fluid of dihydroxyphenylacetic acid (a neuronal metabolite of dopamine), which are lower in patients with MSA or PAF than normal subjects, as also is dihydroxyphenylglycol, a metabolite of norepinephrine.

Endogenous arginine vasopressin is a powerful vasoconstrictor; it also acts on the kidney to control urinary concentrating mechanisms. The cardiovascular responses usually associated with arginine vasopressin are reduced cardiac output, heart rate, and plasma renin activity and increased vascular resistance and blood pressure. Arginine vasopressin helps maintain arterial pressure in certain hypotensive situations such as hemorrhage or volume depletion, but increased levels of arginine vasopressin do not normally affect the blood pressure significantly because the acute vasoconstrictor effects are buffered by the baroreceptor reflex. The chronic effects of vasopressin on renal function do not produce sustained retention of sodium and water, and so produce only minimal changes in mean arterial pressure.

Vasopressin release is influenced by the plasma's osmotic pressure and by the activity of vascular stretch receptors. In normal people, plasma arginine vasopressin increases in response to standing, presumably because a decrease in venous return influences afferent activity from these stretch receptors. In patients with PAF or with MSA, plasma levels similar to control values are found in the horizontal position, but the postural increase is markedly attenuated.

Miscellaneous Disorders

Patients with *Holmes—Adie syndrome* may present with or develop postural hypotension or abnormalities of thermoregulatory sweating. Postural hypotension may occur in *botulism*; however, blurred vision, dry mouth, and constipation are much more common autonomic manifestations. In rare instances, it relates to excessive amounts of endogenous bradykinin (a vasodilator) or a congenital defect of norepinephrine release. In patients with *dopamine β-hydroxylase* *deficiency*, norepinephrine and epinephrine cannot be synthesized, and dopamine is released from central and peripheral adrenergic nerve terminals. Severe postural hypotension is accompanied by other autonomic disturbances in association with absent norepinephrine and excessive dopamine levels in the plasma.

POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME

Orthostatic symptoms may develop in association with a significant and sustained tachycardia within 10 minutes of standing or head-up tilt, but in the absence of postural hypotension or an autonomic neuropathy. A significant tachycardia is defined as an increase in heart rate of 30 beats per minute or more, or a heart rate of at least 120 beats per minute. The designation *postural orthostatic tachycardia syndrome* (POTS) is applied to this disorder, which is more common in women than men and tends to occur in patients between 20 and 50 years of age, with about half the patients developing symptoms in adolescence. The syndrome may have an enormous impact on patients' quality of life.

Symptoms on standing include tremulousness, lightheadedness, palpitations, visual disturbances, "brain fog," generalized weakness, daytime somnolence, fatigue, anxiety, hyperventilation, nausea, postprandial bloating, and sweating, and may occur cyclically. Thus, orthostatic symptoms are accompanied by symptoms of sympathetic activation.

The diagnosis is suggested by the history and examination findings and confirmed by recording the heart rate and blood pressure on standing for 10 minutes after the patient has been lying supine for 10 minutes. Measurements are made at 1, 3, 5, and 10 minutes after standing. Testing is best performed in the morning, when orthostatic tachycardia is typically more pronounced. Other medical problems that may cause a tachycardia (such as pain, infection, anemia, hypovolemia, hyperthyroidism, and various medications) must be excluded before POTS is diagnosed. More detailed testing of autonomic function is sometimes performed in selected patients but is generally not required unless doubt exists about the diagnosis, it is wished to define the subtype of POTS, or the response to treatment is disappointing. Further investigations may be required to explore the basis of other symptoms.

POTS has been subdivided into various overlapping subtypes depending on clinical manifestations and mechanisms presumed to be involved. The pathophysiologic basis of POTS is uncertain and probably multifactorial, but cardiac deconditioning (characterized by physiologic cardiac atrophy and hypovolemia) is held to be a factor. Prolonged bedrest can lead to orthostatic tachycardia and intolerance in previously healthy subjects. POTS has been related also to inadequate venous return to the heart during standing. Specifically, peripheral vasoconstriction is impaired by peripheral sympathetic denervation, leading to venous pooling in the legs on standing and to a compensatory tachycardia. Denervation is evidenced by impaired sweating in the legs or a reduced density of intraepidermal nerve fibers on skin biopsy in many of these patients, who are deemed to have "neuropathic POTS." In other instances, patients with ("hyperadrenergic") POTS may have an exaggerated sympathetic response to standing, with markedly elevated levels of plasma norepinephrine that cause the orthostatic tachycardia. The increased norepinephrine level may relate, in turn, to impaired synaptic clearance by the norepinephrine transporter (NET) either on a genetic basis or because of medications being taken, such as certain antidepressants. Other postulated mechanisms for POTS involve impaired brainstem regulation; immune system dysfunction; hormonal factors; hypovolemia, perhaps from impaired function of the renin-angiotensin system ("volume dysregulation POTS"); and excessive mast cell activation leading to inappropriate release of histamine during physical activity. Psychologic mechanisms have also been invoked. The evidence for these various mechanisms is incomplete, and different mechanisms or combinations of mechanisms may be involved in different patients.

POTS can be associated with certain other disorders, especially joint hypermobility syndrome but also migraine, concussion, chronic fatigue, fibromyalgia, diabetes, paraneoplastic syndrome, amyloidosis, sarcoidosis, alcoholism, lupus, Sjögren syndrome, and heavy metal intoxication, and it may follow pregnancy, surgery, trauma, chemotherapy (especially with vinca alkaloids), vaccinations, or viral infections. It may also occur in association with mitral valve prolapse or a more specific dysautonomia.

The optimal therapy for the disorder is not clear, but treatment may include volume repletion, a high-salt diet and copious fluids, postural and psychophysiologic training, and a 3-month, graduated exercise program. These nonpharmacologic measures—and education of the patient—are often very effective in alleviating symptoms. Waist-high compression stockings may help, especially in patients with low blood pressure. If pharmacologic measures are needed, there are several options. If palpitations are the most conspicuous symptom, a β-blocking agent (e.g., propranolol 10 to 40 mg three times daily) may be used. Phenobarbital (15 mg in the morning, 60 mg at night) or clonidine (0.2 mg twice daily) is sometimes helpful for patients with such hyperadrenergic POTS. If the blood pressure is low and symptoms such as lightheadedness predominate, midodrine (2.5 to 10 mg three times daily) or fludrocortisone (0.1 to 0.2 mg daily) may be prescribed, and pyridostigmine (30 to 60 mg three times daily) is also worthy of trial. In other instances, norepinephrine and serotonin reuptake inhibitors may be worthwhile.

The long-term prognosis is not clear but approximately 50 percent of patients recover within 3 years.

SYMPTOMS OF DYSAUTONOMIA

General

Postural hypotension is usually the most disabling feature of autonomic failure. It leads to symptoms on or shortly after standing; they are relieved by sitting or lying down, and do not occur in the supine position. Such symptoms reflect cerebral hypoperfusion and include faintness, lightheadedness, blurred vision, and syncope. They may be particularly troublesome after exercise or a heavy meal (particularly a meal rich in carbohydrates) or in the morning when the blood pressure tends to be at its lowest (in contrast to healthy subjects). However, in some patients, marked postural hypotension may be clinically asymptomatic or may be accompanied by symptoms not usually regarded as suggestive of postural hypotension, such as nausea, breathlessness, heaviness or weakness of the limbs, episodic confusion, impaired concentration, falling, staggering, headache and neck pain, neck and shoulder discomfort, and generalized weakness. Constipation may precipitate syncopal attacks during straining. Symptoms may also worsen in the heat because of vasodilatation and volume loss due to sweating. The symptoms of idiopathic POTS (discussed earlier) may be mistakenly attributed to postural hypotension, but occur without a significant decrease in blood pressure. Other causes, such as hypoglycemia, cardiac arrhythmias, or transient ischemic attacks, must be excluded if symptoms develop with the patient supine.

Erectile dysfunction is a common initial symptom of autonomic dysfunction in men, often preceding other symptoms by several months or years. Bladder involvement may manifest by urinary frequency, urgency, incontinence, retention, and increased residual urine; urinary infections and renal calculi may occur in some patients with urinary stasis. Gastrointestinal dysfunction may lead to early satiety, constipation, fecal incontinence, and diarrhea. Thermoregulatory sweating may be impaired. Pupillary abnormalities include Horner syndrome and anisocoria. Lacrimal dysfunction may lead to inadequate or excessive production of tears. Other symptoms of dysautonomia include night blindness, nasal congestion, and, sometimes, supine hypertension. Vocal abnormalities and respiratory disturbances (especially involuntary inspiratory gasps, cluster breathing, airway obstruction, and sleep apnea) sometimes occur, especially in patients with multiple system atrophy.

Syncope

Syncope refers to a sudden, transient loss of consciousness due to diffuse cerebral hypoperfusion or hypoxia. It is usually associated with flaccidity, but a generalized increase in muscle tone sometimes occurs with continuing cerebral ischemia/hypoxia, and there may be arrhythmic transient motor activity as well. Postictal confusion is usually brief (less than 30 seconds) when it occurs at all, unlike the marked postictal confusion that often follows a convulsion. Syncope has been divided into syncope from postural hypotension, reflex (i.e., neurally mediated) syncope, and cardiac syncope (arrhythmic or associated with structural cardiac disease).[6]

POSTURAL HYPOTENSION

In patients with postural hypotension due to autonomic dysfunction, there is a decline in blood pressure on standing, without adequate compensatory change in total peripheral resistance or heart rate, and syncope may result. When postural hypotension occurs because of one of the non-neurologic causes discussed earlier, it may also lead to syncope if autonomically mediated compensatory mechanisms fail to limit the decline in blood pressure. In neurogenic postural hypotension, a failure of autonomic activation may result in a lack of premonitory symptoms such as tachycardia, nausea, or diaphoresis.

Neurally Mediated Syncope

During *vasovagal syncope*, there is an initial increase in heart rate, blood pressure, total peripheral resistance, and cardiac output, followed by peripheral vasodilatation, increased blood flow to the muscles, decreased heart rate, and a decrease in venous return to the heart. Blood pressure falls owing to failure to increase the heart rate and cardiac output sufficiently, a decrease in systemic vascular resistance, or both. The decline in heart rate and cardiac contractility constitute the cardioinhibitory response. The vasodilatation and decline in systemic vascular resistance constitute the vasodepressor response. These various phenomena have been related to Bezold–Jarisch reflexes arising from cardiac sensory receptors and subserved by vagal afferent fibers, perhaps as a consequence of a decrease of central blood volume and decreased ventricular filling.[6] Recordings from nerve fibers reveal that impulse traffic ceases in the sympathetic outflow to skeletal muscle during syncope and gradually builds up again over the following 5 minutes or so.[7] Withdrawal of sympathetically mediated vasoconstriction may underlie the profound systemic vasodilatation that leads to hypotension and subsequent syncope, but other mechanisms are probably also involved in the peripheral vasodilation.[7]

Syncope of this sort may be precipitated by pain, fear, emotional reactions, injury, and surgical manipulation. It may occur in association with missed meals, heat, or crowds; it usually occurs while subjects are standing. Warning symptoms include weakness, sweating, pallor, nausea, yawning, sighing, hyperventilation, blurred vision, impaired external awareness, and dilatation of pupils. Lying down or squatting at this time may abort actual loss of consciousness.

Deglutition syncope is characterized by syncope precipitated by swallowing. In such instances, there may be associated esophageal disorders. The syncope has usually been attributed to atrioventricular heart block or cardiac arrhythmia. It is presumed that the prime factor is clinical or subclinical disease of the conducting system of the heart and that disturbances of cardiac rhythm are then triggered by reflexes originating in the esophagus. A pacemaker may prevent further episodes.

Micturition syncope occurs after urination, particularly when the patient has arisen from bed at night. It may relate to sudden release of the reflex vasoconstriction elicited by a full bladder. Assumption of the upright posture, the peripheral vasodilatation resulting from the warmth of the bed, and, particularly in elderly men, straining to micturate may also contribute to the drop in blood pressure. Occasionally, syncope occurs in response to cardiac dysrhythmia induced by a full bladder before micturition.

Carotid sinus syncope may be provoked by neck-turning or a tight collar in susceptible subjects. Certain drugs have also been shown to predispose toward it, especially propranolol, digitalis, and α-methyldopa, and it may occur during internal carotid angioplasty. A hypersensitive carotid sinus reflex is defined by a slowing in heart rate of more than 50 percent or a decline in systolic pressure by more than 40 mmHg during carotid sinus massage. However, less than 50 percent of patients with carotid hypersensitivity have syncope as a result. Conversely, in many patients with syncope of unidentifiable cause, the carotid sinus syndrome may have been overlooked.

The *Valsalva maneuver* may lead to syncope, as when syncope occurs during vigorous coughing or straining at stool as a result of the reduced cardiac output and the peripheral vasodilatation caused by the high intrathoracic pressure. Cerebral perfusion may also be reduced by an increase in intracranial pressure.

Cardiac Syncope

As discussed earlier, postural hypotension may have a cardiac basis. In addition, disturbances of cardiac rhythm may lead to sudden loss of consciousness, regardless of the position of the body (Adams–Stokes attacks). Further discussion of this topic is provided in Chapter 5. Exertional syncope suggests obstructive valvular disease or a right-to-left shunt. Coronary artery disease may lead to arrhythmias that cause syncope.

Hyperventilation

Hyperventilation, with consequent hypocapnia and reduced cerebral perfusion, is a common cause of presyncopal symptoms, but actual loss of consciousness is uncommon.

EVALUATION OF AUTONOMIC FUNCTION

After neurologic, cardiologic, and metabolic causes of syncope have been excluded, a number of patients remain in whom the diagnosis is unclear. The utility of autonomic studies in these circumstances was examined by Mathias and colleagues.[8] They found that screening autonomic function tests revealed postural hypotension and confirmed chronic autonomic failure in 5 percent, and neurally mediated syncope was diagnosed in 43.5 percent based on clinical features and autonomic studies. Thus, in recurrent syncope or presyncope, autonomic studies are worthwhile as they may clarify the diagnosis. In patients with unexplained syncope, the implantable loop recorder is an important diagnostic tool that may clarify the underlying pathophysiology.

Postural Change in Blood Pressure

In investigating patients with suspected autonomic dysfunction or postural hypotension, the blood pressure should be measured with the patient supine for at least 2 (preferably 10) minutes. The patient then stands up, and the blood pressure is measured again after 5 to 10 seconds, and again after 1, 2, 3, and 5 minutes. There is normally an increase in pulse rate on standing, but the pulse rate may not change if there is already a high resting pulse or in patients with dysautonomia; furthermore, the change in heart rate may be blunted in the elderly. As for the blood pressure, there is normally a slight decline in systolic pressure, whereas diastolic pressure increases slightly. The response of the blood pressure is regarded as abnormal if systolic pressure decreases by at least 20 mmHg or diastolic pressure by 10 mmHg on standing. In some instances, postural hypotension develops only after exercise or a meal; it is therefore worthwhile to record the postactivity and postprandial blood pressure if clinically feasible. It may be necessary to record the blood pressure on a number of occasions before the diagnosis of postural hypotension can be confirmed. Normal responses do not exclude postural hypotension as a cause of symptoms. In other instances, prolonged tilt (for up to 60 minutes) on a tilt table may be required to detect abnormalities.

Blood pressure normally is higher in the day, declines at night, and rises prior to awakening. Patients with postural hypotension may show a circadian trend in blood pressure that is the reverse of normal subjects, with the highest pressures found at night and the lowest in the morning. Further, postural hypotension may be more severe in the morning after prolonged nocturnal recumbency due to a decline in stroke volume and cardiac output, resulting not only from nocturnal polyuria but also from a redistribution of body fluid. Such temporal variation in blood pressure implies that physiologic testing should be carried out at a standard time of day, especially if comparative studies are to be performed, and potentially harmful hypertension in response to treatment should be looked for especially during the early part of the night.

Tilt-Table Testing

The effect of postural change on blood pressure can be evaluated more accurately if the blood pressure is measured using an intra-arterial cannula or a noninvasive plethysmographic device with the patient resting quietly on a tilt table. Measurements are made continuously while the patient lies supine for at least 10 minutes and is then maintained at a 60- or 70-degree head-up tilt for up to 60 minutes, depending on the reason for the study. Testing on a tilt table permits longer monitoring of hemodynamic responses than does active standing. The response to head-up tilt differs from that obtained by standing because the venous return to the heart is not aided as much by contraction of leg and abdominal muscles, and thus there is greater peripheral pooling of blood. Compared to passive tilt, active standing leads to a greater but transient decline in blood pressure, a larger increase in heart rate, a greater decline in total peripheral resistance, and a more marked increase in cardiac output during the first 30 seconds.[9]

Tilt-table testing is performed to determine whether patients have postural hypotension and—if so—whether this is the cause of postural symptoms. It is helpful in the diagnosis of POTS and of delayed postural hypotension (i.e., hypotension that occurs after standing for 3 minutes or longer), and in distinguishing between neurogenic and other causes of postural hypotension, between convulsive syncope and epilepsy, and between syncope and psychogenic attacks.[9] With head-up tilt, blood pressure generally falls rapidly and does not recover until the horizontal position is restored.

Postural Change in Heart Rate

A simple, noninvasive test of autonomic function consists of evaluating the response in heart rate to change from a recumbent to a standing position.

There is typically a rapid increase in heart rate that is maximal at approximately the fifteenth beat after standing, with a subsequent slowing from the initial tachycardia (i.e., a relative bradycardia) that is maximal at approximately the thirtieth beat (Fig. 8-3). This response is mediated by the vagus nerve. For testing purposes, the R-R interval at beats 15 and 30 after standing can be measured to give the 30/15 ratio, as reviewed in detail elsewhere. Values greater than 1.03 occur in normal subjects, whereas in diabetic patients with autonomic neuropathy (who typically show only a gradual increase in heart rate), values are 1.00 or less. Some prefer to measure the ratio of the absolute maximum to absolute minimum heart rate after standing, which may not coincide with the heart rates at beats 15 and 30. This test does not depend on the resting heart rate and correlates well with the Valsalva ratio and the beat-to-beat variation in heart rate, described later. The value for the 30/15 ratio declines with age in normal subjects.

In some patients, an excessive and sustained tachycardia develops in response to standing or head-up tilt, without a significant drop in blood pressure. A prolonged tilt (for up to 60 minutes) may be necessary to elicit the abnormality. The mechanisms underlying this postural tachycardia have not been clearly established.

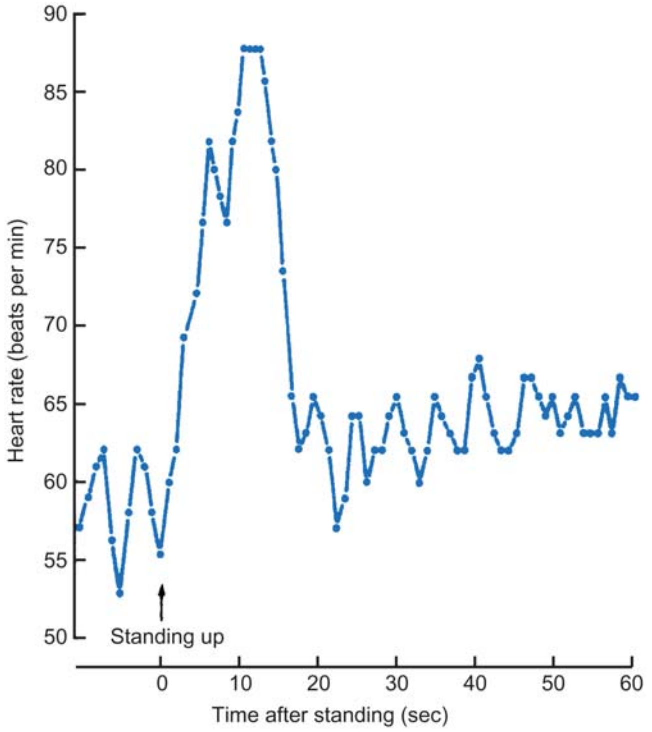


FIGURE 8-3 ■ Heart rate responses to standing in a normal subject. Immediately on standing, there is a rapid increase in heart rate that is maximal at approximately the fifteenth beat after standing.

Valsalva Maneuver

The Valsalva maneuver consists of a forced expiration maintained for at least 10 seconds (preferably 15 seconds) against a closed glottis after a full inspiration. Intrathoracic pressure should be increased by 30 to 40 mmHg. Clinically, this can be ensured by requiring the patient to blow into a mouthpiece connected to a manometer. The response can be recorded with an intra-arterial needle (Fig. 8-4), a noninvasive photoplethysmographic recording device (Finapres), or an electrocardiograph (ECG) (Fig. 8-5).

The cardiovascular response is usually divided into four stages. Stage 1 is characterized by a transient increase in blood pressure at the onset of the forced expiration, reflecting the increased intrathoracic pressure. In stage 2, there is normally a gradual decrease in systolic and diastolic pressures, pulse pressure, and stroke volume for several seconds because of a reduction in venous return to the heart, with an associated reflex tachycardia. Reflex vasoconstriction arrests the decline in blood pressure after about 5 to 7 seconds. Stage 3 occurs when the patient releases the expiratory maneuver and is characterized by a transient fall in the blood pressure because of pooling of blood and expansion of the pulmonary vascular bed with the abrupt decline in intrathoracic pressure. In stage 4, there is an overshoot of the blood pressure above baseline value as a result of the peripheral vasoconstriction, with a compensatory bradycardia.

The Valsalva maneuver is an accurate indicator of baroreceptor reflex sensitivity. Abnormalities are found in patients with dysautonomia (Fig. 8-4) and may consist of loss of the overshoot in systolic blood pressure and compensatory bradycardia in stage 4, a fall in mean blood pressure in stage 2 to less than 50 percent of the previous resting mean pressure, and loss of the tachycardia in stage 2, or a lower heart rate in stage 2 than stage 4. However, abnormalities may also be found in patients with severe congestive heart failure and in those with cardiac lesions other than primary myocardial dysfunction.

If the response is recorded noninvasively using an electrocardiograph, the ratio of the shortest R-R

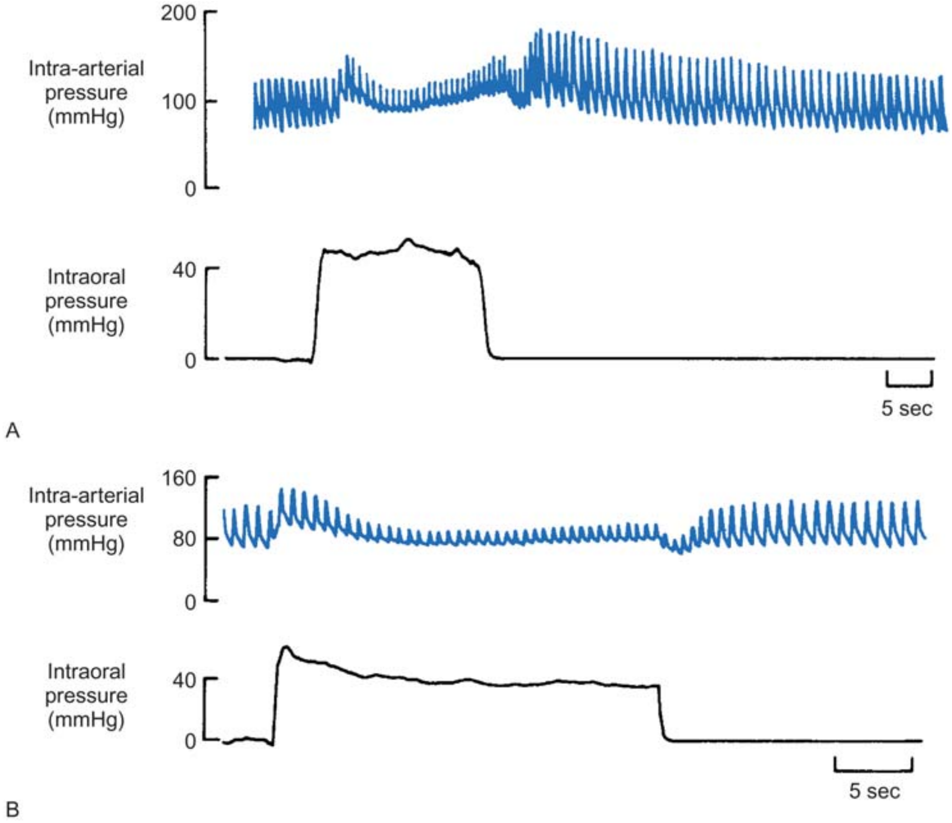

FIGURE 8-4 ■ Cardiovascular responses to the Valsalva maneuver, as recorded with an intra-arterial needle. *A*, Normal response. *B*, Abnormal response in a patient with multiple system atrophy. (From Aminoff MJ: Electromyography in Clinical Practice. 3rd Ed. Churchill Livingstone, New York, 1998, p. 206, with permission.)

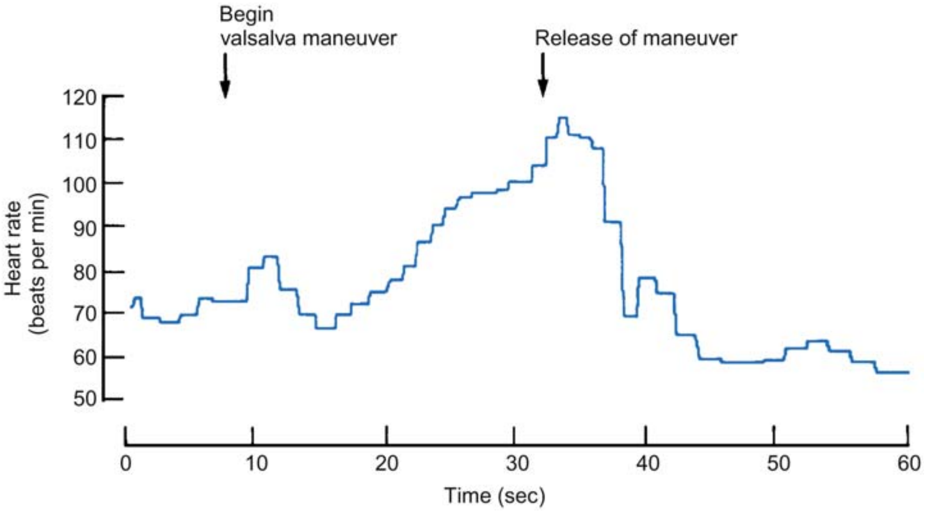

FIGURE 8-5 ■ Valsalva maneuver as recorded using an electrocardiograph (ECG) or heart rate monitor in a normal subject. The tachycardia that occurs during the forced expiratory maneuver is clearly evident, as is the compensatory bradycardia that occurs when the maneuver is released.

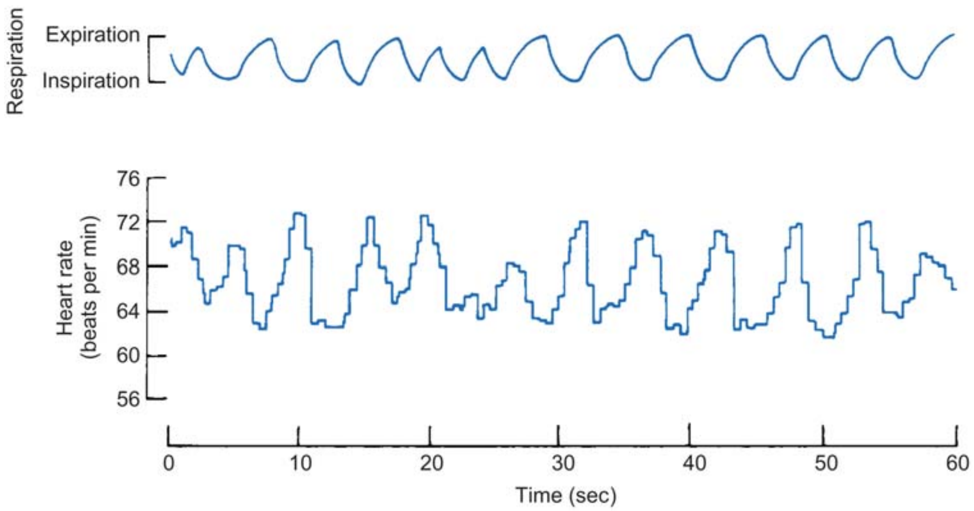

FIGURE 8-6 ■ Normal variation in heart rate that occurs in response to deep breathing.

interval (the tachycardia) during the maneuver to the longest R-R interval (bradycardia) after it is determined and expressed as the Valsalva ratio. In early studies, a value of 1.1 or less was arbitrarily defined as an abnormal response, 1.21 or greater as a normal response, and 1.11 to 1.20 as borderline. Using such criteria, the Valsalva maneuver was found to be abnormal in about 60 percent of diabetic patients with symptoms and signs suggestive of autonomic neuropathy. When more generous criteria for abnormality were used, with a lower limit for normal of 1.50, the value was abnormal in 86 percent of these patients, and such an abnormality correlated well with the presence of a significant postural drop in blood pressure. Subsequent studies have shown that age- and gender-based normal values should be used.

Other Cardiovascular Responses

Other cardiovascular responses can also be measured noninvasively (e.g., the beat-to-beat variation in heart rate and the heart rate responses to deep breathing and sustained hand grip). Such tests of parasympathetic function appear to give abnormal results more often and earlier than tests of sympathetic efferent function (blood pressure response to change in posture and isometric exercise), at least with the dysautonomia that occurs in diabetes. Reduced cardiovascular autonomic function, as reflected by heart rate variability, is associated with an increased risk of silent myocardial ischemia and death in patients with diabetic autonomic neuropathy.

A particularly useful test is to measure the heart rate variation during deep breathing (Fig. 8-6). In normal subjects, there is considerable heart rate variation, which is accentuated during deep breathing. This variation is reduced or absent in diabetic patients with autonomic neuropathy. The optimal breathing rate for this test is six breaths per minute (i.e., inspiration = expiration = 5 seconds). Heart rate variation scores can be calculated by measuring the difference between the maximal and minimal heart rates in inspiration and expiration, taking the average from 10 breaths in and 10 breaths out. Normal subjects usually have a score greater than 9, and autonomic neuropathy is probably absent if scores greater than 12 are obtained; the normal range, however, is age dependent. Thus, heart rate variability declines with age in normal subjects. The use of a single normal value regardless of age may therefore limit the utility of the test. Physical fitness, body weight and position, time of testing, and concomitant medication may affect the test results.

An increase in heart rate and blood pressure should also occur in response to startle, such as occurs with a sudden loud noise, and to mental stress, as is produced when the patient attempts to subtract 7 serially from 100 while constantly being distracted.

Digital Blood Flow

Blood flow to a finger can be measured by conventional plethysmography or photoplethysmography. A sudden inspiratory gasp causes reflex digital vasoconstriction as a spinal or brainstem reflex, and this is easily measured plethysmographically (Fig. 8-7). The response is impaired or absent in patients with a lesion of the cord or sympathetic efferent pathway, as in peripheral neuropathy or pure autonomic failure. In entrapment neuropathy, such as carpal tunnel syndrome, the vasoconstrictor response may be abolished in fingers supplied by the affected nerve but not in those supplied by other nerves.

Mental stress (e.g., performing mental arithmetic despite distraction) or startle (as from a sudden loud noise) leads to a transient increase in sympathetic vasomotor activity and thus to a reduction in digital blood flow; this can be used to evaluate sympathetic efferent pathways. Normal subjects sometimes have no response to these tests, however, leading to false-positive results.

Cold Pressor Test

In the cold pressor test, one hand is immersed in ice water at 4°C, and this normally produces an increase in systolic pressure of 15 mmHg or more within 1 minute. The afferent pathway involves the spinothalamic tract, and if this tract is intact, the lack of a pressor response suggests a lesion centrally or in the sympathetic efferent pathway. A normal response in a patient with an abnormal Valsalva response and intact pain and temperature sensation suggests an afferent baroreceptor lesion.

Plasma Norepinephrine Level and Infusion

The plasma norepinephrine level can be used as an index of sympathetic activity. In normal subjects the level doubles within 5 minutes of standing. In patients with a central dysautonomia such as MSA, plasma norepinephrine levels are normal, whereas in PAF they are low. Perhaps of greater value, the blood pressure can be measured in response to intravenous infusion of norepinephrine at several dose rates up to 20 μg/min.[5] In this way, a dose—response curve can be constructed. In normal subjects, it is usually necessary to administer 15 to 20 μg/min to increase systolic blood pressure to 40 mmHg above baseline. A similar increase in blood pressure results from doses of 5 to 10 μg/min in MSA and less than 2.5 μg/min in patients with PAF.[5]

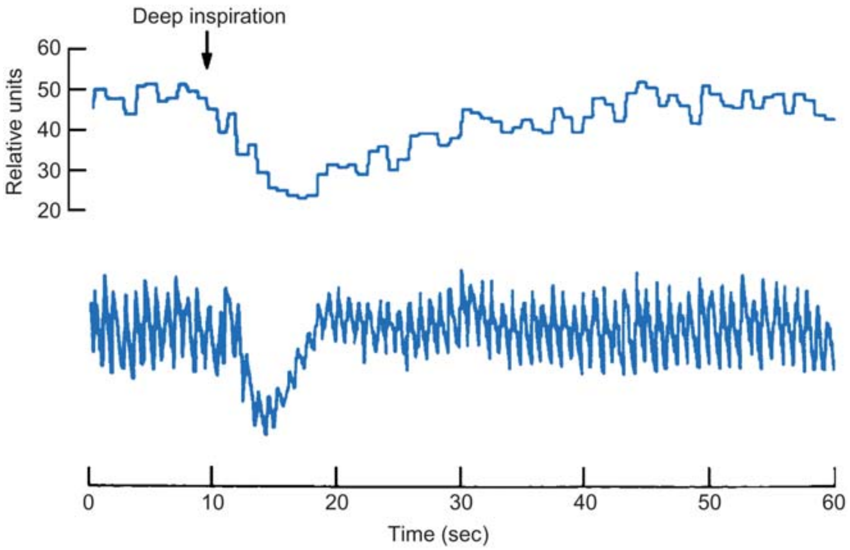

FIGURE 8-7 ▪ Variation in blood volume after a deep inspiration in a normal subject, measured photoplethysmographically by means of an infrared emitter and detector placed on the pad of the index finger. The bottom trace represents the sensor output after it has been amplified by the photoplethysmographic module of a computerized autonomic testing system; it is a function of the absolute blood volume in the finger. Each peak represents a heartbeat, and the amplitude of each wave reflects blood volume in the area about the sensor. The apparent shift of the direct-current signal component is due to the long time constant that is necessary so that signal information is not lost. The relative voltage, representing the amplitude of each pulse, is shown in the upper trace. It is evident in both traces that after the deep inspiration there is a reduction in digital blood flow (i.e., reduced amplitude of the waveforms in the lower trace and a corresponding decline in the upper trace).

Response to Tyramine

Tyramine, an indirectly acting sympathomimetic drug, can be used to test neuronal uptake and release of norepinephrine. Bolus injections ranging from 250 to 6,000 μg are administered and blood pressure is measured at 1-minute intervals. The amount of norepinephrine released into plasma by tyramine can be quantified by obtaining a blood sample shortly after the rise in blood pressure.[5]

Sweat Tests

Cutaneous blood vessels and sweat glands are supplied by sympathetic fibers intermingled in the same fascicles but of different size and conduction velocity. Commonly used tests of sweating are messy and require application of heat, which is time-consuming. A heat cradle placed over the trunk is used to produce an increase of 1°C (from a resting level of 36.5° to 37.0°C) in the oral temperature over the course of 30 to 60 minutes, and the presence of sweat over selected regions of the trunk and limbs is detected by the change in color produced in quinizarine powder, a starch—iodide mixture, or some other indicator powder. The pattern of any impairment of sweating may be helpful in suggesting the underlying cause (Fig. 8-8). For example, impairment is usually distal in the limbs in patients with polyneuropathies. The method does not distinguish preganglionic from postganglionic lesions.

The volume of sweat produced by axon-reflex stimulation either electrically (faradic sweat response) or with parasympathomimetic drugs under specified conditions indicates the state of sudomotor innervation in the tested limb (Fig. 8-9). After a short latent period, sweating occurs in an area that is approximately 4 to 5 cm in diameter about the site of stimulation. The reflex is subserved by sympathetic postganglionic fibers; impulses pass centripetally along these fibers until they reach a branch point and then pass distally again. The receptor involved in the reflex has not been defined. To quantify the volume of sweat, recordings are made of the humidity change of an air stream of defined flow. Such quantitative sudomotor axon reflex testing (QSART) is a sensitive means of assessing postganglionic sympathetic function by using iontophoresed acetylcholine to stimulate the involved receptors; it yields reproducible results but requires sophisticated and expensive equipment. Yet another approach to evaluating postganglionic sympathetic sudomotor function is with the silicone mold technique, in which imprints are made of sweat droplets stimulated by iontophoresed acetylcholine.

Sudomotor function can also be evaluated by measuring changes in skin resistance. With sweating,

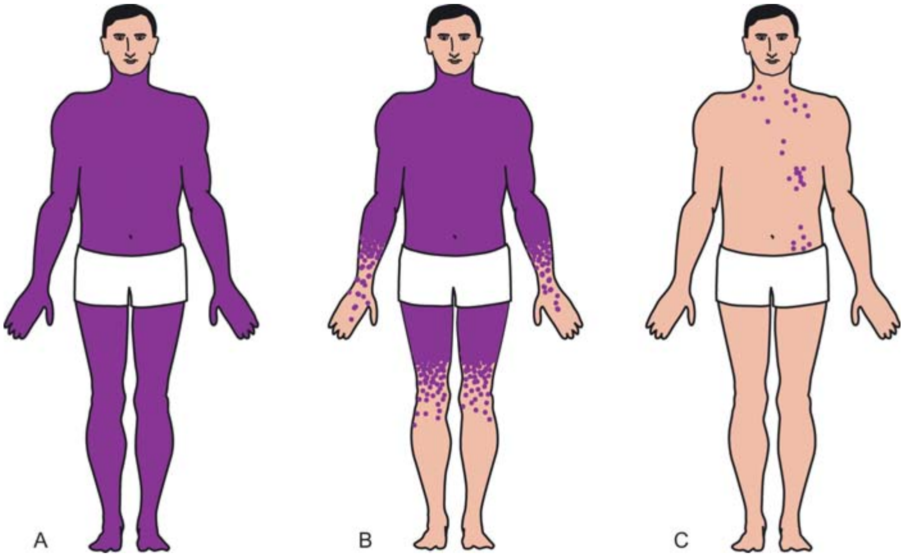

FIGURE 8-8 ■ Thermoregulatory sweat tests. *A*, An increase in body temperature leads normally to sweating over the entire body. An indicator powder becomes discolored (purple) by the moisture. It was not placed on the face and head, so that no discoloration is seen in these regions. *B*, In a patient with a length-dependent neuropathy involving the sudomotor fibers, sweating is absent in a stocking-and-glove-pattern. *C*, A patient with multiple system atrophy and almost complete anhidrosis, showing only small scattered areas of sweating.

FIGURE 8-9 ▪ Sweating induced through an axon reflex. Iontophoresed acetylcholine stimulates sweat gland production locally and—by an axon reflex—in adjacent areas.

there is a reduction in skin resistance. This is the so-called *galvanic skin response*, which can be elicited by painful or emotional stimuli or by deep inspiration.

Sudomotor function has been evaluated also by recording the change in voltage measured from the skin surface after deep inspiration or startle or after electrical stimuli applied to a contralateral mixed or cutaneous nerve at the wrist or ankle (*sympathetic skin response*). Responses are recorded from a pair of electrodes placed on the palm and dorsum of the hand or the sole and dorsum of the foot. The sympathetic skin response is simple to record, but responses tend to habituate and are affected by the recording technique and a number of other factors. The absence of a response, and not the absolute values of latency or amplitude, is regarded as significant for determining abnormality. The normal latency in the upper limb is on the order of 1.5 seconds and in the lower limb is about 2 seconds, reflecting the slow conduction velocity of postganglionic C fibers (approximately 1 m/sec). Abnormalities of the sympathetic skin response reportedly correlate well with the quantitative sudomotor axon reflex test.

Other Studies

PUPILLARY RESPONSES

Pupillary constriction with 2.5 percent methacholine applied locally indicates denervation supersensitivity due to interruption of postganglionic parasympathetic fibers, as in the Holmes–Adie syndrome. Local instillation of 1:1,000 epinephrine hydrochloride (one or two drops) produces little or no response unless there is postganglionic sympathetic denervation, in which case marked pupillary dilatation occurs. A 4 percent solution of cocaine hydrochloride applied to the conjunctival sac dilates the normal pupil, but fails to do so if sympathetic innervation has been interrupted outside the CNS.

RADIOLOGIC STUDIES

Radiologic studies may be helpful in characterizing gastrointestinal and bladder function but are beyond the scope of this chapter.

PATIENT MANAGEMENT

The initial investigative approach to patients presenting with syncope or other symptoms suggestive of postural hypotension or autonomic dysfunction is to exclude reversible causes such as hypovolemia or certain medications, discussed earlier in this chapter. The history must include a detailed account of illnesses and drug intake. An instrument (questionnaire) to assess autonomic symptoms has been developed and validated.[10]

Simple laboratory investigations may include a full blood count and erythrocyte sedimentation rate as well as determination of plasma urea, electrolytes, glucose, morning and evening cortisol levels, and lying and standing catecholamine concentrations.

Urinary screen for porphyrins, serum protein electrophoresis and immunophoresis, hepatic, renal, and thyroid function tests, chest radiograph, and electrocardiogram (to exclude recent cardiac infarction or cardiac ischemia, heart block, or persisting cardiac dysrhythmia) may also be performed, as may serologic tests for syphilis and nerve conduction studies. Neuroimaging studies may be helpful if a structural intracranial lesion is suspected. An echocardiogram may help when evaluating patients with suspected structural lesions of the heart predisposing to syncope. Prolonged tilt-table evaluations and invasive cardiac electrophysiologic studies may be necessary when an arrhythmia is likely. In patients with symptoms of uncertain etiology in whom general medical causes have been excluded, more detailed evaluation of autonomic function in the manner suggested earlier may be helpful.

Treatment

If a specific reversible cause, such as a metabolic or endocrinologic disturbance, can be recognized, it must be treated appropriately. Anemia should be treated. The need for continuing with drugs likely to be responsible should be reviewed and, if feasible, treatment discontinued. Patients should be advised against using alcohol. Treatment with antiarrhythmic agents, cardiac pacemaker, or surgery may be indicated in patients with a cardiac cause of syncope or postural hypotension. Pacemaker therapy may also help patients with syncope due to carotid sinus hypersensitivity. The treatment of POTS was considered earlier.

NONPHARMACOLOGIC MEASURES

If no specific cause can be identified, treatment should be directed to the minimization of symptoms (Tables 8-1 and 8-2). The actual extent to which the blood pressure falls on standing, for example, is of less significance than the occurrence of symptoms. Patients without symptoms generally require no treatment. Symptomatic patients with dysautonomia should avoid extreme heat, alcohol, caffeinated beverages, large meals, rapid postural changes, prolonged periods of recumbency, and excessive straining (e.g., during micturition or defecation), each of which may exacerbate symptoms. Diuretics should be stopped, if possible, and salt intake liberalized.

TABLE 8-1 ■ Management of Postural Hypotension

Treatment of Specific Underlying Cause or Aggravating Factors

- Discontinue drugs that may be responsible, if feasible
- Correct electrolyte/metabolic/hormonal disorders and anemia
- Avoid alcohol and caffeinated beverages
- Eliminate conditions that favor pooling of blood or that impede venous return
- Prescribe antiarrhythmic drugs, pacemaker, or surgery for selected cardiac disorders
- Consider a cardiac pacemaker for carotid sinus hypersensitivity

Symptomatic Treatment

- Nonpharmacologic management
  - Stand up gradually
  - Eat small meals and avoid postprandial activity
  - Wear waist-high elastic stockings
  - Elevate the head of the bed
  - Ingest fluid (approx. 500 ml) before arising
  - Eat a liberal salt diet
- Pharmacologic and other treatment
  - Fludrocortisone
  - Indomethacin; ibuprofen; flurbiprofen
  - Midodrine
  - L-Dihydroxyphenylserine (Droxidopa)
  - Pyridostigmine
  - Sympathomimetic drugs (phenylephrine, ephedrine)
  - Dihydroergotamine; Cafergot
  - Cardiac pacing in selected circumstances
  - Other approaches
    - Vasopressin; desmopressin
    - Erythropoietin
    - Yohimbine
    - Atomoxetine
    - Clonidine
    - Octreotide
    - Norepinephrine (by infusion pump)
    - Deep brain stimulation

When standing, patients often find it helpful to work the leg muscles because this aids the venous return to the heart. Symptoms may also be reduced if patients stand up gradually (e.g., by first adopting the seated position and, after a short pause, getting up from this position). Other physical maneuvers

TABLE 8-2 ■ Mechanisms Involved in the Management of Postural Hypotension by Selected Drugs

Mechanism	Medication
Reduced sodium excretion	Fludrocortisone
Sympathetic vasoconstriction	Midodrine; L-dihydroxyphenylserine; phenylephrine; ephedrine; norepinephrine; yohimbine
β-Blocker with sympathomimetic activity	Pindolol
Enhanced ganglionic cholinergic stimulation (increased total peripheral resistance)	Pyridostigmine
Reduced vasodilatation	Prostaglandin synthetase inhibitors (e.g., indomethacin; ibuprofen; flurbiprofen)
Increased red cell mass	Erythropoietin

that may be helpful include standing with legs crossed, bending forward, squatting, or placing a foot on a chair, thereby slightly increasing the mean arterial pressure so that cerebral blood flow remains adequate. The underlying common mechanism is held to be an increase of thoracic blood volume by transfer from below the diaphragm to the chest. Resistance exercise may increase orthostatic tolerance, plasma volume, and baroreflex gain.

Waist-high elastic stockings may be helpful in alleviating postural symptoms but are often difficult to put on (especially for elderly patients) and may be uncomfortable in hot weather. To be effective, the stockings must extend at least as high as the waist. They should not be worn at night as they may then aggravate nocturnal diuresis. Antigravity suits have been used in the past but are awkward, restrictive, impractical, and not generally available.

Many dysautonomic patients have a disturbance in the regulation of body fluids. In particular, there is defective sodium conservation, especially during recumbency at night, associated with, but not entirely due to, low aldosterone levels; there are also abnormal posture-dependent changes in urine volume (Fig. 8-10), accompanied by an alteration in the secretion of antidiuretic hormone. This leads to relative hypovolemia and postural hypotension that are worse in the morning and improve during the day. The disturbed regulation of body fluids could be due, at least in part, to diminished adrenergic activity in the renal nerves, which affects tubular reabsorption and renin release (and thus angiotensin formation). The effect of recumbency can be minimized by elevating the head of the bed by about 6 inches (20 to 30 degrees), so that the head and trunk are above the legs. This leads to reduced renal artery pressure, thereby stimulating the renin-angiotensin system and promoting sodium retention. Head-up tilt at night reduces nocturnal shifts of interstitial fluid from the legs into the circulation; furthermore, such interstitial fluid may exert hydrostatic force, opposing the tendency of blood to pool in the legs on standing. Head-up tilt at night also reduces supine hypertension.

Patients are sometimes helped by drinking 500 ml water about 15 to 30 minutes before arising from bed in the morning, as this has a transient pressor effect that may diminish postural hypotension at a time when it is usually most troublesome.

PHARMACOLOGIC TREATMENT

If these measures are unsuccessful, the mineralocorticoid fludrocortisone can be tried. This agent seems to exert its effect in part by temporarily increasing plasma volume and also by increasing vascular sensitivity to norepinephrine and improving the vasoconstrictor response to sympathetic stimulation. Treatment is usually commenced with a daily dose of 0.1 mg, which can be increased by 0.1 mg after 2 weeks or so, and then again if necessary. Rare patients may require as much as 0.5 mg daily, but usually a dose of 0.3 mg or less is sufficient. During treatment with fludrocortisone, a positive sodium balance should be ensured, with a sodium intake of at least 150 mEq/day. Side effects include pedal edema, weight gain, recumbent hypertension, cardiomegaly, hypokalemia, and retinopathy; co-existing diabetes mellitus may also be exacerbated.

Prostaglandin synthetase inhibitors should expand plasma volume and inhibit vasodilator prostaglandin synthesis. Indomethacin (25 to 75 mg three times daily with meals) increases peripheral vascular resistance, promotes fluid retention, and may increase the sensitivity of the peripheral vasculature to norepinephrine and angiotensin II. It is said to be helpful in some patients with postural hypotension, especially if they are also on fludrocortisone, but, in general, the results with it have been rather disappointing despite the theoretical advantages of its use. Ibuprofen (200 to 600 mg four times daily before

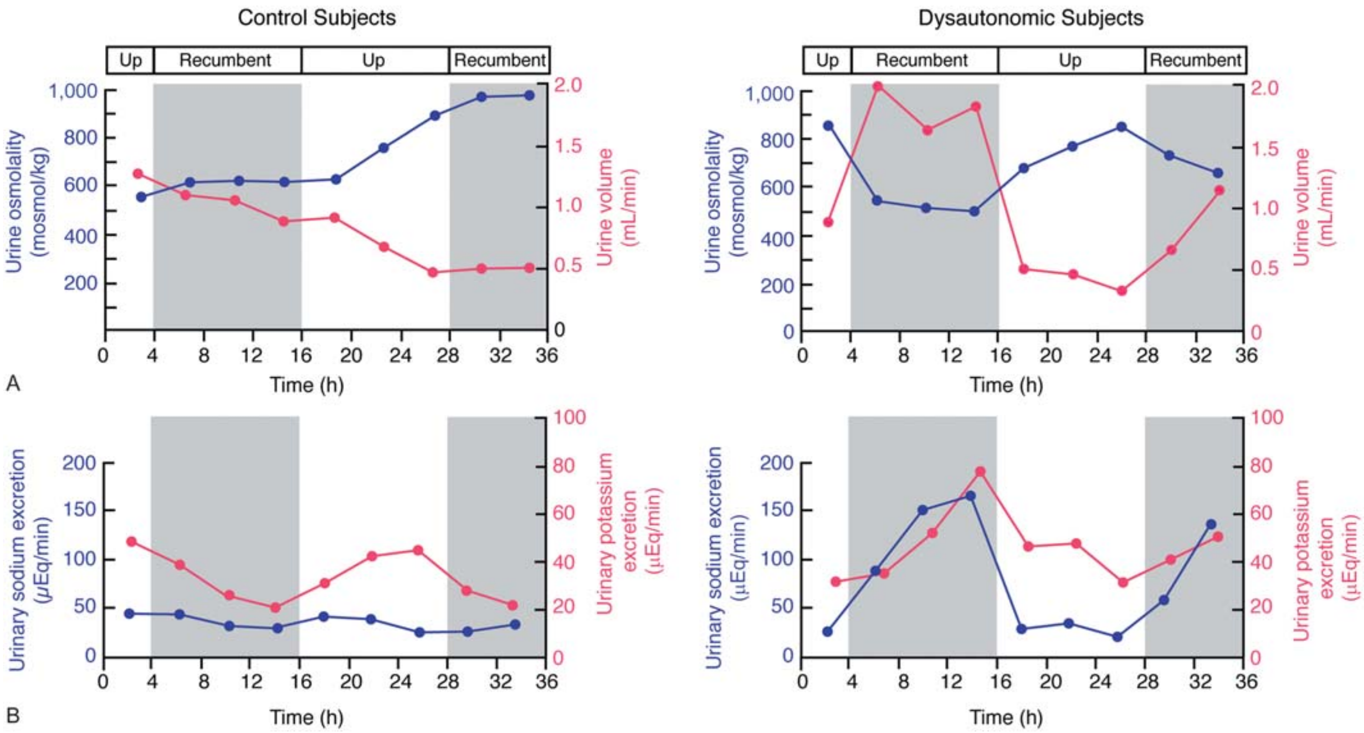

FIGURE 8-10 ■ Renal responses to fluid deprivation for 36 h of five dysautonomic patients with multiple system atrophy (right panels) and four control subjects with Parkinson disease and preserved autonomic reflexes (left panels). Deprivation commenced at 6 P.M. Mean results for each successive 4-hour period are shown for urine osmolality (blue) and volume (red) in *A*, and for sodium (blue) and potassium excretion (red) in *B*. Subjects were recumbent during the night (10 P.M. to 10 A.M.; shaded area) and were up and about during the day (10 A.M. to 10 P.M.). In the control subjects, urine volume declined and osmolality increased during the period of fluid deprivation; sodium excretion was unchanged whereas potassium excretion was greater during the day than night. In the dysautonomic subjects, similar changes were seen during the day; during recumbency at night, however, a considerable increase occurred in urinary volume and sodium and potassium excretion, and urinary osmolality declined. (Data from Wilcox CS, Aminoff MJ, Penn W: Basis of nocturnal polyuria in patients with autonomic failure. J Neurol Neurosurg Psychiatry 37:677, 1974.)

meals) can also be tried and is sometimes helpful. Side effects include gastric irritation, nausea, constipation, and skin rashes. Flurbiprofen has also been used with benefit by some.

Midodrine is a direct α-adrenergic agonist that causes constriction of arterioles and venous vessels. It is started in a low daily dose (2.5 mg three times daily) that is built up gradually to 10 mg three times daily, depending on response and tolerance. Side effects include supine hypertension, piloerection, and pruritus. It is best avoided within 4 hours of bedtime to reduce the risk of nocturnal hypertension.

The use of L-dihydroxyphenylserine (Droxidopa), which is converted by aromatic acid decarboxylase to norepinephrine after oral administration, has been helpful for neurogenic postural hypotension in patients with PAF, Parkinson disease, MSA, dopamine *β*-hydroxylase deficiency, and nondiabetic autonomic neuropathy. Dosage is 100 to 600 mg three times daily, with the last dose taken at least 4 hours before bedtime to reduce the risk of supine hypertension during sleep. The drug is well tolerated, but side effects include headache, nausea, and hypertension.

A related approach is with the off-label use of atomoxetine, which inhibits norepinephrine reuptake. It may helpful for patients with the central lesions of MSA but not for those with a peripheral dysautonomia, in whom any effect on blood pressure is minimal. Its efficacy is currently under study. Side effects include headache, anorexia, nausea, xerostoma, sleep disturbances, depression, behavioral changes, erectile dysfunction, and urinary retention. It may also cause a sinus tachycardia, systolic hypertension, and palpitations.

Pyridostigmine bromide (30 to 120 mg two or three times daily) may reduce postural hypotension by enhancing ganglionic cholinergic transmission without aggravating or precipitating supine hypertension. Its greatest effect is on diastolic blood pressure, suggesting that improvement is due to increased total peripheral resistance. Greater benefit occurs if pyridostigmine is combined with midodrine (5 mg).

There are anecdotal reports of benefit from dihydroergotamine, which is a relatively selective constrictor of peripheral veins. Its action may be mediated partially through α-adrenoreceptors, and enhanced synthesis of a vasoconstrictor prostaglandin may also be important. It is sometimes helpful for treating postural hypotension, but may cause recumbent hypertension. Although it is effective when administered intravenously, its efficacy when taken orally (5 to 10 mg three times daily) is more limited and variable. Inhaled preparations may be effective. Cafergot (caffeine and ergotamine) suppositories have sometimes been helpful.

Sympathomimetic drugs that either act directly to constrict blood vessels (e.g., phenylephrine) or that have an indirect action, preventing the destruction of norepinephrine at sympathetic nerve terminals (e.g., ephedrine, 25 to 50 mg three times daily), have been used to treat postural hypotension. These drugs can sometimes be helpful, but any benefit is often mild and temporary, and they may cause severe recumbent hypertension. Other side effects include nervousness, anxiety, restlessness, tachycardia, and tachyphylaxis.

Octreotide (a somastatin analogue) has also been used, with mixed results and frequent adverse effects, such as nausea, abdominal cramps, flushing, and brady- or tachycardia.

In patients with sympathetic efferent failure, clinical benefit, with a decline in the severity of postural hypotension and an increase in blood pressure on standing, may follow cardiac pacing to protect against vagal overactivity. However, the benefits of this approach are not clear, with benefit reported by some authors but not others in patients with orthostatic hypotension.

Vasopressin responses to upright posture are often defective in autonomic failure, and patients are hypersensitive to exogenous vasopressin. The antidiuretic, V2-receptor specific, vasopressin analogue desmopressin increases the intravascular volume. Intranasal desmopressin administered once at night in patients with multiple system atrophy and nocturnal polyuria has led to an improvement in nocturia without serious adverse effects.[11] If this approach is to be used, serum sodium should be monitored, especially during the first 4 to 5 days of treatment and then at monthly intervals. The long-term therapeutic utility of vasopressin is unclear, however, and treatment with desmopressin should be limited to patients with severe, refractory disease.

Recombinant erythropoietin helps the mild anemia that is common in dysautonomic patients; it increases the red cell mass, blood pressure, and cerebral oxygenation, and reduces postural hypotension.[12] It is expensive, may require concomitant iron supplementation, can lead to thromboembolism or infarction, and sometimes leads to supine hypertension. It can be tried in cases that are otherwise difficult to manage but is otherwise not recommended. It is given subcutaneously, with the dose and frequency of administration individualized.

There have been a variety of other investigative therapeutic approaches. Yohimbine, a centrally acting α_2-adrenoreceptor antagonist, potentiates sympathetic activity and may reduce the postural decline in blood pressure in dysautonomic patients,[13] but its clinical utility and role are not clear because the findings in different studies are inconsistent.[14]

Administration of caffeine with meals may markedly reduce postprandial hypotension and is worthy of trial when symptoms are particularly troubling after meals. A possible role for deep brain stimulation of the periventricular/periaqueductal gray region has been suggested.

Patients with vasovagal syncope require reassurance coupled with advice about ensuring adequate fluid and salt intake and about sympathetic activation techniques (such as isometric hand exercises) to increase the blood pressure[15]; sitting or lying down or sitting with head between the knees may help to abort attacks.

One common consequence of the pharmacologic treatment of postural hypotension is *supine hypertension*. This can be minimized by avoiding lying down during the day, sleeping in the head-up position, and by avoiding pressor agents within 3 hours of bedtime. A carbohydrate snack at bedtime may also help, but fluid intake should be limited. Monitoring the nocturnal blood pressure also provides useful information about the severity of hypertension and whether it persists throughout recumbency. If supine hypertension persists, pharmacologic treatment may be necessary but risks worsening postural hypotension.[16]

The effects of impaired thermoregulatory sweating may be alleviated by external temperature regulation, such as by air conditioning. High-fiber diets, bulking agents, fecal softeners, laxatives, osmotic agents (e.g., lactulose), and glycerine suppositories may reduce constipation. Depending on their nature, urinary disturbances may be helped by bladder training and timed urination, avoidance of diuretics and certain foods and beverages, physical therapy to strengthen the pelvic floor muscles, anticholinergic medications, intermittent self-catheterization or suprapubic catheterization, and measures to contain incontinence such as penile sheaths and pads. The treatment of erectile dysfunction is discussed in Chapter 30.

General Precautions in Dysautonomic Patients

Patients may show postprandial falls in blood pressure because blood is diverted to the hepatic and splanchnic beds. Vasoactive substances may also contribute to the hypotensive response. To avoid or minimize this postprandial hypotension, it is helpful to eat smaller meals and to avoid excessive activity during the immediate postprandial period.

Dysautonomic patients often have low circulating catecholamine levels and denervation supersensitivity to sympathomimetic amines. Medications containing such substances should therefore be avoided, even though they are often available without prescription in over-the-counter preparations.

Patients with dysautonomia pose special problems during anesthesia. They are unable to tolerate hemodynamic stresses normally because of impaired cardiovascular reflexes. Maintenance of fluid balance is more difficult because of the abnormal manner in which they handle salt and water, and their enhanced sensitivity to volume changes influences blood pressure control.

  Accurate Prognostication
  Discussion with Surrogate Decision-Makers

Despite advances in the management of cardiac arrest, patients continue to have high mortality, exceeding 90 percent. Following the return of spontaneous circulation, dysfunction of multiple organ systems along with a systemic inflammatory response, collectively termed the "post-arrest syndrome," can lead to substantial morbidity. The diagnosis of primary hypoxic-ischemic brain injury and the prevention of secondary neurologic injury are the primary goals of early management. Persistence of coma or the prediction of long-term severe neurologic deficits commonly leads to withdrawal of life support; therefore, accurate prediction of neurologic outcome early after resuscitation is important. This chapter reviews the pathophysiology of hypoxic-ischemic brain injury and the neuroprotective mechanisms of therapeutic hypothermia (TH). In addition, the clinical, biochemical, radiographic, and electrophysiologic tests used to predict neurologic outcome following cardiac arrest are reviewed, as are the ethical implications that follow prognostication.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

There is a delay between the time of ischemic cell injury and the manifestation of cell death. This delay may be hours or up to 4 days following the initial insult. During cardiac arrest, oxygen levels decline, cerebral blood flow ceases, and cells must switch to anaerobic metabolism in order to produce adenosine triphosphate (ATP). Anaerobic glycolysis leads to an accumulation of hydrogen ions, phosphate, and lactate, all of which result in intracellular acidosis. The resulting excess of hydrogen ions displaces calcium from intracellular proteins, increasing its intracellular concentration. Dysfunction of the Na^+/K^+ ATP pump and ATP-dependent channels leads to further increases in intracellular calcium. In addition, hypoxia results in the release of excitatory neurotransmitters, such as glutamate, that cause the endoplasmic reticulum to release calcium stores. This excess calcium activates intracellular proteases and leads to further release of excitatory neurotransmitters following

depolarization of the cell membrane. Activation of *N*-methyl-D-aspartate (NMDA) glutamate receptors results in sodium and chloride influx, leading to hyperosmolarity that causes water influx and neuronal death.[1] Restoration of the circulation can lead to further glutamate release and the formation of oxygen-derived free radicals and reperfusion injury, which can cause additional damage.[1] In addition, apoptosis, due to caspase-3 activation in neurons and oligodendroglia in the cerebral neocortex, hippocampus, and striatum, can contribute to cell death, at least in perinatal models of anoxia-ischemia.[1]

Distinct brain regions and specific neuronal populations appear more susceptible to hypoxic-ischemic injury, probably due to their location in a vascular border-zone or to higher metabolic rates requiring increased oxygen or density of various glutamate receptors on neuronal membranes.[1] The CA1 neurons of the hippocampus are the most sensitive to ischemia, and injury commonly results in memory dysfunction. The Purkinje cells of the cerebellum, the pyramidal neurons in layers 3, 5, and 6 of the neocortex, and the reticular neurons of the thalamus are also commonly affected. In addition, three vascular border-zones are susceptible to a reduction in blood flow due to their distance from the parent vessel; these areas become clinically important in cases of severe hypotension and incomplete cardiopulmonary arrest. The cortical border-zones are the anterior border-zone between the anterior cerebral artery and the middle cerebral artery territories and the posterior border-zone between the middle cerebral artery and posterior cerebral artery territories. Infarction of the anterior border-zone results in brachial diplegia, or "man-in-a-barrel" syndrome. Infarction of the posterior border-zone results in visual deficits including cortical blindness if bilateral. The internal, or subcortical, border-zone is found at the junctions between the branches of the anterior, middle, and posterior cerebral arteries with the deep perforating vessels, including the lenticulostriate and anterior choroidal arteries.

TARGETED TEMPERATURE MANAGEMENT

The use of TH in patients after cardiac arrest was first reported in the 1950s, but the complication rate was high and results were inconclusive. In 2002, two landmark studies were published showing that TH improves neurologic outcomes following cardiac arrest when the initial rhythm was ventricular fibrillation (or possibly pulseless ventricular tachycardia). Patients randomized to moderate hypothermia (32° to 34°C) had a more favorable neurologic outcome, defined as Cerebral Performance Category (CPC) 1 (normal) or 2 (moderate disability), compared with controls randomized to standard care. No significant differences were found between the groups with respect to complications, including bleeding, infection, and arrhythmias, and the number needed to treat in these trials was impressively in the single digits.[2]

However, whether the therapeutic benefit observed in these trials was due to TH or fever prevention remained unclear until publication of the targeted temperature management (TTM) trial in 2013. This study randomized patients to moderate hypothermia (32° to 34°C) or 36°C for 24 hours, followed by 48 hours of fever prevention using acetaminophen and surface cooling in both groups. No difference was observed in outcome, with 46 to 48 percent of patients in both groups achieving a CPC of 1 or 2 at 6 months, a rate similar to that observed in the treatment arms of both 2002 TH studies.[2] This study is the basis for current guidelines that recommend a target temperature of 32° to 36°C for 24 hours, followed by 48 hours of fever prevention.[2]

There are many postulated mechanisms to explain the neurologic benefits that occur with TH, including a decrease of the extracellular levels of excitatory neurotransmitters such as glutamate and dopamine. The NMDA receptor is glycine dependent, and TH has been shown to decrease cerebral levels of glycine following ischemia, and thus to lessen glutamate-related hyperexcitability. TH reduces the proliferation of astroglial cells and their release of inflammatory cytokines and free radicals. TH also results in decreased cerebral blood flow as well as decreased metabolism and oxygen and glucose utilization. Conversely, fever may exacerbate brain injury following cardiac arrest due to increased glutamate production and excitotoxicity, increased cerebral metabolism, blood–brain barrier permeability leading to hyperemia, cerebral edema, and increased intracranial pressure.[1]

PROGNOSTIC DETERMINATION

Following return of spontaneous circulation, neurologists are often consulted to determine prognosis, specifically the probability of regaining consciousness and of the likely presence, severity, and extent of any persistent neurologic deficits. While prognostication with 100 percent certainty is not possible, a reasonable goal is to identify those patients who will have severe neurologic deficits with complete dependency at 6 months. Because many patients and their families choose withdrawal of life support when faced with this unfavorable prognosis, it is essential that the combination of clinical, radiographic, and electrophysiologic tests used to arrive at this conclusion therefore have a positive predictive value (PPV) as close to 100 percent as possible.

Much of the published literature attempts to predict which patients will have a CPC of 3 or greater 6 months after cardiac arrest.[3] Such an outcome includes death, vegetative state, and severe disability with dependency on caregivers for daily support. However, because studies of prognosis after cardiac arrest include patients whose families elected to withdraw life support, the true range of long-term functional outcomes remains unknown and the prognostication algorithms discussed in this chapter suffer from the risk of self-fulfilling prophecy. In addition, because studies tend to group CPC 3 to 5 and label them all "unfavorable," distinguishing between the possibility of severe disability with dependency but some retained ability to communicate or even ambulate (CPC 3) and a persistent vegetative state or death (CPC 4 or 5) remains difficult.[3] Further complicating prognosis and blurring the lines of what some consider meaningful recovery is the discovery through functional brain imaging techniques that some patients in a persistent vegetative state retain awareness and potentially even comprehension of spoken language.

Most studies of prognosis after cardiac arrest report false-positive rates (FPRs), yet this is a difficult number to translate for families. In prognostic studies, true positives are generally defined as patients with a poor prognostic sign who have a poor outcome, and false positives are those with a poor prognostic sign who have a good outcome. The FPR (or 1-specificity) is determined by dividing the number of false positives by the number of patients who had a good outcome. In lay terms this can be stated as the percentage of patients with good outcome who had the poor prognostic sign, a number that carries little practical meaning. The PPV provides more clinically relevant information: the percentage of patients with a poor prognostic sign who have a poor outcome. Surrogate decision-makers want to know (1−PPV), or the chance that a patient with the poor prognostic sign will still have a good outcome. When there are more patients with a good outcome than patients with a specific poor prognostic sign, (1−PPV) is often larger than the FPR, and thus the FPR can be misleadingly low.

No neurologic prognostication should occur until a minimum of 24 hours after the arrest; in patients treated with TTM, it may take days to establish a prognosis because both the lowered temperature and associated sedation required may profoundly affect clinical and electrophysiologic findings. The neurologic examination should be performed approximately 72 hours after the arrest and all sedatives should be discontinued with enough time for them to have reliably cleared from the body. The examination should focus on the level of consciousness, the pupillary light reflex, corneal reflex, spontaneous eye movements, the oculocephalic reflex, and the motor response to central and peripheral painful stimuli. Quantitative pupillometry is less likely to mistake minimally reactive pupils for unreactive pupils and is therefore preferred to the standard pupillary light reflex.[4] The presence of status myoclonus, defined as spontaneous, repetitive, unrelenting, and generalized myoclonus affecting the face, limbs, and axial musculature lasting more than 30 minutes should be noted. Electroencephalography and somatosensory evoked potentials (SSEPs) are performed after rewarming, between 24 and 72 hours after the arrest, and serum neuron-specific enolase can be measured at 24, 48, and 72 hours. The combination of clinical, electrophysiologic, and serum biomarker data derived from these tests forms the basis of the modern multimodal approach to prognostication.[2]

Prognostication in the Absence of Targeted Temperature Management

Prognostication following cardiac arrest is largely based on the work of Levy and colleagues, who analyzed a single cohort of 210 patients and identified factors that could accurately predict, at various time points post-arrest, a poor neurologic outcome.[4] In 2006, the American Academy of Neurology (AAN) published practice parameters that summarized the available literature and provided an algorithm to establish prognosis.[4] In patients who remain comatose but do not meet criteria for brain death, clinical signs and electrophysiologic tests can be used to establish a poor prognosis. The clinical signs that predicted poor neurologic outcome were status myoclonus on day 1 (FPR 0%, CI 0−8.8), absence of the pupillary light reflex or corneal reflex on day

3 (FPR 0%, CI 0–3), and best motor response of extension or worse on day 3 (FPR 0%, CI 0–3). SSEPs recorded between days 1 and 3 demonstrating bilaterally absent N20 responses also predicted poor outcome (FPR of 0.7%, CI 0–3.7). Serum neuron-specific enolase (NSE) levels greater than 33 μg/L on days 1 to 3 were also a negative prognosticator (FPR 0%, CI 0–3).[4] These practice parameters allow a physician to identify patients who will almost certainly have a poor neurologic outcome, but it is important to note that many other patients not meeting these criteria will also have a poor outcome.

Caution must be exercised when applying these prognostic criteria to patients who have undergone TTM, a well-established confounder of the neurologic and electrophysiologic examination, as the practice parameters were based on literature published before its widespread adoption.

Targeted Temperature Management and the Neurologic Examination

Soon after the introduction of TH, some clinical signs including the pupillary light reflexes, corneal reflexes, motor responses, and presence of status myoclonus were found to have reduced accuracy for predicting poor neurologic outcome. Among patients treated with TTM, no features of the neurologic examination at 24 hours after the arrest reliably predict outcome, and determination of brain death should wait until it is certain that the effect of sedation and hypothermia are negligible. At 72 hours after the arrest, the absence of pupillary light reflexes and the absence of corneal reflexes have a reasonably high PPV for a poor outcome, but rare patients with these findings will recover with good outcome (Table 9.1). Patients with extensor posturing or no motor response at 72 hours recover functional independence at a high enough rate that this sign is no longer considered a reliable prognostic indicator. Conversely, patients with flexor or better motor response at 72 hours have a 67 percent chance of recovering the ability to function independently (Table 9.2).

Myoclonus may arise from the cerebral cortex, subcortical structures such as the thalamus, or brainstem. The cortical form, unlike the brainstem form, has a reliable correlate on the electroencephalogram (EEG). The presence of status myoclonus was considered uniformly fatal based on studies in the prehypothermia era; postmortem studies found severe damage to various gray matter structures in the brain

TABLE 9-1 ■ Poor Prognostic Signs and Their Test Characteristics

Prognostic Sign	Patients with Sign		Patients without Sign		PPV (95% CI)	FPR (95% CI)
	Poor Outcome	Good Outcome	Poor Outcome	Good Outcome		
Absent bilateral pupillary light reflex[7,11–15]	161	5	124	177	97% (94–100)	1.4% (0.2–2.7)
Absent bilateral corneal reflex[7,11–15]	213	10	104	175	96% (93–98)	3.2% (1.2–5.1)
No or extensor motor response to pain[7,11–17]	623	69	203	417	90% (88–92)	14% (11–17)
Status myoclonus[7,13,17,18]	178	6	639	671	97% (94–99)	0.9% (0.2–1.6)
Absent bilateral median SSEP [7,12–17]	265	1	316	219	99.6% (99–100)	0.5% (0–1.3)
Highly malignant EEG (suppressed background with or without continuous periodic discharges, burst suppression)[5,6,15,19,20]	208	1	259	225	99.5% (99–100)	0.4% (0–1.3)

PPV, positive predictive value (likelihood of poor outcome in patients with poor prognostic sign); FPR, false-positive rate; CI, confidence interval; SSEP, somatosensory evoked potential; EEG, electroencephalogram. Results are pooled from multiple studies that assessed outcome at 3 or 6 months. Neurologic examination performed off sedation and after rewarming. Status myoclonus defined as spontaneous, repetitive, unrelenting, and generalized myoclonus affecting the face, limbs, and axial musculature lasting more than 30 minutes. SSEP performed after rewarming. Some studies define burst suppression by >10 percent background suppression, others by >50 percent.

TABLE 9-2 ■ Favorable Prognostic Signs and Their Test Characteristics

Prognostic Sign	Patients with Sign		Patients without Sign		PPV (95% CI)
	Good Outcome	Poor Outcome	Good Outcome	Poor Outcome	
Flexor or better motor response to pain[7,11–17]	417	203	69	623	67% (64–71)
Benign EEG (reactive, continuous background, or no malignant features)[5–7,15,17,20]	335	171	46	433	66% (61–70)

PPV, positive predictive value (likelihood of good outcome in patients with good prognostic sign); CI, confidence interval; EEG, electroencephalogram. Results are pooled from multiple studies that assessed outcome at 3 or 6 months.

and spinal cord in these patients, demonstrating the cause of death to be hypoxic-ischemic insult rather than status epilepticus. However, cases of good outcome despite status myoclonus in patients treated with TTM indicate the presence of this sign is suggestive of a poor neurologic outcome but should not be used in isolation to prognosticate (Table 9.1).[4]

Following cardiac arrest, many patients have confounders of the neurologic examination other than hypothermia, including cardiogenic shock, metabolic acidosis, and other metabolic derangements that must be accounted for when interpreting the examination. Organ failure, especially hepatic and renal dysfunction, may cause reversible encephalopathy and cloud the predictive power of the neurologic examination. Comatose patients require sedation for presumed pain or distress, ventilator asynchrony, or as part of many TTM protocols; clearance of these drugs may be delayed due to organ dysfunction. TTM itself can also result in increased serum concentrations of certain drugs, increased duration of action, and decreased clearance, including fentanyl, midazolam, propofol, and neuromuscular blocking agents. These drugs are commonly used in TTM protocols, rendering the neurologic examination unreliable for prognostication until they are sufficiently cleared.

Specifics of the Cardiac Arrest

Characteristics of the cardiac arrest, including anoxia time (the time from onset to initiation of cardiopulmonary resuscitation) and total arrest duration, have been explored as predictors of prognosis. Although longer anoxia time and duration of resuscitation are associated with poorer outcomes, these associations are not specific enough to be useful for prognostication purposes.[2] Prognosis is more favorable after arrest due to shockable (ventricular fibrillation or pulseless ventricular tachycardia) than nonshockable rhythms (asystole or pulseless electrical activity), but similarly, there are enough survivors with good outcome after the latter to preclude the use of initial rhythm for prognostication.

Electrophysiologic Tests

Electrophysiologic tests, including SSEPs and EEG, can aid in prognostication after cardiac arrest. The most common SSEP utilized involves stimulation of the median nerve at the wrist and recording the response over the contralateral scalp, specifically over the primary somatosensory cortex. In a normal adult, this response occurs 20 msec from the time of median nerve stimulation and is therefore called the N20 response (Fig. 9-1). During this test, additional electrodes are placed over Erb's point (over the brachial plexus) and high on the posterior neck (over the dorsal columns of the spinal cord); stimulation of the median nerve results in responses at these electrodes at approximately 9 and 13 msec, respectively. These N9 and N13 responses, along with the N20, examine the continuity of the nervous system from the median nerve through the brachial plexus and high cervical cord to the cortex and reduce false-positive results from conduction problems below the cranium. Among patients treated with TTM, the vast majority with bilaterally absent N20 responses have poor neurologic outcomes (Table 9.1). Very rare patients have

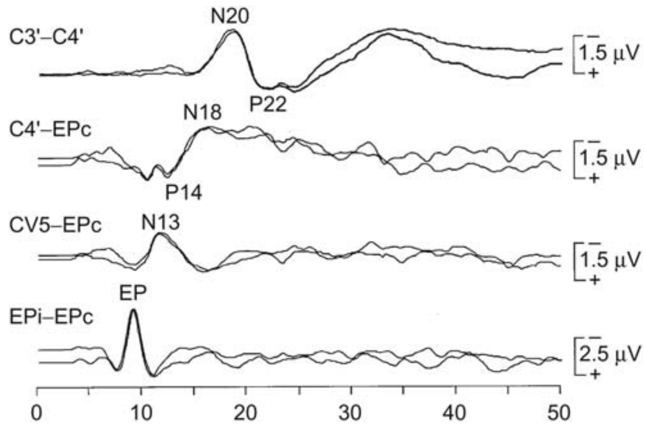

FIGURE 9-1 ▪ Normal somatosensory evoked potential elicited by stimulation of the right median nerve at the wrist. Responses were recorded over the brachial plexus at ipsilateral Erb point (EPi), over the fifth cervical spine (CV5), and over the ipsilateral scalp (C4′) with the contralateral Erb point (EPc) used as a reference, as well as over the contralateral scalp (C3′) referenced to the ipsilateral scalp (C4′). An N9 potential is seen over the Erb point, an N13 over the cervical spine, subcortical far-field P14 and N18 potentials over the ipsilateral scalp area, and an N20 over the contralateral "hand" area (C3′) of the scalp. Loss of the N20 response bilaterally (with preserved N9 and N13 responses) portends a poor neurologic prognosis. (From Aminoff MJ, Eisen A: Somatosensory evoked potentials. p. 581. In Aminoff MJ (ed): Aminoff's Electrodiagnosis in Clinical Neurology. 6th Ed. Elsevier, Oxford, 2012, with permission.)

survived with good outcome, again emphasizing that in patients who have undergone TH, no test should be used in isolation to determine prognosis.

The EEG may be used to prognosticate after cardiac arrest when interpreted using a set of standard criteria. Westhall and colleagues recorded routine EEGs 12 to 36 hours after rewarming in patients who remained comatose in the TTM trial and categorized the EEG patterns as highly malignant, malignant, or benign based on American Clinical Neurophysiology Society terminology.[5] Highly malignant EEG patterns included a suppressed background without discharges; a suppressed background with continuous periodic discharges; or a burst-suppressed background with or without periodic discharges (with suppression $<10\ \mu\text{V}$ constituting $>50\%$ of the recording, Fig. 9-2). Malignant EEGs demonstrated malignant periodic or rhythmic patterns (abundant periodic discharges, abundant rhythmic polyspike-/spike-/sharp-and-wave, unequivocal electrographic seizure); malignant background (discontinuous background, low-voltage background, reversed anterior–posterior gradient); or unreactive EEG (absence of background reactivity or only stimulus-induced discharges). Benign EEGs were defined as those without any malignant features (but not necessarily reactive).

The prognostic value of EEG was first reported in 103 patients at 8 centers in the TTM trial, and later in 207 patients at 20 additional centers. A highly malignant EEG pattern had a PPV for CPC 3 to 5 of 98.8 percent (CI 96.4–100).[6] The single false-positive patient was sedated during the EEG, emphasizing the need to consider the role of sedation in EEG interpretation. Several other studies have reported similar findings (Table 9.1). EEG reactivity is defined as a change in frequency or amplitude that occurs in response to verbal or noxious stimuli and is a marker of good prognosis following cardiac arrest. In a study of 357 patients who underwent EEG after cardiac arrest at two large medical centers, both early (during TTM) and late (after return to normothermia and off sedation) reactive EEG was predictive of eventual CPC 1–2 with a PPV of 72 and 69 percent, respectively (Table 9.2).[7]

After cardiac arrest, up to one-third of patients may develop electrographic status epilepticus.[4] Electrographic status epilepticus is most often associated with clinical myoclonus, but may also be subclinical or associated with generalized tonic-clonic convulsions. Post-hypoxic status epilepticus is a poor prognostic sign, but enough patients survive with good functional outcome that seizures should be treated aggressively unless other prognostic criteria indicate a poor prognosis.

The EEG may also help identify patients with a favorable prognosis among those with status myoclonus. Most patients with status myoclonus will have a highly malignant EEG with a burst-suppressed background; outcome in such patients is very poor.[8] Rare patients with status myoclonus demonstrate a more benign EEG pattern, with a continuous background and epileptiform discharges correlating only to myoclonic jerks; four of eight such patients (from a total of 69 patients with status myoclonus) awoke and survived to discharge home or to rehabilitation in one study.[8]

Neuroimaging

Computerized tomographic (CT) imaging performed early after cardiac arrest is usually normal, although in severe cases of hypoxic-ischemic injury,

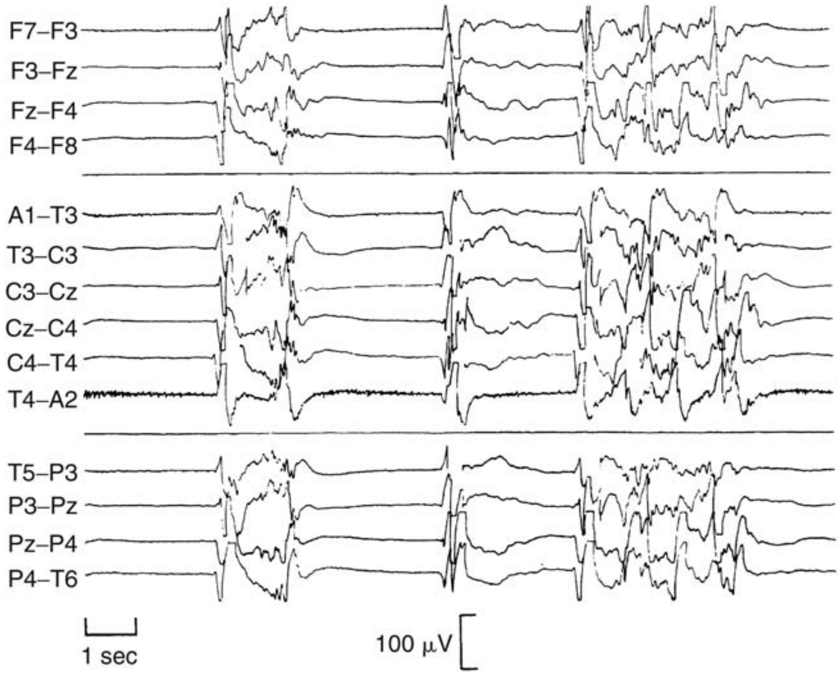

FIGURE 9-2 ■ Burst-suppression pattern recorded in the EEG of a 70-year-old man after a cardiac arrest from which he was resuscitated. (From Aminoff MJ: Electroencephalography: General principles and clinical applications. p. 37. In Aminoff MJ (ed): Aminoff's Electrodiagnosis in Clinical Neurology. 6th Ed. Elsevier, Oxford, 2012, with permission.)

loss of gray–white differentiation and cerebral edema may be seen. Out-of-hospital cardiac arrest has been associated with both subarachnoid and intraparenchymal hemorrhage in as many as 10 percent of patients, and therefore routine brain CT is recommended in European resuscitation guidelines to rule out these possibilities. Both CT and magnetic resonance imaging (MRI) have been studied as a prognostic tool.[4] Several retrospective studies identified decreased gray–white attenuation ratios on CT as a marker of poor prognosis. Abnormal diffusion-weighted imaging and the related apparent diffusion coefficient (ADC) on MRI correlates with poor neurologic outcomes. Attempts have been made to establish cut-points for total area of reduced ADC that has a high PPV for poor outcome, but further validation is needed. Other brain MRI modalities such as diffusion tensor imaging and functional MRI are also being investigated as prognostic tools.

Biomarkers

Several biomarkers have demonstrated potential for prognostication following cardiac arrest. The use of serum or cerebrospinal fluid (CSF) biomarkers is appealing as it does not require either patient transport or trained technicians, nor are the levels affected by sedation. NSE is a gamma isomer of enolase, an intracytoplasmic enzyme found in neurons and neuroectodermal cells. Damage to neurons results in release of NSE into the CSF and eventually it is measurable in the serum. The threshold of NSE above which a poor prognosis can be predicted with an acceptably low FPR varies depending on the laboratory performing the test, the timing between the arrest and blood sampling, and whether or not the patient was treated with TTM. A meta-analysis of multiple studies in patients treated with TTM found thresholds associated with a 0 percent FPR of 49.6 to 151.4 μg/L at 24 hours; 25 to 151.5 μg/L at 48 hours; and 57.2 to 78.9 μg/L at 72 hours.[2] In the TTM trial, thresholds with 0 percent FPRs were 107, 120, and 50 μg/L at 24, 48, and 72 hours, respectively.[4] While no universally accepted value of NSE definitively predicts poor outcome, using the upper limit of these ranges is a reasonable approach.

S100B is a calcium-binding protein secreted by glial and Schwann cells. It may also act as a cytokine, resulting in neuronal apoptosis, and it has a biologic half-life of 2 hours. When it is elevated in the serum after cardiac arrest, neurologic outcome is generally poor, but measuring S100B does not appear to add prognostic information to NSE. More promising is serum neurofilament light chain (NFL), a neuronal cytoplasmic protein expressed in myelinated axons and released into the CSF and blood after neuronal injury. After cardiac arrest, there appears to be less overlap between values in patients with good and poor prognoses, but this finding needs to be validated in prospective studies. In addition, serum NFL may be elevated in a wide range of neurologic disorders, and it is not known how it may inform prognosis in patients with pre-existing neurologic conditions.

Multimodal Prognostication Algorithms

Ensuring the presence of at least two negative prognosticators can improve prognostic accuracy. Among 134 patients treated with TH at 33°C, two or more of the following negative prognostic findings demonstrated a PPV of 100% for CPC 3 to 5: at least one absent brainstem reflex (pupillary, corneal, or oculocephalic) at 72 hours, myoclonus, unreactive EEG during TH and after rewarming, and bilaterally absent N20 responses in the median-derived SSEP performed after rewarming.[9] A second study of 61 patients treated at 36°C found 100% PPV for CPC 3 to 5 with the presence of two or more of the following negative prognostic findings: unreactive first EEG (performed at least 6 hours after arrest but during TTM and under sedation); epileptiform findings on the first EEG; absent pupillary reflex, corneal reflex, or both at 72 hours; early myoclonus; bilaterally absent SSEP measured at least 24 hours after arrest; and NSE $>75\ \mu g/L$ (the higher value of measurements taken at 24 and 48 hours).[10]

Most of the literature on prognosis following cardiac arrest aims to identify with accuracy those patients who will die or be left severely disabled with complete dependency. However, many patients who do not have these prognostic signs will also have a poor outcome. For example, the negative predictive values of the two prognostic algorithms described above are approximately 60 percent, meaning that 40 percent of the patients without two negative prognostic signs will also have a poor outcome. Further research is needed to help differentiate those patients who will have near-complete neurologic recovery from those who will have moderate disability.

ETHICAL CONSIDERATIONS

Patients who have been resuscitated from cardiac arrest and are left with significant neurologic deficits pose several ethical challenges. Physicians tend to overestimate poor outcomes and underestimate good outcomes, especially in the first days following arrest. Some families express doubt about the accuracy and sincerity of physicians' prognostic opinions and management suggestions. Ultimately, however, what experts say to families, fellow physicians, and other caregivers has enormous influence. There is a need for accuracy, honesty, frankness, consideration, acknowledgment, and patience in discussions that involve possible end-of-life decisions. The principal issues include accurate prognostication and discussions with surrogate decision-makers, in which the autonomy of the patient is given primacy.

Accurate Prognostication

Most of this chapter has been devoted to accurate prognostication. Using the results of studies, it should be possible in most patients to arrive at some estimate of the probability that recovery of awareness will occur. In some cases, the prognosis will remain uncertain and more time and possibly more or repeated testing will be necessary.

Discussion with Surrogate Decision-Makers

Patient autonomy is given the greatest priority in most North American and European cultures. After cardiac arrest, patients generally are unable to participate in discussions regarding prognosis and management, and so this responsibility falls to surrogate decision-makers. In hierarchical order, this person is typically: the spouse or partner, children older than 18 years, a parent or guardian, a sibling, or the closest next-of-kin. In some cases, the surrogate decision-maker is identified in a Power of Attorney statement or similar document. In rare cases, no person can be identified and a public trustee is often then appointed.

Research indicates that there are often problems in the communication between physicians and surrogate decision-makers in the critical care setting. Often surrogate decision-makers experience anxiety and depression, and these issues can interfere with comprehension and executive decision-making functions. Physicians, along with nursing staff, need to be sensitive to these issues and involve surrogate decision-makers in repeated discussions while providing empathy and support. Information pamphlets or visual aids may be helpful in improving comprehension of the severity of the illness. If the neurologist will be involved in discussions of prognosis and goals of care with the family, it is helpful to meet the family on the first hospital day to establish rapport and orient the surrogate decision-maker to the neurologist's role, even though no prognostic information can be given at this early stage.

A good starting point for discussion is to ask surrogate decision-makers about their understanding of the patient's illness—further explanation and clarification then follow. Surrogate decision-makers should be forewarned if there is "bad news," and the emotional reaction acknowledged. They need to understand that they are speaking for the patient and should be encouraged to help the healthcare team understand what the patient would want to do, given the prognosis provided. Surrogate decision-makers should be asked whether there are advance directives, either written or verbally stated, which may give a clear idea of the patient's perspectives, at least at some point in the past. If there are no clear advance directives, surrogate decision-makers and family members are asked to describe their understanding of the patient's values and to formulate a response for him or her.

Occasionally differences of opinion among family members arise or the surrogate decision-maker cannot make a decision. Cultures also vary in their view of what constitutes meaningful recovery, and even if the medical team is convinced that the patient will not recover beyond a vegetative state, this may be acceptable to some families. Physicians should maintain respect and understanding, while providing further meetings. Involvement of an ethicist or a member of the clergy is sometimes helpful. In rare instances the issue needs to be resolved legally, either in court or by the appointment of a special board.

CARDIAC EVALUATION

CLINICAL MANAGEMENT

CONCLUDING COMMENTS

Cardiac abnormalities are common after acute neurologic injury. Disturbances can range in severity from transient electrocardiographic (ECG) abnormalities to profound myocardial injury and dysfunction. Evidence from animal models and clinical observations indicate that the central nervous system (CNS) is involved in the generation of cardiac arrhythmias and dysfunction even in an otherwise normal myocardium. Neurologic lesions may influence cardiovascular function and affect cardiac prognosis, and—in addition—the presence of cardiac abnormalities may be associated with poor neurologic outcomes. A better understanding of cardiac abnormalities after acute neurologic injury can improve the clinical management of patients and may also have important prognostic implications.

This chapter briefly outlines the cardiac manifestations that follow acute neurologic injury, summarizes the neurophysiology and neuroanatomy of cardiac control, and discusses the clinical implications and diagnostic and treatment recommendations for the most common cardiac complications.

HISTORICAL PERSPECTIVE

Harvey Cushing first described hemodynamic changes after acute intracerebral hemorrhage (ICH) in 1903. The bradycardia and hypertension in response to increased intracranial pressure (ICP), known as the Cushing reflex, was later proved in animal models to be mediated by the CNS. Over subsequent decades, clinical observations began to identify the importance of the brain–heart interaction in patients with cerebral lesions. Cardiac abnormalities were described with various CNS diseases including seizures, trauma, ischemic stroke, and ICH, and less commonly with tumors, electroconvulsive therapy, and meningitis.

Cardiac pathology with features of subendocardial hemorrhage was observed in neurologic patients without known previous cardiac disease. After World War II, patients with subarachnoid hemorrhage (SAH) were noted to have cardiac myocytolysis similar to that in pheochromocytoma. An emotional- and stress-induced cardiomyopathy was then described in Japan, and subsequently reported in other populations.

ANATOMY AND PHYSIOLOGY

Medullary Control of Cardiovascular Function

The interplay between the heart and brain is best exemplified through the medullary control of the autonomic nervous system. Disruptions to this pathway can lead to arrhythmias and other autonomic disturbances as occur in epilepsy, traumatic brain injury, and genetic cardiac conditions. In general, the rostral ventral lateral medulla is a principal site of sympathetic activation, sending presympathetic neurons to the intermediolateral cell column of the spinal cord, which projects onto the stellate ganglion. The stellate ganglion then sends postganglionic sympathetic fibers directly to cardiac myocytes, activating beta-1 adrenergic receptors. Through a G-protein coupling process, intracellular cyclic adenosine monophosphate levels and protein kinase A activity are elevated, triggering a phosphorylation cascade on multiple downstream targets including L-type calcium channel receptors, the sarcoplasmic reticulum, and slow-delayed potassium channels. The outcome is an influx of calcium causing increased myocardial contractility, as well as a shortening of the myocardial action potential that promotes chronotropy.

When the blood pressure is low, baroreceptor activity from the aortic arch and carotid sinuses is diminished. This signal is relayed to the solitary nucleus of the medulla, which decreases activation of the caudal ventrolateral medulla and increases activity of the rostral ventral lateral medulla. A heightened sympathetic cardiovascular response ensues. Conversely, when blood pressure is elevated, increased baroreceptor activity inhibits the rostral ventral lateral medulla, resulting in an attenuated sympathetic response. Direct parasympathetic influences on cardiac function can also occur through excitatory neurons in the nucleus ambiguus and dorsal motor nucleus of the vagus nerve, which synapse with postganglionic neurons in the intrinsic cardiac ganglia. Acetylcholine activation of the cardiac muscarinic receptors reduces myocyte contractility and decreases the heart rate.

Genetic imbalances in the autonomic control of cardiac function can lead to life-threatening conditions. In catecholamine polymorphic ventricular tachycardia (CPVT), mutations in the cardiac RYR-2 ryanodine receptor result in abnormal levels of intracellular calcium, causing arrhythmias during sympathetic stimulation from stress and exercise. Surgeons have therefore attempted sympathetic denervation of the heart by resecting the left lower stellate ganglion and parts of the thoracic ganglia. Among a cohort of 63 patients with CPVT who underwent cardiac sympathetic denervation between 1988 and 2014, the incidence of major cardiac events was reduced from 100 to 32 percent ($P < 0.001$) over a 43-month period, and the rate of associated shocks from an implanted cardioverter defibrillator declined from 3.6 to 0.6 shocks per person per year ($P < 0.001$).[1]

Paraventricular Nucleus of the Hypothalamus

In addition to the medulla, the paraventricular nucleus of the hypothalamus plays an important role in both autonomic and neurohumoral regulation of the heart. On a neural level, the paraventricular nucleus receives afferent information from the solitary nucleus, and transmits efferent signals to the rostral ventral lateral medulla to regulate sympathetic activity. Overactivation of this sympathetic outflow has been implicated in the pathology of ischemic heart failure, particularly in chronic settings. By inhibiting activity of the paraventricular nucleus in mice, researchers have demonstrated reduced peri-infarct apoptosis and improved cardiac recovery after myocardial infarction, highlighting the link between the hypothalamus and cardiovascular function.[2] Electrical stimulation of the hypothalamus has also been associated with cardiac arrhythmias, with sympathetic regions located posteriorly, and parasympathetic areas anteriorly.

On an endocrine level, the paraventricular nucleus is involved in the stress response of the hypothalamic–pituitary–adrenal axis by secreting corticotropin-releasing factor into the portal system. This stimulates the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary lobe. Elevations in ACTH increase serum cortisol levels, which can contribute to a multitude of long-term cardiovascular complications, including hypertension, obesity, and insulin resistance.

The Limbic System and Amygdala

Emotional stimuli such as fear and anxiety can trigger autonomic responses related to the central nucleus of the amygdala. Sitting deep within the medial temporal lobes, the amygdala receives information from the prefrontal and orbitofrontal regions and sends projections to brainstem areas involved in autonomic control, thereby mediating the cardiac response to emotion. Chronic stress has been associated with cardiovascular disease, but the mechanism by which the brain is involved is poorly understood. In 2017, Tawakol and co-workers studied 293 patients with imaging techniques and found that higher levels of resting amygdalar activity predicted the risk of developing future cardiovascular events, including myocardial infarctions and unstable angina, independent of baseline cardiovascular risk. The higher levels of amygdalar activity were also associated with increased bone-marrow activity and arterial inflammation. One hypothesis is that amygdala-mediated stress increases the production of inflammatory cytokines from the bone marrow, triggering a cascade of downstream arterial inflammation leading to cardiovascular disease.[3]

Functional magnetic resonance imaging (fMRI) has now elucidated a complex network of regions involved in cardiac control. By having subjects complete tasks to elicit autonomic responses, and observing heart rate variability together with fMRI data, researchers have identified both cortical (prefrontal area, insula, anterior cingulate) and subcortical (amygdala, hypothalamus, hippocampus formation) structures involved in autonomic regulation. Moreover, sympathetic activity has been shown to localize to the prefrontal region, anterior cingulate, right anterior insula, and the left posterior insula, whereas parasympathetic activity is derived from the posterior cingulate and lateral temporal cortices, hippocampal formation, and bilateral dorsal insula. The left amygdala also contains features of both sympathetic and parasympathetic activity. This topography in function may help explain the variety of cardiac manifestations seen after ischemic injury to the brain, ranging from alterations in blood pressure to heart rate variability and arrhythmias.[4]

Insular Cortex

The insular cortex has widespread connectivity with areas of the brain that are known to be involved in autonomic control. Injury to this region has been associated with increased renal sympathetic nerve activity, elevated norepinephrine levels, and adverse cardiac events including QT prolongation, abnormal repolarization, tachycardia/bradycardia, and new-onset atrial fibrillation. Historically, it was believed that greater sympathetic representation occurred in the right insula and more parasympathetic representation featured on the left. This led to speculation that left-sided insular strokes manifested with increased and often unchecked cardiac sympathetic tone, resulting in worse cardiac outcomes, arrhythmias, and even sudden death. By contrast, however, it has also been argued that the morbidity and mortality of patients is higher among those with right-sided insular strokes, especially in the context of ECG abnormalities. The clinical significance of laterality in insular involvement remains controversial.

Using voxel-based lesion mapping on MRIs, a study in 2017 revealed that injury to the dorsal-anterior aspect of the insula was associated with elevations in cardiac troponin and myocardial damage. This suggests that in addition to the classic right-to-left grouping of insular injury, there also exists a ventral-to-dorsal subdivision that plays an equally important role in autonomic function. Ischemic injury to the dorsal anterior insula impairs parasympathetic tone, despite being on the sympathetically associated right side.[5] Indeed, conflicting observational outcomes in patients with insular strokes may well be attributed to the heterogeneity of autonomic mapping on the insular structure itself.

MECHANISM OF NEUROCARDIOGENIC INJURY

Myocardial infarction in the setting of acute stroke is not uncommon, and often represents concomitant coronary artery disease (CAD) in older patients with ischemic stroke and vascular risk factors. However, evidence from autopsy series in both ischemic and hemorrhagic stroke indicates that cardiac dysfunction may occur in the absence of underlying CAD. The Troponin Elevation in Acute Ischemic Stroke (TRELAS) study in 2015 identified 29 ischemic stroke patients with elevated cardiac troponin levels (median 95 ng/L, IQR 48–227), who simultaneously underwent diagnostic coronary angiography. Of the 29 patients, only seven (24%) were found to have a coronary culprit lesion and only 15 (51%) had obstructive CAD at all. These rates were significantly less compared to a control population of patients with non-ST elevation acute coronary syndrome and similar troponin levels.[6] Evidently, when myocardial tissue injury is present, suspicion for underlying cardiac disease increases, but such studies suggest a mechanism of injury distinct from large coronary artery–induced ischemia. Subendocardial hemorrhages described in patients dying after acute strokes and seizures also suggest pathologic changes to the heart that may be associated with neurologically mediated dysfunction. Here, we describe a commonly proposed mechanism for neurocardiogenic injury known as the catecholamine surge hypothesis.

Catecholamine Surge on Cardiomyocytes

It has been speculated that during neurologic injury, increased sympathetic activity triggers a massive release of catecholamines directly at the myocardial nerve endings. Myocardial tissue adjacent to these nerve endings is thereby vulnerable to excitatory damage. Excessive binding of catecholamines to the beta-receptors on cardiomyocytes leads to an abnormal influx of intracellular calcium, resulting in electrical instability, abnormal myocyte contraction, and oxidative stress. These processes then converge into cardiac injury in the form of arrhythmogenesis, coagulative myocytolysis, and microvascular dysfunction.

Histologically, catecholamine-induced subendocardial lesions include scattered foci of swollen myocytes surrounded by infiltrating monocytes, interstitial hemorrhages, and myofibrillar degeneration. Collectively, these pathologic changes have been called contraction band necrosis or coagulative myocytolysis (Fig. 10-1). The pattern of myofibrillar necrosis localizing near cardiac nerves is identical to other lesions thought to be of sympathetic origin such as catecholamine infusion, "voodoo death," hypothalamic stimulation, or reperfusion of transiently ischemic cardiac muscle. In patients with CAD, myocardial necrosis typically follows a vascular distribution where timing of injury occurs in a delayed fashion after progressive ischemia and muscle cell death. In neurogenic myocytolysis, however, myocardial damage can be visible within minutes of onset, with appreciable differences observed on a cellular level that include mononuclear infiltration, early calcification, and a hypercontracted state of myocardial cells.

Experimental and clinical studies have addressed the neurogenic catecholamine-mediated mechanism of cardiac dysfunction. In a cohort of patients with SAH who had echocardiograms and nuclear scans of cardiac innervation and perfusion, regions of contractile dysfunction were associated with abnormalities in myocardial sympathetic innervation while cardiac perfusion was normal. The degree of cardiac innervation was measured with a scintigraphic evaluation using [^{123}I]metaiodobenzylguanidine (MIBG), cardiac perfusion was measured using [^{99m}Tc]sesta-methoxyisobutylisonitrile (MIBI), and regions of myocardial dysfunction were determined by echocardiography simultaneously in the patients. Patients with functional cardiac denervation had worse regional wall motion scores and more troponin release than patients without evidence of cardiac denervation. Fig. 10-2 illustrates normal perfusion and global denervation in a patient with SAH whose echocardiogram showed global left ventricular systolic dysfunction. All study subjects had normal perfusion imaging, which excluded significant CAD and supported a neurogenic mechanism of cardiac injury.[7]

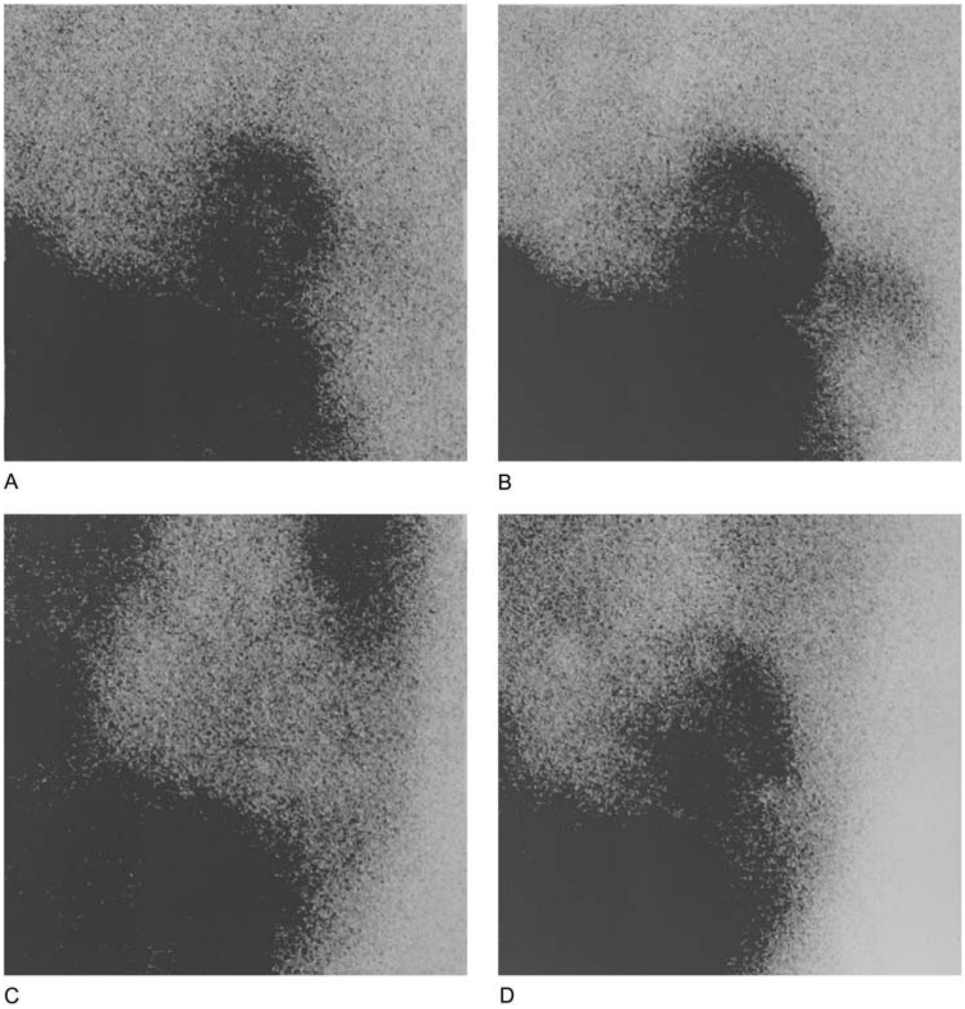

FIGURE 10-2 ■ Normal myocardial innervation, *A*, and perfusion, *B*, in a 71-year-old man with SAH. Global functional denervation, *C* and normal perfusion, except for a nonspecific apical irregularity, *D*, in a 41-year-old woman with SAH. (From Banki NM, Kopelnik A, Dae MW, et al: Acute neurocardiogenic injury after subarachnoid hemorrhage. Circulation 112:3314, 2005, with permission.)

Catecholamine Surge on Coronary Microvasculature

Despite the evidence for a neurologically mediated mechanism of cardiac impairment independent of CAD, there is also evidence to support a centrally mediated source of injury to the coronary microvasculature. During SAH, the body's stress response leads to elevated levels of cortisol (via the hypothalamic–pituitary–adrenal axis), endothelin/angiotensin II (via neurohumoral responses), and circulating catecholamines (via the adrenal medulla). Together, these factors incite peripheral vascular constriction and induce coronary microvascular spasm, contributing to demand ischemia of the heart. Catecholamines and endothelin bind directly to α_1-receptors and endothelin A receptors on the coronary microvasculature, respectively, which leads to vasoconstriction and a reduction in coronary blood flow. In Takotsubo cardiomyopathy, which can be seen after SAH, studies have shown increased plasma levels of the vasoconstricting peptide, endothelin-1, as well as decreased expression of the endothelin-1 regulating miRNA 125a-5p, when compared to healthy controls.[8] Delivery of intravenous adenosine, a potent vasodilator, has also been shown transiently to improve left ventricular function and myocardial perfusion in patients with Takotsubo cardiomyopathy, as compared to patients with ST-elevation myocardial infarctions.[9] As a result, these studies support the hypothesis that microcirculatory vasospasm may be a cause of transient cardiac injury and is potentially driven by the neurohumoral and catecholaminergic responses to neurologic injury.

CARDIAC MANIFESTATIONS OF GLOBAL NEUROLOGIC INJURY

Reduced Left Ventricular Function

Much of the evidence for a neurogenic mechanism of cardiac injury comes from studies of cardiac function after SAH, which typically affects younger patients without a history of co-existent cardiac disease. Global or regional left ventricular systolic dysfunction on echocardiogram has been described after SAH and is strongly associated with the severity of neurologic injury. Diastolic dysfunction is also common after SAH, is similarly associated with the severity of neurologic injury, and may cause pulmonary edema. The onset of left ventricular dysfunction occurs early after SAH. In a large prospective study, a regional wall motion abnormality was observed in 28 percent, and global left ventricular dysfunction in 15 percent of patients with SAH, all of which was present within the first 2 days.[10] The prevalence then declined during days 3 to 8 after hemorrhage. In this same study, the authors demonstrated complete or partial resolution of left ventricular dysfunction in the majority of patients during their acute hospitalization. Thus, cardiac dysfunction appears to be reversible in most cases and normalizes over time.

Regional Wall Motion Abnormalities

There is a well-demonstrated, unique, apical-sparing pattern of regional wall motion abnormality, often involving the anterior and anteroseptal walls, that differentiates SAH patients from those with the typical patterns seen in CAD. The presence of wall motion abnormalities in SAH is not only a predictor of adverse clinical outcomes, but has also been associated with the increased incidence of delayed cerebral ischemia.[11] Given that patients with SAH have impaired cerebral autoregulation and are at risk of vasospasm and hypovolemia, it is speculated that wall motion abnormalities impair overall cardiac output, thereby reducing cerebral perfusion and causing delayed cerebral ischemia. Apical wall motion abnormalities with hyperdynamic basal contractility suggestive of Takotsubo cardiomyopathy can also be seen in SAH, with an increased predominance in females and insular involvement. In both patterns of injury (apical-sparing and Takotsubo cardiomyopathy), the wall motion abnormality does not follow a distinct vascular distribution, thereby reinforcing the notion of a neurally mediated process. In 2019, researchers investigating resting-state functional connectivity on fMRIs found that decreased baseline connectivity in the limbic–autonomic pathways of the brain was associated with Takotsubo cardiomyopathy. While it remains difficult to ascertain the causal relationship of such findings, it is possible that the inherent limbic–autonomic reserve of certain patients makes them more vulnerable to maladaptive sympathetic responses after neurologic insults, resulting in cardiac impairment.[12]

Cardiac Biomarkers of Neurologic Injury

Creatine Kinase-MB

In addition to pathologic data and measurements of cardiac function, elevations in cardiac enzymes provide evidence of myocardial injury after stroke and SAH. Creatine kinase (CK) and specifically the cardiac isoenzyme CK-MB are released from damaged myocardium. Elevated serum levels can occur after both stroke and SAH, and there is a good correlation between elevation in CK-MB and stroke-induced ECG changes or cardiac arrhythmias. Unlike acute myocardial infarction, a stroke-induced increase in serum CK-MB levels occurs more slowly and peaks at a much lower value on around day 4 after stroke.

Troponin

Cardiac troponin I is a specific and more sensitive marker of myocardial damage. Elevations in troponin I have been described in up to 30 percent of patients with SAH, with stepwise increases in levels correlated to the severity of initial injury (i.e., Hunt Hess score). SAH patients with elevations in troponin have higher rates of prolonged QTc on ECGs, more frequent ventricular tachycardia on Holter monitoring, and features of impaired LV function and regional wall motion abnormalities, as compared to those without troponin elevations. Such cardiac manifestations are associated with increased mortality, poorer functional outcomes, and delayed cerebral ischemia.[11,13] A rise in cardiac troponin is similarly seen in acute ischemic strokes. Of the 2123 consecutive patients with ischemic strokes in the TRELAS study, 13.7 percent were found to have cardiac troponin levels greater than 50 ng/L. Among these patients, a predefined subset subsequently underwent coronary angiography, with less than a quarter of the patients showing a coronary lesion, and only half showing any features of CAD at all.[6]

B-Type Natriuretic Peptide

Serum B-type natriuretic peptide (BNP) is often used as a marker of heart failure. Elevated serum BNP levels after SAH have been independently associated with systolic and diastolic dysfunction, pulmonary edema, elevated troponin I levels, and lower cardiac ejection fractions. The predominance of cardiac abnormalities similar to heart failure suggests that although BNP is found in heart and brain, elevated levels are likely to be of cardiac origin. Moreover, elevated troponin I and BNP levels are independent and strong predictors of inpatient mortality after SAH and may have a similar link to mortality in acute ischemic stroke as well.

CARDIAC MANIFESTATIONS OF FOCAL NEUROLOGIC INJURY

Clinical observations in patients with stroke have greatly advanced the understanding of interactions between the brain and heart. Cardiac abnormalities occur in a majority of patients after stroke, and can range from transient ECG findings to serious cardiac events and cardiac death. Distinguishing cardiac abnormalities caused directly by stroke, however, remains difficult because of the high prevalence of pre-existing cardiac disease. Substantial evidence supports the occurrence of new cardiac disturbances after stroke, even in the absence of significant CAD. Epidemiologic evidence supports the presence of stroke as a significant contributor to absolute risk estimates for outcomes of vascular disease, including risk of myocardial infarction and cardiac causes of death. Understanding the mechanisms of cardiac disturbances may prevent future cardiac complications and improve survival in stroke patients.

Electrocardiographic Findings

ECG abnormalities are common, presenting in the majority of patients with acute stroke. Historically, an ECG pattern after acute stroke consisting of large inverted T waves, prolonged QT intervals, and large septal U waves has become distinctive of cerebrovascular injury (Fig. 10-3). Abnormal ECGs are most frequently observed after hemorrhagic rather than ischemic strokes, even in patients who never had an abnormal ECG prior to the stroke event. A variety of abnormalities have been described including ST depression, prolongation of the QT interval, T-wave inversion, and ventricular premature beats. Studies suggest that ECG abnormalities can occur with or without co-existing heart disease.

QT Prolongation

The most common stroke-related ECG abnormality is QT prolongation, a myocardial repolarization abnormality associated with an increased risk of a characteristic life-threatening cardiac arrhythmia, known as torsades de pointes (Fig. 10-4). Interestingly, imbalance of the sympathetic innervation of the heart has been described in congenital forms of long QT syndrome, suggesting a common mechanism with the catecholamine hypothesis described earlier. Prolonged QT interval is more frequently observed after hemorrhagic than ischemic strokes. Early recognition of this ECG abnormality is clinically important because ventricular tachyarrhythmias including sudden death and torsades de pointes are often preceded

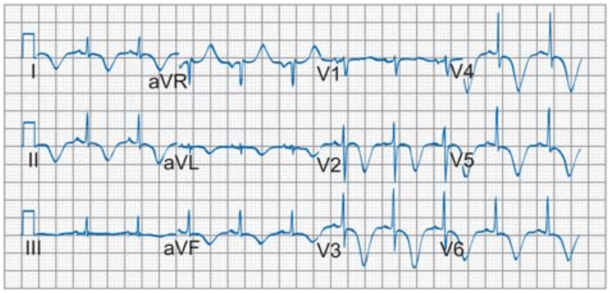

FIGURE 10-3 ■ Typical "neurogenic" electrocardiographic changes with symmetric deep T-wave inversions in a patient with acute subarachnoid hemorrhage. These abnormalities were transient and not associated with myocardial infarction. (Courtesy of Dr. Jonathan Zaroff, MD.)

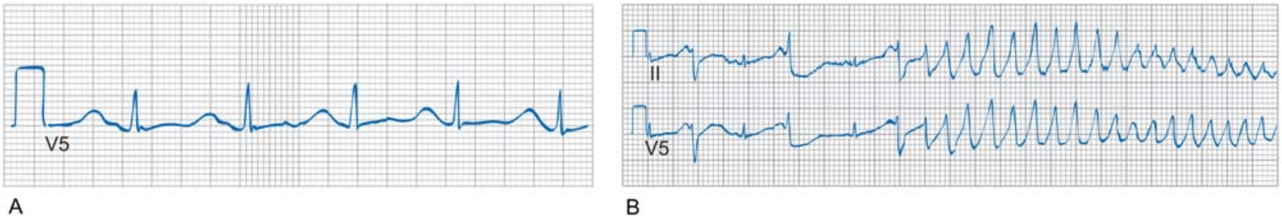

FIGURE 10-4 ■ Electrocardiographic (ECG) changes can precede pathologic arrhythmias in patients with severe neurologic injuries. *A*, Prolongation of the QT interval is common after subarachnoid hemorrhage. Electrolyte abnormalities or medications can also prolong the QT interval. *B*, Torsades de pointes is a polymorphic ventricular tachycardia associated with QT prolongation. (Courtesy of Dr. Byron Lee, MD.)

by QT prolongation. Assessment and management of common causes of these ECG changes, such as hypokalemia, hypomagnesemia, and medication toxicity, is recommended before attributing them to the underlying stroke.

REPOLARIZATION ABNORMALITIES

The similarities between ECG changes due to acute myocardial ischemia and infarction and those associated with acute stroke are most striking with repolarization abnormalities involving the ST segment, leading many investigators to hypothesize co-existing cardiac disease as the primary cause. Interpretation of ST segment changes (including ST elevations) is complicated by the increased prevalence of cardiac disease among ischemic stroke patients. However, studies have shown new T-wave abnormalities after acute stroke in the absence of electrolyte disturbances or primary ischemic heart disease (as determined by detailed cardiac assessments including echocardiogram and cardiac angiography). These findings, along with the observation that stroke-induced ECG changes are evanescent, resolving over a period of days to months with little residuum, argue against myocardial ischemia or infarction as the only cause of repolarization changes on ECG.

Q WAVES AND U WAVES

New Q waves similar in morphology to those observed in acute myocardial infarction are also common after acute stroke. To complicate matters, Q waves may be transient or proceed through the evolutionary changes seen in myocardial infarction. Further cardiac evaluation may be necessary in high-risk patients with Q waves and ST segment alterations, particularly if they are over 65 years of age with coronary risk factors such as diabetes mellitus, hypertension, and hyperlipidemia.

New U waves occur in isolation or with T waves and QT abnormalities after acute stroke. Isolated U waves are equally distributed between ischemic and hemorrhagic strokes, but the combination of U waves and QT prolongation is more common among patients with hemorrhagic strokes. There is no relationship between the presence of U waves and stroke mortality, suggesting that this ECG change should not require any specific treatment or evaluation.

Disturbances of Cardiac Rhythm

ARRHYTHMIAS

Nearly every type of cardiac arrhythmia has been reported after acute stroke, including bradycardia, supraventricular tachycardia, atrial flutter, atrial fibrillation, ectopic ventricular beats, multifocal ventricular tachycardias, torsades de pointes, ventricular flutter, and ventricular fibrillation. Most arrhythmias occur within the first week after all stroke subtypes, particularly in the first 24 hours. Atrial fibrillation is the most common cardiac arrhythmia reported after ischemic stroke. Not surprisingly, since the ECG is a relatively insensitive test for arrhythmia, a higher incidence of ventricular extrasystoles, atrial extrasystoles, supraventricular tachycardia, and atrial fibrillation can be captured using cardiac telemetry monitoring. Importantly, the presence of arrhythmias after stroke is significantly associated with increased mortality, and guidelines recommend cardiac monitoring in hospitalized stroke patients during the first 72 hours. Newer literature supports extended cardiac event monitoring for cryptogenic embolic strokes.

In studies of hemorrhagic strokes, the incidence of ventricular arrhythmias is higher. Location of hemorrhage appears to correlate with the rhythm disturbances. Ventricular arrhythmias are correlated with temporoparietal location, whereas sinus bradycardia and supraventricular tachycardias are seen more commonly with traumatic frontal lobe hemorrhage.

Patients with SAH may have even more profound rhythm disturbances that may be related to the diffuse nature of the injury and the degree of monitoring in the intensive care unit. Because the frequency and severity of arrhythmias are significantly higher in patients studied within 48 hours of onset of SAH, we recommend continuous cardiac monitoring in an intensive care setting for all such patients.

HEART RATE VARIABILITY AND BARORECEPTOR REFLEX SENSITIVITY

During the acute phase after ischemic stroke, autonomic dysfunction can present with decreased heart rate variability and impaired baroreflex sensitivity, particularly among patients with higher stroke scale severity, right insular involvement, and carotid injury. Decreased heart rate variability correlates with short-term mortality and sudden cardiac death, and patterns of beat-to-beat variability have been used to predict which patients will go on to develop neurocardiogenic injury after SAH.[14] Similarly, impaired baroreflex sensitivity is thought to reflect a pathologic shift toward sympathetic predominance leading to dynamic fluctuations in blood pressure. Although not fully understood, impaired baroreflex sensitivity has predictive value in both cardiac and neurologic conditions, including mortality after myocardial infarction, perihematomal edema size after ICH, and the incidence of malignant cerebral edema after infarcts in the territory of the middle cerebral artery.[15] One hypothesis involves a stroke-induced decoupling of cerebrovascular autoregulation, thereby making the brain vulnerable to wide fluctuations in blood pressure, which, in turn, trigger local inflammation and edema formation.

EPILEPSY AND TRAUMA

Similar cardiac arrhythmias and ECG findings have been described in patients with epilepsy, brain tumors, head trauma, meningitis, multiple sclerosis, and spinal lesions. In all cases, a common mechanism of neurogenic cardiac injury is supported by increased sympathetic nervous system discharge and increased catecholamine production by the adrenal medulla. Analogous to SAH, patients with chronic temporal lobe epilepsy may have baseline dysfunction in cardiac sympathetic innervation with normal myocardial perfusion scans.

Epilepsy

Sinus tachycardia is by far the most common cardiac manifestation during epileptic seizures, occurring in up to 90 percent of instances and present in both clinical and subclinical events. The increase in heart rate typically occurs at ictal onset, followed by variable heart rate patterns thereafter. Cardiac arrhythmias in the form of asystole, atrioventricular block, and bradycardia may also be present in seizures, with contrasting mechanisms between the ictal and postictal phases. During the ictal period, there is a sudden release of catecholamines triggered by cortical discharges often arising in regions of the insula. This sympathetic surge, as seen with sinus tachycardia, can be followed by a centrally mediated vasovagal response, with rebound parasympathetic activity causing bradyarrhythmias. As the arrhythmias persist, cerebral perfusion declines and the ictal onset aborts, stimulating arousal. This process may explain the self-limiting properties of ictal asystole, and its lack of association with long-term complications. Arrhythmias during the ictal phase are more frequently seen with focal seizures involving the temporal lobe, but the laterality of onset remains controversial.

In contrast, postictal arrhythmias such as postictal asystole and AV block are more associated with convulsive seizures, and thought to play a role in the phenomenon of sudden unexpected death in epilepsy (SUDEP).[16] In 2013, the MORTEMUS study analyzed continuous cardiac rhythms of 16 patients who developed SUDEP in epilepsy monitoring units across multinational centers. The findings demonstrated for the first time a sequential mechanism of convulsive seizures, followed by central apnea, bradycardia, and eventually asystole. During these events, there was also a concomitant pattern of prolonged postictal generalized EEG suppression, reflecting a "postictal coma." One theory is that during central apnea, the body's chemoreceptor response not only induces bradycardia, but also facilitates arousal and resumption of ventilation. When this arousal is blocked by "postictal coma," ventilation remains impaired and prolonged bradycardia and asystole ensue. This mechanism of injury leads to a potentially fatal cardiovascular collapse, occurring in both an acute and delayed fashion. In the MORTEMUS cohort, the incidence of SUDEP was estimated to be about 5.1 cases per 1,000 patient-years, with increased incidence during the nocturnal period.[17] The risk of sudden unexpected death has previously been related to increased seizure frequency, generalized seizures, younger age, lower concentration of antiepileptic medications, use of multiple medications, and duration of epilepsy.

Long-term cardiac monitoring with implantable loop recorders suggests that ictal and postictal bradyarrhythmias may be more common than previously supposed. Other types of arrhythmias seen during or after epileptic seizures include atrial flutter, atrial fibrillation, and ventricular tachycardia/fibrillation.

Traumatic Brain Injury

Paroxysmal sympathetic hyperactivity (PSH) is a term coined to describe the excessive sympathetic response seen in patients with severe traumatic brain injury, which occurs in 8 to 33 percent of patients. In this hyperdynamic cardiac state, paroxysmal clinical symptoms are triggered by external stimuli, and include tachycardia, tachypnea, hypertension, hyperthermia, diaphoresis, tremors, dystonic posturing, and decreased levels of consciousness—all of which portend worse clinical outcomes. PSH may begin within 2 weeks of the neurologic insult and persist for as long as several months. Although its underlying pathophysiology remains unknown, it is postulated to involve a disconnect of the brainstem nuclei and their inhibitory pathways to the spinal interneurons modulating spinal reflex arcs. This results in a maladaptive reaction to afferent sensory stimuli that induces an overactive spinal circuit excitatory response, leading to increased motor and sympathetic output. The periaqueductal gray matter is believed to play a key role in the supraspinal inhibitory control of this mechanism.[18] Thus, midbrain lesions have been implicated in the manifestation of PSH.

Risk factors for PSH include younger age, presence of diffuse axonal injury, and lesions to white matter tracts. As previously described, the balance between sympathetic and parasympathetic activity in the brain is also regulated by communication between the cortical (i.e., insula, cingulate gyrus) and subcortical structures (i.e., amygdala, hypothalamus, medulla). Damage to this network during trauma, as seen with diffuse axonal injury and shear injury to the white matter tracts, may contribute to the dysregulation of autonomic responses in PSH, in addition to any involvement of the periaqueductal gray matter.

Treatment for PSH focuses primarily on reducing the provoking stimuli and dampening the sympathetic outflow. This usually involves opioid analgesia and benzodiazepines as first-line treatment, followed by β-blockers, gabapentin, α-blockers, and bromocriptine. Although such medications afford symptomatic relief, no treatments have proven effective in improving outcomes in patients with PSH after traumatic brain injury.

CARDIAC EVALUATION

Proper evaluation of cardiac injury and dysfunction remains important for both cardiac and neurologic prognosis. Patients with ischemic stroke, in particular, are more likely to have concomitant significant CAD. A strong association between cerebrovascular disease and CAD has been established in a number of clinical studies, with nearly half of patients with TIAs or ischemic stroke showing CAD on coronary angiography or on functional testing with thallium stress images. Given the higher probability of CAD, several diagnostic evaluations are recommended in the acute period for all patients with ischemic stroke including an ECG and measurement of serum troponin I levels. Further functional testing with echocardiogram and continuous cardiac monitoring are often initiated to determine the risk of a cardiogenic source of embolic ischemic strokes. Exercise or pharmacologic stress test (nuclear or echocardiographic) and coronary angiogram should be obtained based on the patient's risk level and functional status.

The majority of patients with acute stroke will not be considered for acute treatment for myocardial infarction, but coronary angiography may be indicated if there is a strong clinical suspicion of plaque rupture or thrombus formation that may be safely treated endovascularly. As previously described, distinguishing cardiogenic from neurogenic causes of myocardial injury can be problematic. Evaluation for clinical signs of heart failure, such as cardiogenic pulmonary edema and hypotension, careful analysis of the ECG, assessment of cardiac function by echocardiogram, and evaluation of myocardial necrosis by cardiac markers may help to determine the need for cardiac catheterization. The serum CK-MB levels are insensitive and should not be used for differentiation between neurogenic and cardiogenic injury. A large increase in serum troponin I levels with a significant temporal trend, along with ECG changes that correlate with the location of left ventricular systolic dysfunction on echocardiogram, may be more suggestive of CAD. In contrast, common neurogenic ECG changes, including T-wave inversion, QTc prolongation, a shorter PR interval, and the presence of U waves, may aid in differentiating neurogenic injury from myocardial infarction.

In hemorrhagic strokes, the frequency of cardiac arrhythmias is high and often correlates with ECG changes. Baseline ECG and continuous cardiac monitoring in this population are often performed in the intensive care unit. Patients with SAH pose a greater challenge when the complication arises of cerebral vasospasm and delayed cerebral ischemia. Unless contraindicated, the typical management of these patients may include induced hypertension with pressors to improve cerebral blood flow through narrowed vasculature. SAH patients could potentially benefit from measurement of serum troponin I and BNP levels as well as a transthoracic echocardiogram as part of their initial management. A close, independent relationship has been established between the severity of SAH and the probability of troponin release, and could be used to anticipate greater risk of cardiac abnormalities in these patients. Coronary angiography after SAH is generally not recommended because most patients with left ventricular dysfunction following SAH who undergo cardiac catheterization have normal epicardial coronary arteries and no evidence of large coronary vasospasm.

For patients with epilepsy, sudden unexpected death is the most feared complication. Growing evidence suggests that neurogenic cardiac arrhythmias may contribute to the risk of sudden death. Identifying patients at highest risk of this complication has been challenging. In addition to clinical risk factors and promoting better compliance with medication, advanced cardiac monitoring with ambulatory ECG and long-term implantable loop recorders may help to identify patients with pathologic arrhythmias. In addition, other methods for measuring cardiac autonomic input, such as heart rate variability and spectral analysis, may be useful.

In patients with traumatic brain injury, continuous cardiac monitoring in the intensive care unit often detects heart rate and blood pressure variability and, combined with multimodality monitoring, can correlate changes associated with elevations in ICP and cerebral perfusion pressure. Incorporating measurements of heart rate variability may also be useful for prognosis.

CLINICAL MANAGEMENT

After identification of the common cardiac abnormalities, management should be initiated to prevent their detrimental effect on patient outcomes. The most common ECG changes generally do not require specific treatment, but may prompt further testing and continuous monitoring. Identification of other causes or contributors to ECG changes can lead to rapid resolution. In particular, specific treatment of hypokalemia, hypomagnesemia, and medication toxicity may correct a prolonged QT interval. Antiarrhythmic (e.g., quinidine, sotalol, amiodarone) or antipsychotic drugs (e.g., haloperidol) known to affect the QT interval should be avoided in these patients, especially if their neurologic injury exacerbates underlying hereditary long QT syndrome. When repolarization abnormalities occur, it may be necessary to exclude acute myocardial infarction. Common electrolyte abnormalities such as hyperkalemia can produce tall T waves, whereas hypokalemia is the most common cause of U waves. Correction of electrolyte abnormalities may reduce the risk of arrhythmias.

Cardiac rhythm disturbances after neurologic injury can be complex, requiring cardiology consultation. The most important aim is to identify patients who may be hemodynamically unstable in the presence of an arrhythmia. This is a medical emergency and should be managed immediately by appropriate personnel in the intensive care unit, with the involvement of a cardiac team. In a stable, asymptomatic patient, identifying the type of arrhythmia can guide management. Atrial or ventricular premature contractions generally do not require specific treatment. For sinus bradycardia or tachycardia, identification and treatment of the common underlying conditions, such as fever, thyroid dysfunction, anemia, pain, sepsis, and anxiety, will often correct the rhythm disturbance.

Specific pharmacologic treatment may be required if the patient develops stable tachyarrhythmias. A trial of adenosine can terminate supraventricular tachycardia and assist in determining the underlying rhythm disturbance. Rate control with an intravenous β-blocker, calcium-channel blocker, or amiodarone can be used in patients with atrial fibrillation or flutter, most common after ischemic stroke and ICH. Stable ventricular tachyarrhythmias can also be managed with intravenous amiodarone or lidocaine. Specific treatment of torsades de pointes includes intravenous magnesium. Any arrhythmia more complex than ectopic beats or sinus bradycardia or tachycardia should prompt a cardiology consultation.

When more significant cardiac dysfunction or injury is identified by elevated serum markers or dysfunction on ECG, several steps can be taken to improve cardiac prognosis. If CAD is present, management of atherosclerosis risk factors (diabetes, hyperlipidemia, hypertension, and smoking) and treatment with antiplatelet agents and lipid-lowering agents may help both the ischemic stroke and heart disease. The β-blockers reduce the risk of vascular events after myocardial infarction, but their role in the prevention of cardiac events in other high-risk patients with stroke is unclear. Finally, revascularization by angioplasty or coronary artery bypass grafting is beneficial for patients with symptomatic CAD, but the decision to treat must balance the risk to the patient with an acute neurologic injury.

In the rare event of coronary plaque rupture in a patient with SAH, coronary angioplasty along with stenting may be considered once the aneurysm is secured and the necessary anticoagulation regimen can be tolerated safely. Although further studies are needed to determine the safety of percutaneous coronary intervention and anticoagulation after successful aneurysmal intervention, patients with unsecured aneurysms should not undergo any coronary intervention given the unacceptably high risk of rebleeding.

In patients with SAH, the presence of cardiac injury and dysfunction often directly affects management. The decision to treat a ruptured aneurysm should not be delayed because of concerns regarding cardiac injury. Because the mechanism of neurogenic cardiac injury is probably mediated by catecholamines, treatment should focus on correcting or improving the underlying neurologic process. Prevention of rebleeding with early aneurysm clipping or endovascular coiling has proved beneficial, but selection of treatment modality may be influenced by cardiac risk.

Management of cerebral vasospasm in the setting of significant neurocardiogenic injury is challenging and directly impacts neurologic prognosis. Permissive hypertension requiring pressors to improve cerebral blood flow often leads to increased myocardial wall stress and oxygen consumption. Although most patients tolerate treatment for cerebral vasospasm, selection of the most appropriate vasopressor agent must take underlying cardiac function into account. Phenylephrine, a commonly used pressor in the intensive care unit, is predominantly an alpha-1 agonist that increases systemic vascular resistance, and thus may worsen cardiac output in those with a poor ejection fraction. Studies have suggested the use of alternative positive inotropic agents such as norepinephrine, dobutamine, and milrinone, which may be more effective at improving cerebral perfusion pressure in patients with low cardiac output. In those patients with diastolic dysfunction, attention to volume status is important as hypervolemia may cause increased filling pressures, leading to pulmonary edema. In patients with severe neurogenic cardiac injury and evidence of heart failure who are unable to tolerate medical therapy for delayed cerebral ischemia, placement of an intra-aortic balloon pump to increase cerebral perfusion pressure has been successful.

Given the potential role of excessive catecholamines in neurocardiogenic injury, β-blockers may have a role in providing cardioprotection if administered early in the hospital course, but supporting evidence is limited and based on small studies. Pathologic correlation suggests that β-blockade may protect myocytes from the hostile environment caused by massive levels of catecholamines released from cardiac sympathetic nerve terminals following SAH. Larger studies will help to determine the role of early administration of β-blockers in patients with cardiac dysfunction following SAH. Calcium-channel blockers targeting the calcium overload preceding contraction-band necrosis have not been well studied. There does not appear to be a significant cardiac benefit from nimodipine, the calcium-channel blocker already administered to patients with SAH for vasospasm prophylaxis.

CONCLUDING COMMENTS

Cardiac disturbances are diverse and frequent in the setting of acute neurologic injury. More importantly, the presence of cardiac abnormalities has significant impact on clinical management and affects cardiac and neurologic outcomes adversely. Understanding of the underlying pathophysiology and localization of the important autonomic regulatory centers involved in brain–heart interactions has progressed significantly in recent years. Animal models have been translated into important clinical research studies that have revealed further complexity in the brain regulation of cardiac function. Early recognition and appropriate treatment interventions have already impacted clinical management and may influence treatment for prevention and improving outcomes for both the heart and the brain.

GENETICS OF STROKE

Stroke broadly describes the sudden onset of neurologic dysfunction due to an abnormality of blood supply to the brain, retina, or spinal cord. Ischemic stroke makes up the majority of all strokes and is often considered synonymous with stroke although the definition extends to intracerebral hemorrhage, cerebral venous sinus thrombosis, subarachnoid hemorrhage, and retinal and spinal ischemia. In a 2013 update from the American Heart Association and the American Stroke Association, cerebral ischemia and cerebral hemorrhage that were present on brain imaging without an overt neurologic symptom (i.e., were "silent") were included in the definition of stroke to underscore the significance of the pathology regardless of clinical manifestation.[1] This definition of stroke is not widely accepted outside of the United States and will have implications for comparing outcomes and disease prevalence internationally. Cerebrovascular accident (CVA) is a related term that has fallen out of favor in part because it implies the outcome as unanticipated. On the contrary, ischemic and hemorrhagic strokes are usually not "accidents," but rather manifestations of chronic conditions.

Ischemic stroke has an association with many general medical conditions. It is a heterogeneous disorder caused by any combination of thrombosis, embolism, or hypoperfusion. Ischemic stroke etiology is commonly subtyped into broad categories including small artery (lacunar), large vessel

atherosclerotic, or cardioembolic, and there is overlap in the medical conditions that lead to these stroke subtypes. This chapter will review the most common medical conditions that underlie stroke.

HYPERTENSION

Hypertension is the most common risk factor for ischemic stroke and is responsible for the greatest proportion of preventable strokes. The relationship between stroke and blood pressure seems to be maintained well under the traditional threshold of 140/90 mmHg, and even modest decreases in blood pressure reduce stroke risk. Elevated blood pressure exerts injury throughout the cerebrovascular system and is a risk factor for multiple types of stroke including intraparenchymal hemorrhage, aneurysmal subarachnoid hemorrhage, and ischemic stroke of multiple subtypes, including small vessel, large vessel, and cardioembolic. The mechanisms underlying each stroke type are distinct but result from a combination of mechanical and inflammatory injury to both small and large vessel artery walls. Elevated blood pressure also increases the risk of cardiac structural changes, atrial fibrillation, and myocardial infarction and therefore is an indirect but important cause of cardiac embolus formation leading to stroke.

Treatment of blood pressure is effective for both primary and secondary stroke prevention, and higher intensity strategies of blood pressure reduction are thought to have played a major role in the reduction of the population stroke risk in the United States over the past half century (see Chapter 7).

BLOOD LIPIDS

Elevated total cholesterol and low-density lipoprotein (LDL) are correlated with atherogenesis of the carotid arteries and with heart disease, while high-density lipoprotein seems to be protective. Although the correlation between atherosclerotic disease and heart disease is well known, there is little correlation between the absolute levels of serum cholesterol and LDL and ischemic stroke risk.

HMG-CoA reductase inhibitors (statins) reduce LDL by inhibiting their synthesis and are an important component of stroke prevention therapy. Although their effect can be measurable in terms of LDL reduction, it is currently believed that statin medications exert their stroke reduction via other antiatherogenic mechanisms. Ezetimibe and PCSK9 antibodies are mechanistically distinct from statins and are used as add-on therapy for further LDL reduction when required; currently, these medications are recommended for use in patients who are considered to be at high risk for atherosclerotic cardiovascular disease.

DIABETES MELLITUS

While often present with other metabolic risk factors, the presence of diabetes independently increases stroke risk (see Chapter 19). The pathogenesis may be mediated by an enhanced atherogenesis in diabetics, microvascular disease of the arterial walls, and the promotion of coagulation by way of platelet activation and changes in coagulation factors. As with hypertension, diabetes mellitus is associated with several ischemic stroke subtypes.

Hyperglycemia is associated with an increased risk of mortality following stroke, and prevention of *severe* hyperglycemia during this period confers an improved outcome. However, intensive blood glucose control in the immediate period following acute stroke (i.e., maintaining blood glucose less than 130 mg/dL) does not seem to render any benefit in stroke recovery compared to strategies that aim to prevent hyperglycemia (blood glucose greater than 180 mg/dL).

HOMOCYSTEINE

Homocysteine is an intermediate in methionine metabolism, and hyperhomocysteinemia may result from an acquired or genetic deficiency in the enzymes or co-factors involved. Elevated plasma homocysteine is associated with all-cause vascular disease, mortality, and an increased risk of ischemic stroke. High levels of homocysteine are also linked to vascular injury and atherosclerotic plaque formation.

Severe hyperhomocysteinemia results in homocystinuria and is usually caused by inborn errors of metabolism. Individuals with homocystinuria experience premature atherosclerosis, thromboembolic disease including stroke, developmental delay, osteoporosis, marfanoid appearance, and ectopia lentis. This condition is usually diagnosed prior to young adulthood due to the overt manifestations.

In contrast, mild to moderate hyperhomocysteinemia may be clinically asymptomatic and accompany vitamin deficiencies (e.g., B_{12}, B_6, folate), and genetic variants including mutations in the methylenetetrahydrofolate reductase gene (*MTHFR*). Mild to moderate elevations of homocysteine are also associated with vascular disease and ischemic stroke; however, whether mild to moderate elevations of homocysteine directly contribute to vascular injury or are merely a marker of vascular disease is debated.

Folate, B_{12}, and B_6 vitamin supplementation reduce levels of plasma homocysteine, even in the absence of overt vitamin deficiency, and have been studied for their effect on stroke reduction without much promise to date. In a 2017 Cochrane review including 15 randomized trials, 71,422 participants, and up to 7.3 years follow-up concluded that homocysteine-lowering interventions had a possible but small reduction in stroke risk.[2] In combination with antihypertensive medications, homocysteine-lowering treatments may prevent one stroke in 143 people treated for 5.4 years. At this time, routine screening and treatment for hyperhomocysteinemia in stroke patients is not recommended unless there is clinical suspicion for homocystinuria.[3]

CARDIAC DISEASE AND STROKE

Cardiogenic thromboemboli are a common source of ischemic stroke. Thrombi may originate from the chambers of the heart, the cardiac valves, or from systemic veins gaining access to the arterial system through a right-to-left shunt in the heart (e.g., a patent foramen ovale (PFO) or atrial septal defect). The latter, termed *paradoxical embolism,* is still referred to as a cause of cardiogenic stroke though this may be a misnomer since the embolus comes from a noncardiac source, accessing the cerebral circulation via a structural heart defect. Paradoxical emboli can also occur in the setting of noncardiac shunts such as a large arteriovenous malformation (AVM) located elsewhere in the body.

Atrial Fibrillation/Atrial Flutter

Atrial fibrillation (AF) and atrial flutter combined are the most frequently associated conditions with cardiogenic stroke. Traditionally, AF was thought to lead to intracardiac clot formation from dysrhythmic contractility leading to stasis and subsequent thrombus formation in the left atrium or atrial appendage. However, given the dependence on comorbid vascular risk factors and advanced age to substantiate a high stroke risk in AF, this mechanism is probably not entirely explanatory.

In elderly patients with vascular risk factors, AF leads to structural remodeling of the left atrium. Whether AF is directly causal to stroke or whether stroke results from an atrial cardiopathy remains a matter of debate. Nevertheless, the discovery of persistent or episodic atrial fibrillation in patients with cardiogenic stroke is important as these patients benefit from anticoagulation more than antiplatelet therapy in the secondary prevention of stroke; long-term rhythm monitoring for the detection of atrial fibrillation is recommended following embolic stroke. The benefit of anticoagulation in patients without known atrial fibrillation but with atrial cardiopathy is not yet known.

Valvular atrial fibrillation, commonly from mitral valve stenosis, is also associated with an increased risk of stroke. Anticoagulation with warfarin is recommended for stroke prevention in patients with valvular AF, whereas direct oral anticoagulants have emerged as a preferred therapy for nonvalvular AF. See Chapter 5 for further discussion.

Patent Foramen Ovale

A PFO occurs when the foramen ovale fails to close after birth. This is a common cardiac finding, estimated to occur in one out of every four individuals and generally thought to be of no consequence in otherwise healthy people. However, young patients with embolic-appearing stroke tend to have a higher proportion of PFO, raising the question of causality in certain patients with stroke. Previously, surgical closure of PFO for secondary stroke prevention was not known to be of benefit but recent studies have suggested a long-term benefit for closure in select young patients with high-risk PFO and cryptogenic embolic stroke.

WOMEN'S HEALTH AND STROKE

In the United States, women are disproportionally impacted by stroke. Women experience a higher life-time risk of stroke, and as a result of stroke, women are more likely to be institutionalized and

have poorer outcomes including a higher mortality rate. Some of these sex-specific differences may be due to longer life expectancies in women and their older age at stroke onset, but certain vascular risk factors have higher prevalence or risk attribution in women including hypertension, diabetes mellitus, migraine with aura, and atrial fibrillation.[4]

There are also sex-specific stroke risk factors unique to women including pregnancy, pre-eclampsia, gestational diabetes, menopause, and exposure to exogenous hormones from oral contraceptives and hormone replacement therapy (Table 11-1). Because women tend to be underrepresented in major stroke trials, increasing inclusion and awareness in order to understand the unique aspects of stroke in women is critical.

Stroke in Pregnancy

Stroke in pregnancy is a major cause of long-term morbidity and an important cause of mortality for these women. Recent pooled estimates suggest that stroke may complicate as many as 30 out of 100,000 pregnancies, which is a threefold higher risk compared to young adults overall.[5] Stroke in pregnant women includes ischemic, hemorrhagic, and cerebral venous sinus thrombosis occurring in roughly equal proportions, which diverges from the general population where stroke incidence is predominantly ischemic.

The peripartum and postpartum periods tend to be the highest risk periods for stroke, with pregnancy-related hypertension and the acquired thrombophilia of pregnancy factoring most prominently (see Chapter 31). Other conditions that predispose to stroke can also manifest during pregnancy such as vascular dissection, congenital cardiac complications, moyamoya disease, and hemorrhage from aneurysm or vascular malformation.

Changes in the coagulation system that accompany pregnancy tend to manifest in the third trimester and are implicated in the increased risk of ischemic stroke and cerebral venous sinus thrombosis during pregnancy. These changes include a general increase in procoagulant factors (e.g., I, VII, VIII, IX, X, XII, XIII, and functional APC resistance), and a decrease in anticoagulants (e.g., antithrombin III and protein S).

Pre-eclampsia manifests in the latter half of pregnancy and is common among pregnant women with ischemic stroke, hemorrhagic stroke, and subarachnoid hemorrhage. The mechanism of stroke related to pre-eclampsia and eclampsia is likely complex related to both abnormal vascular tone and prothrombotic effects. Pregnancy cardiomyopathy and amniotic fluid embolization are other causes of ischemic stroke in pregnancy.

Successful use of tissue plasminogen activator (tPA) as a treatment for acute ischemic stroke in pregnant women is understood at the case report level, and has not been studied empirically. Since tPA does not cross the placenta, it would not be expected to cause direct harm to the fetus; however, the major concern is the risk of placental hemorrhage and abruption prompting preterm delivery. Based on these limited case reports, tPA should be considered in the treatment of disabling ischemic strokes in pregnant women. For large-vessel occlusions, thrombectomy without intravenous thrombolysis is also a reasonable approach.

Women who experience stroke related to pregnancy may also have a higher risk of lifetime recurrent stroke. This may be due to a persistence of vascular risk factors that were simply unmasked in pregnancy (e.g., women with gestational diabetes have a higher risk of developing diabetes mellitus later in life). Women with stroke related to pregnancy should therefore be monitored closely to ensure proper lifetime risk reduction and optimal prenatal planning for future pregnancies.

Menopause

The physiologic transition into menopause is associated with an increased risk of ischemic stroke, and the preponderance of current data suggests that earlier menopause may be associated with a greater risk of stroke compared to those with typical age of onset.[4] Endogenous estrogen in the premenopausal state has been hypothesized as providing a protective effect against stroke risk; however, as reviewed in the section below, exogenous hormone replacement is now thought to increase the risk of stroke. Thus, hormone replacement therapy should be used cautiously in women with vascular risk factors, and only with the intent to control symptoms related to menopause.

Postmenopausal women experience an increase in all subtypes of ischemic stroke. While premenopausal women tend to have lower rates of hypertension when compared to their age-matched male counterparts, this reverses in postmenopausal women; hypertension tends to be more common in women with stroke than men with stroke, and women are also less likely to achieve adequate blood pressure control pre- and post-stroke. Whether there is a physiologic basis for medication resistance or higher rates of nonadherence is unknown. There is an increased incidence of comorbid vascular risk factors in elderly women including central obesity and elevated total cholesterol and LDL.

HEMATOLOGIC DISORDERS

While many conditions that predispose to stroke are broadly prothrombotic, there are a variety of major hematologic disorders that result in pathologic activation of hemostatic pathways and the coagulation cascade. These can arise from inherited, acquired, or mixed causes. Procoagulant perturbations of the coagulation cascade result from loss of function of a natural anticoagulant, such as protein C, protein S, or antithrombin III inherited or acquired deficiencies, or a gain of function of a procoagulant such as factor V Leiden, activated protein C (APC) resistance, or prothrombin gene mutations. Other conditions can bolster the hemostatic pathway including the antiphospholipid antibody syndrome, heparin-induced thrombocytopenia (HIT), and certain malignancies and their treatments (see below).

TABLE 11-2 ■ Components of Thrombophilia Screening

Basic coagulation screen: INR, aPTT
Antithrombin III functional assay
Protein C functional assay
Protein S functional assay
APC resistance assay, including genetic testing for factor V Leiden if APC abnormal
Prothrombin (factor II) gene mutation 20210A genetic testing
Antiphospholipid antibodies: anticardiolipin IgG and IgM, β2-glycoprotein-1 IgG and IgM, lupus anticoagulant assay

INR, international normalized ratio; aPTT, activated partial thromboplastin time; APC, activated protein C.

Current clinical guidelines from the American Heart Association and American Stroke Association do not specify for whom testing for hypercoagulable states should be performed post-stroke and this continues to be an area of variability in practice. The yield of thrombophilia testing is probably greatest in young patients with a cryptogenic stroke, or those with a personal or family history of thrombosis or unexplained pregnancy loss. See Table 11-2 for a suggested work-up for thrombophilia.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibodies, a misnomer given their indirect action on anionic phospholipids, function in various ways to enhance hemostasis through their interaction with vascular endothelial cells and subsequent activation of the coagulation cascade. Antiphospholipid syndrome (APS) is defined by a venous or arterial thrombosis or pregnancy loss in the presence of persistent positivity of one or more antiphospholipid antibodies (aPL). APS can be a primary disorder or secondary to a rheumatologic condition such as systemic lupus erythematosus (SLE). The mechanism of stroke in APS may be a result of in situ arterial thrombosis or cardioembolism secondary to APS-related nonbacterial endocarditis (Fig. 11-1).

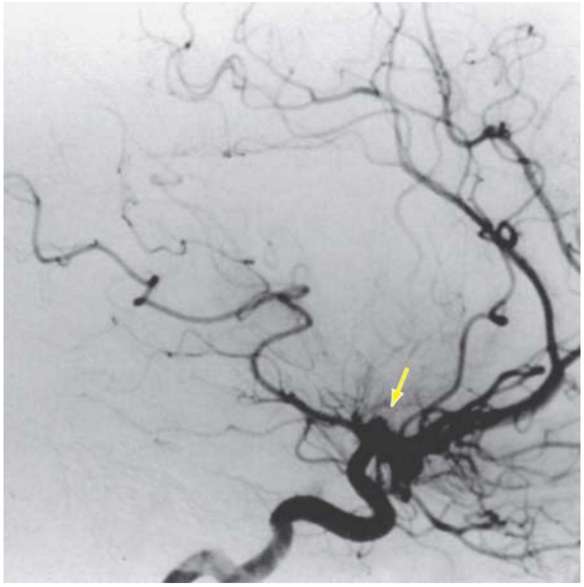

FIGURE 11-1 ■ Angiogram showing a middle cerebral artery occlusion (*arrow*) in a young woman with anticardiolipin antibodies, the lupus anticoagulant, and myxomatous mitral valve thickening. (From Coull BM, Levine SR, Brey RL: The role of antiphospholipid antibodies in stroke. Neurol Clin 10:130, 1992, with permission.)

Antiphospholipid antibodies that fulfill diagnostic criteria for APS include anti-β2 glycoprotein-I antibodies (aβ2GPI), anticardiolipin antibodies (aCL), or a positive functional lupus anticoagulant (LA) assay. There is emerging evidence that other antiphospholipid antibodies may be relevant to APS and stroke, although they are not yet formally part of the diagnostic criteria. These other antibodies include antiphosphatidylserine (aPS), antiphosphatidylserine-prothrombin antibodies (aPS/PT), antiannexin A5, and antiphosphatidylethanolamine (aPE).[6] In terms of serologic risk prediction, the highest risk is often attributed to (1) triple positivity (aβ2GPI, aCL, and LA), (2) moderate to high titers, and (3) IgG isotype (versus IgM). The strongest association with noncriteria antibodies and risk of stroke and death is with aPS/PT.

There are currently no disease-modifying drugs used in the management of APS, and the mainstay of therapy consists of antithrombotic medications to reduce the risk of future thrombotic events. The data regarding an optimal regimen do not address the safety and efficacy of newer oral anticoagulants for APS. Current expert consensus is that standard intensity warfarin (INR 2–3) should be used for secondary stroke prevention in APS unless there are significant bleeding concerns or a perceived low risk of recurrent thromboembolic events.[3] If warfarin is not initiated for any reason, patients should be treated with antiplatelet therapy for secondary prevention. Patients with stroke and aPL who do not meet criteria for APS are not recommended for treatment with anticoagulation for secondary stroke prevention.

Given the increasing awareness that aPL may be an independent risk factor for thromboembolism, primary stroke prevention is an important clinical question with insufficient data. At this time, many consider antiplatelet therapy in asymptomatic aPL carriers if there are co-morbid vascular risk factors; however it is unknown whether this exerts a significant stroke risk reduction in otherwise healthy, young patients.

Sneddon Syndrome

Sneddon syndrome is a neurocutaneous disorder associated with antiphospholipid antibodies that primarily affects middle-aged women. Histopathologically, Sneddon syndrome is a noninflammatory thrombotic arteriopathy of medium and small vessels in the dermis and in the brain. Skin biopsy reveals dermal inflammation without vasculitis. Clinically, it is characterized by recurrent strokes and livedo reticularis. Affected patients may also have Raynaud phenomenon or acrocyanosis of the digits. Antiphospholipid antibodies are often prominent and progressive cognitive decline from the arteriopathy may occur even in young persons. Accordingly, any young patient presenting with progressive cerebrovascular disease or cognitive decline and livedo reticularis should be evaluated for the presence of antiphospholipid antibodies. Optimal treatment is unknown and both antiplatelets and anticoagulants have been used. Immunosuppressive therapy is not routinely indicated.

Factor Deficiencies

Antithrombin III, protein C, and protein S are natural anticoagulants that regulate the coagulation cascade (Fig. 11-2). While these genetic deficiencies are more strongly implicated in the pathogenesis of venous thromboembolism, they underlie a small proportion of arterial stroke, notwithstanding the presence of a venous–arterial conduit such as a PFO. They factor more prominently in the pathogenesis of ischemic stroke in children and young

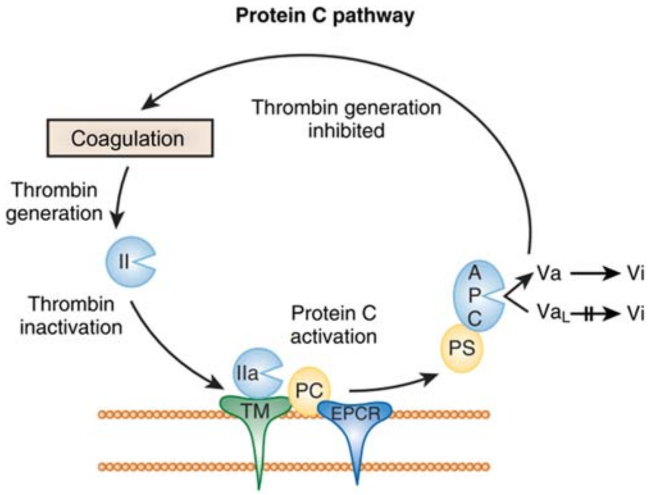

FIGURE 11-2 ■ Protein C pathway. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin (TM) on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered so that it no longer acts as a procoagulant but becomes a potent activator of protein C (PC). Endothelial protein C receptor (EPCR) binds PC and presents it to thrombomodulin-bound thrombin, where it is activated. Activated protein C (APC), together with its cofactor, protein S (PS), binds to the activated platelet surface and proteolytically degrades factor Va (Va) into inactive fragments (Vi). Because factor Va is a critical component of the prothrombinase complex, factor Va inactivation by APC attenuates thrombin generation. Because factor $\text{Va}_{\text{Leiden}}$ (FVa_{L}) is resistant to inactivation by APC, patients with the factor V_{Leiden} mutation have reduced capacity to regulate thrombin generation. (From Anderson JA, Weitz JI: Hypercoagulability and uncommon vascular diseases. In Jaff MR, White CJ (eds): Vascular Disease: Diagnostic and Therapeutic Approaches. Cardiotext Publishing, 2011. Used with permission from Cardiotext Publishing.)

adults, and their significance in older adults is less clear.

Inherited deficiencies occur in an autosomal dominant fashion, thus family history may be revealing. Acquired deficiencies may be due to conditions that decrease synthesis, increase consumption, or facilitate clearance. Common sources of acquired deficiencies include liver disease, treatment with L-asparaginase therapy, therapy with vitamin K antagonists, sepsis, disseminated intravascular coagulation (DIC), and acute thrombosis, including stroke. Any abnormal result in the setting of an acute stroke should be repeated at a later date to assure the result is not a false positive in the setting of an acute thrombosis. Acquired antithrombin III deficiency has also been described in polytrauma, malignancy, burns, extracorporeal circulation, concurrent hormone replacement therapy or oral contraceptive use, preeclampsia, and pregnancy-induced hypertensive illness.[7] Antithrombin III and protein S deficiencies can be secondary to nephrotic syndrome. Functional assays are the preferred method for screening for these disorders since deficiencies may be quantitative or qualitative. Any abnormality detected on initial screening should be repeated at an interval to ensure validity.

There is a lack of prospective studies guiding therapy for secondary stroke prevention in the setting of these thrombophilias. Antithrombin III deficiency has the highest risk for recurrence of thrombotic events. Options for treatment range from lifelong anticoagulation for secondary prevention to anticoagulation only during high-risk periods. Counseling is important as any patient with an inherited deficiency should be advised of the risks of thrombosis with oral contraceptive use, prolonged bed rest, the post-operative state, and pregnancy.

Inherited Thrombophilias

Certain inherited thrombophilias result from gain-of-function mutations whose cumulative effects are procoagulant. Factor V Leiden refers to a single-point mutation on factor V that renders the protein resistant to neutralization by APC. Factor V Leiden is a primary cause of APC resistance but acquired APC resistance can also occur as a result of pregnancy, oral contraceptives, and hormonal replacement therapy. Both factor V Leiden heterozygosity and homozygosity confer an increased risk of venous thromboembolism; however, the association with arterial stroke independent of a PFO is debated.

The prothrombin (or factor II) G20210A gene mutation leads to an increased production of prothrombin, which results in a procoagulant state either by enhancing thrombin generation or inhibiting factor Va inactivation by APC, resulting in increased risk of venous thromboembolism. Similar to factor V Leiden, there is an association with arterial stroke in young patients; however the contribution of a PFO has not been consistently addressed in studies.[8]

The decision to treat with antiplatelet or anticoagulation for secondary stroke prevention due to these gene mutations is made on an individual basis. In those who have recurrent stroke in the setting of these abnormalities, anticoagulation should be considered.[3]

Sickle Cell Anemia

In addition to a host of peripheral complications, sickle cell anemia is a strong risk factor for ischemic stroke in children and adults. Incidence is highest in children, with most strokes occurring in the first decade of life. Silent infarcts are common in patients with sickle cell disease as well. Hemorrhagic strokes and cerebral venous sinus thromboses are less common manifestations of sickle cell anemia.

The mechanism of stroke in sickle cell anemia was believed to be analogous to the peripheral complications of sickle cell formation during sickle cell crises involving insoluble deoxygenated hemoglobin aggregates within vessels that form local thromboses during crises. However, the current consensus is that stroke in sickle cell anemia stems from an acquired vasculopathy secondary to accumulated endothelial damage in large- and medium-sized vessels. Vessel imaging shows characteristic segmental stenosis in the internal carotid and proximal portions of vessels in the circle of Willis. These stenoses can evolve into a moyamoya-like vasculopathy featuring progressive narrowing and resulting in the development of arcades of collateral vessels. The locations of vessel stenoses are thought to be the primary sites of thrombosis leading to ischemic stroke and the pattern of ischemic stroke on imaging is typically a combination of watershed and thromboembolism.

Transcranial Doppler (TCD) ultrasonography is a useful screening tool to monitor pediatric patients with sickle cell anemia for vasculopathy by way of measuring flow velocity at regular intervals. Studies have shown that the risk of stroke could be reduced from 10 percent per year to less than 1 percent per year with routine exchange transfusion therapy guided by TCD velocities. Subsequent trials investigated the effect of stopping exchange transfusions once TCD velocities had normalized and were ended prematurely because about one-third of patients who had stopped monthly exchange transfusions redeveloped high-risk velocities. Based on these data, it appears that exchange transfusions may be required indefinitely, although such an extensive treatment regimen should be weighed against the risks of iron overload, transfusion reactions, and donor-borne transmission of infectious diseases. Guidelines on primary prevention of ischemic stroke from the American Heart Association and the American Stroke Association recommend that children with sickle cell disease be screened with TCD beginning at 2 years of age.

Cryoglobulinemia

Cryoglobulins are serum immunoglobulins with abnormal thermal solubility which precipitate below 37°C in vitro. They can be monoclonal and driven by a primary B-cell malignancy or monoclonal gammopathy or they can be polyclonal and driven by persistent lymphoproliferation in the setting of an autoimmune disorder or chronic infection. The autoimmune diseases associated with cryoglobulins include SLE, Sjogren syndrome, and rheumatoid arthritis. Infections commonly associated with cryoglobulins include hepatitis C and B, human immunodeficiency virus (HIV), and other bacterial or parasitic infections.

Cryoglobulins may be asymptomatic, but cryoglobulinemia manifests with certain core features including cutaneous vasculitis, arthralgias, peripheral neuropathy, and glomerulonephritis. Stroke and other central nervous system (CNS) manifestations are a less commonly recognized presentation of cryoglobulinemia, usually in association with hepatitis C infection. The mechanism of stroke in cryoglobulinemia is speculative but may result from cryoprecipitation, defective clotting and platelet functions, immune complex-mediated vasculitis and intravascular hemolysis, or progressive vasculopathy.

Plasmapheresis has been effective in some patients with neurologic complications, presumably through lowering of cryoglobulinemia and therefore improvement of the microcirculation. Beneficial results may be obtained in some cases by minimizing cold exposure. Immunosuppressive agents have been used in noninfectious cryoglobulinemia, but controlled clinical trials are lacking and current treatment regimens are based on expert opinion.

INFECTIONS

Acute systemic infections have been linked to an increased risk of ischemic stroke, highlighting some of the speculation underlying the seasonal variation of stroke incidence, which is higher in winter months. Stimulation of inflammatory cascades with systemic infection is thought to promote atherosclerotic plaque formation and rupture as well as thrombosis.

Bacterial endocarditis is an important mechanism of stroke in the setting of systemic infection wherein septic debris embolize to the brain and lead to ischemia, microhemorrhages, and mycotic aneurysms due to degradation of the vessel wall from pathogen infiltration (see Chapter 6). Given the proclivity for vessel wall fragility and hemorrhage, intravenous thrombolysis for acute stroke is contraindicated in the setting of known bacterial endocarditis.

Stroke may complicate certain CNS infections as well. Stroke may be due to an infectious vasculitis wherein pathogenic invasion of blood vessels leads to segmental vessel narrowing, thrombosis, or both. A parainfectious vasculitis, one mediated by the inflammatory response itself, may also underlie stroke in CNS infections. While some infections are readily apparent such as acute bacterial meningitis, others present with nonspecific features and may go undiagnosed. Particularly in young patients without traditional stroke risk factors or in those who are immunocompromised, stroke evaluation should include a thorough evaluation for infection including systemic and cerebrospinal fluid (CSF) evaluations. Table 11-3 summarizes the common mechanisms and infectious triggers of stroke.

	Infectious causes
Preceding or concomitant systemic infection, outside the CNS	Influenza *Chlamydia pneumoniae* *Helicobacter pylori* *Porphyromonas gingivalis*
Preceding or concomitant infection, contiguous with the CNS	*Streptococcus pneumoniae* sinusitis *Haemophilus influenzae* sinusitis *Moraxella catarrhalis* sinusitis *Aspergillus fumigatus* sinusitis Mucormycosis sinusitis
Total non-specific infectious burden	More than one current or previous systemic infection
Vasculitis and mycotic aneurysm	HIV Varicella zoster virus Syphilis Neuroborreliosis Epstein-Barr virus Cytomegalovirus Tuberculosis Neurobrucellosis
Vascular remodeling	HIV Syphilis
Promotion of a hypercoagulable state	Hepatitis C
Infectious endocarditis	*Staphylococcus aureus* Coagulase-negative staphylococci Viridians group streptococci *Streptococcus bovis* Enterococci HACEK bacteria *Escherichia coli* *Klebsiella pneumoniae*
Cardiogenic emboli to the cerebral vasculature from dilated cardiomyopathy	Chagas disease

HACEK=*Haemophilus parainfluenzae, Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominus, Eickenella corrodens,* and *Kingella kingii.*

Acute Bacterial Meningitis

Ischemic strokes are relatively common and highly morbid complications of pyogenic bacterial meningitides (see Chapter 38 for a further discussion of acute bacterial meningitis and Chapter 47 for a discussion of chronic meningitis). The presentation of stroke in the context of a bacterial meningitis may be indistinguishable from other complications such as cerebritis, abscess, and seizure, and therefore ancillary testing with imaging is critical to diagnose stroke in this setting.

The timing of stroke related to bacterial meningitis is typically within days to weeks of the infection and often occurs despite appropriate antimicrobial therapy and sterilization of the CSF. Strokes make be due to a large- and medium-vessel vasculopathy as many of these vessels are located at the base of the brain in close proximity to subarachnoid exudates. Many patients therefore present with large-territory ischemic lesions or those in a watershed pattern. Small-vessel thrombotic strokes may occur as well. A chronic vasculopathy resembling moyamoya syndrome has also been described and may increase the risk of delayed stroke. Beyond antimicrobial therapy and adjunctive corticosteroids, the optimal management of vascular complications related to bacterial meningitis is not known. There is no known benefit of antithrombotic medications or an extended course of corticosteroids in these circumstances.

Tuberculous Meningitis

Tuberculosis (TB) remains an international public health concern, and it affects both immunocompromised and competent patients (see Chapter 40). Tuberculous meningitis (TM) is the primary neurologic complication of TB and can occur during primary infection or in the latent stage due to reactivation of the dormant mycobacterium. TM is characteristically a subacute meningitis and may be complicated by ischemic stroke, intraparenchymal tuberculomas, or multiple cranial neuropathies due to compression from hydrocephalus. Intracerebral hemorrhage and aneurysm formation related to tuberculous meningitis are rare.

Ischemic stroke that complicates TM is characteristically localized to the "tuberculoid zone," which includes the caudate nucleus, anterior thalamus, and anterior limb of the internal capsule; this location's involvement is due to smaller perforator vessels affected by a TM-related infiltrative vasculitis which may be further stretched by concomitant hydrocephalus. Cortical and subcortical stroke may also occur from vasculitis of the larger intracranial arteries embedded in inflammatory exudate. A prothrombotic state may also contribute to stroke in TM.

The risk of ischemic stroke is thought to be related to the severity of meningitis at presentation.[10] In addition to antitubercular treatment, there may be a benefit of adjunctive steroids in reducing mortality and morbidity related to TM complicated by stroke. Aspirin has been considered as an adjunct for preventing stroke related to TB meningitis but there are little data to support its use.

Syphilis

Despite a downtrend in syphilis infections following the introduction of penicillin, the incidence of syphilis has been on the rise over the past two decades. Co-infection with HIV is also common and thus neurologic and neurovascular complications of these combined infections may be compounded (see Chapter 39).

The pathogenesis of syphilis is often referred to in stages, and the neurologic consequences of syphilis vary accordingly. *Treponema pallidum*, the pathogen responsible for syphilis, is known to enter the CNS during primary infection and may remain clinically silent in untreated patients. Meningitis and meningovascular syphilis manifest in the early stages (i.e., within months to several years) of the infection, while parenchymal disorders, dementia, and tabes dorsalis occur in the late stage (i.e., after 1–2 decades) of the infection.

Ischemic stroke is a consequence of the meningovascular form of syphilis, and frequently due to large and medium-sized vessel involvement. The presentation is frequently, but not always, preceded by a subacute encephalitic prodrome with symptoms including insidious headache, neck pain, or seizure.

The diagnosis of neurosyphilis is challenging. *T. pallidum* cannot be cultured in vitro, and the identification of infection is therefore dependent on serologic evaluation. Treponemal serum testing (i.e., fluorescent treponemal antibody absorption or syphilis enzyme immunoassay) is a useful screening tool for detecting antibodies to the bacterium; however these tests remain reactive indefinitely despite treatment. A negative test can therefore be useful in ruling out neurosyphilis, but a positive test will not distinguish current from a prior treated infection. Non-treponemal tests such as rapid plasma reagent (RPR) and venereal disease research laboratory (VDRL) are useful for diagnosing meningovascular syphilis since they are usually reactive in the early phase of the infection. Classic CSF findings include an elevated protein and lymphocytic pleocytosis.

Treatment of neurosyphilis including meningovascular syphilis consists of intravenous penicillin G. It is recommended to perform regular screening with repeat CSF testing every few months to ensure a resolution of pleocytosis and loss of reactivity of VDRL. Vascular changes may be permanent, and daily aspirin may be useful for secondary stroke prevention.[10]

SYSTEMIC LUPUS ERYTHEMATOSUS

Stroke is common in patients with SLE. Although most strokes in SLE are ischemic, intracerebral hemorrhage has been reported typically in the setting of concurrent thrombocytopenia. Ischemic stroke in SLE most commonly affects younger patients, although elderly patients with SLE also are at high risk likely due to the presence of other vascular risk factors that may act synergistically with SLE.

Antiphospholipid antibody syndrome can be seen secondary to SLE. The most frequent mechanisms for ischemic stroke in SLE are either cardiogenic embolus from nonbacterial thrombotic endocarditis (termed Libman–Sacks endocarditis in SLE) or an antibody-mediated hypercoagulable state. Both tend to be associated with antiphospholipid antibodies, and therefore laboratory testing for APS should be performed in any patient with SLE and an unexplained stroke.

The incidence of an inflammatory cerebral vasculitis in SLE is extremely low in autopsy studies, making this an unlikely cause of stroke in these patients. A noninflammatory vasculopathy secondary to vessel-wall hyalinization and endothelial proliferation has been described more frequently. The mechanism of SLE-related vasculopathy is unclear, although possible mechanisms include endothelial damage by antineuronal antibodies or immune complex deposition.

Anticoagulant therapy may reduce the risk of stroke recurrence in patients with SLE. Oral anticoagulation is warranted in patients with SLE who have concurrent risk factors of cardiac valvular lesions or APS. Outside of these indications, standard secondary prevention involves antiplatelet medications. Given the absence of inflammatory vascular lesions in patients with SLE who have strokes, corticosteroids probably have no role outside of their treatment for systemic inflammation.

ONCOLOGY AND STROKE

Ischemic and hemorrhagic strokes are common in patients with both solid and hematologic malignancies and present unique challenges in management. The unique mechanisms of stroke in this population include acquired coagulopathy leading to a thromboembolic state or in situ thromboses, nonbacterial endocarditis resulting in cardioembolic stroke, and direct tumoral invasion of vascular structures. The cause of cerebrovascular events in patients with cancer can vary with the type of primary tumor, extent of malignant dissemination, and the type of anticancer therapy administered.

Coagulopathy in the Setting of Cancer

Disorders of coagulation in cancer patients have been linked to many different malignancies but are most commonly described with adenocarcinomas, such as pancreas, lung, colon, breast, prostate, and gastric cancer, and leukemias. Although abnormalities of coagulation are seen quite commonly in patients with cancer, these coagulopathies are rarely symptomatic. When present, a coagulation disorder may manifest with superficial or deep venous thromboses, nonbacterial thrombotic endocarditis (NBTE), or migratory thrombophlebitis, all of which may lead to ischemic stroke. Malignancy-related coagulopathy can culminate in DIC and result in both ischemic and hemorrhagic complications, the latter due to the consumption of platelets and clotting factors. Patients with coagulopathy in the setting of malignancy tend to have a poor prognosis since this usually occurs in the setting of advanced and disseminated disease.

Nonbacterial Thrombotic Endocarditis

NBTE, also known as marantic endocarditis, is an important source of stroke in patients with cancer. The pathophysiology involves the deposition of sterile, friable fibrin on heart valves that may result in systemic embolization to the brain and other organs (Fig. 11-3).

The pathogenesis of NBTE in malignancies may emanate primarily from an underlying cardiac valvular abnormality that predisposes to the deposition of platelets and fibrin, facilitated by malignancy-related hypercoagulability. Once valvular damage occurs, underlying exposed collagen can act as a nidus for platelet adhesion and subsequent thrombus formation. Microscopically, the valvular lesions consist of agglutinated blood and platelet thrombi in the absence of an inflammatory reaction. Embolic fragments are primarily composed of fibrin.

Most vegetations are multiverrucous and less than 3 mm in size, which accounts for the relatively low

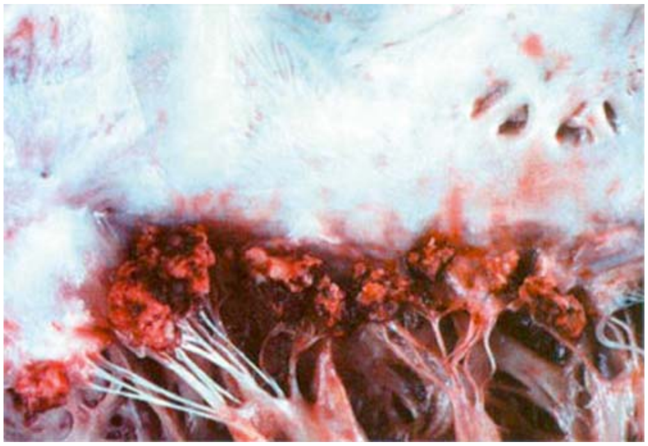

FIGURE 11-3 ■ A typical mitral valve lesion in a patient with lupus and nonbacterial thrombotic endocarditis (NBTE). (Photograph courtesy of Dr. William D. Edwards, Division of Anatomic Pathology, Mayo Clinic Rochester.)

diagnostic yield of conventional transthoracic echocardiography compared with transesophageal echocardiography. Diffusion-weighted MRI sequences of the brain may show multiple strokes of differing sizes in multiple vascular territories or border zone regions. Once a diagnosis of NBTE is made, treatment of the primary malignancy should be the primary focus. If there is no recognized malignancy, a thorough search should be undertaken for occult cancer as well as autoimmune and rheumatologic disorders that can share this appearance. Recent guidelines have recommended use of low-molecular-weight or unfractionated heparin for treatment of NBTE with evidence of emboli.

Stroke Related to Cancer Therapy

Stroke directly related to chemotherapy is a relatively rare occurrence. Platinum-containing compounds are most commonly implicated; the pathophysiology of this relationship is not entirely known, but may be a consequence of induced vasospasm, endothelial dysfunction, or other procoagulant changes.

The chemotherapeutic agent L-asparaginase is frequently associated with cerebral infarction, typically from cerebral venous sinus thrombosis. Most patients make a good clinical recovery. Although the cause of sinus thrombosis is unclear, L-asparaginase may lead to a decreased partial thromboplastin time (PTT) and increased platelet aggregation, as well as antithrombin III and plasminogen deficiencies.

Radiation-induced vasculopathy of the cervical and intracranial carotid arteries is an additional potential cause of stroke in patients treated for cancer. The interval from radiation treatment to onset of occlusive cerebrovascular disease ranges from month to decades. Angiography reveals occlusion or extensive stenosis of the arteries in the previous radiation field; carotid artery lesions in patients irradiated for head and neck cancers are the most common. Limited data on treatment options for symptomatic extracranial carotid disease in the setting of radiation damage are available, but carotid stenting is typically preferred over endarterectomy as surgical dissection can be challenging.

Intracerebral Hemorrhage

Intracerebral hemorrhage is most commonly reported with leukemic conditions, specifically acute promyelocytic leukemia. Although the pathogenesis of the hemorrhage has been postulated to involve infiltration and rupture of vessels by leukemic nodules or damage to small vessels from hyperviscosity, most patients with intracranial hemorrhage do not have evidence of leukostasis, leukemic nodules, or perivascular leukemic infiltration on histologic examination. Among the patients who do have evidence of leukemic infiltration, the peripheral white blood cell count is usually above $70,000/\text{mm}^3$. In addition to leukemic conditions, lymphoma and multiple myeloma may cause hemostatic deficiencies that predispose to brain hemorrhage through inhibition of fibrin formation by excess immunoglobulins.

Direct Tumor Effects

Direct tumor effects include intratumoral hemorrhage, arterial and venous invasion by tumor mass or leptomeningeal infiltrates, and tumor emboli. Tumor emboli occur rarely and exclusively in patients with solid tumors; they are virtually impossible to distinguish from thrombogenic emboli on clinical grounds alone. These metastatic emboli typically result from heart or lung tumors—atrial myxomas may shower small tumor fragments into the vasculature and lung tumor embolism may occur at the time of thoracotomy. Tumors that demonstrate aggressive intravascular invasion such as choriocarcinoma may also cause cerebrovascular events. Neoplastic aneurysms, with subsequent rupture causing hemorrhage, have been described; tumor emboli may invade an arterial wall after acute occlusion of the vessel, eventually resulting in dilatation and aneurysm formation. Cerebral venous sinus thrombosis may occur by direct tumor invasion from neuroblastoma, lung carcinoma, and lymphoma.

MIGRAINE AND STROKE

Migraine is a highly prevalent and costly disorder affecting both children and adults. While often thought of as a pure headache syndrome, it is a major cause of disability worldwide.

There is a strong relationship between stroke and migraine. The most frequent association between the two entities is the clinical overlap of their two presentations. The cortical-spreading depolarization that is the pathophysiologic underpinning of a migraine aura causes symptoms that may be indistinguishable from cerebral ischemia including aphasia, hemibody sensorimotor phenomena, and a myriad of vision changes.

Migraineurs, specifically those with the migraine with aura subtype, have an independently increased risk for stroke and other cardiovascular disorders including coronary artery disease, peripheral vascular disease, and retinal vascular disorders. Migraine patients also have a higher frequency of silent white matter abnormalities on MRI. The association between migraine and hemorrhagic stroke is less well-established.

The mechanism linking migraine and stroke is largely speculative, but hypotheses relate to intrinsic endothelial dysfunction in migraineurs, neurogenic inflammation from prolonged cortical-spreading depolarization, hypercoagulability with microemboli formation and right-to-left shunting, and the potential vasoconstrictive effects of migraine medications.[11]

Evidence for overlapping pathophysiology is best typified by the rare occurrence of a *migrainous stroke*. Migrainous strokes present initially as a migraine with an aura typical of the individual's previous attacks; however, the aura persists, and subsequent neuroimaging demonstrates an acute stroke in a causal vascular territory.

Stroke Prevention in Migraine

Given the rarity of migrainous stroke and lack of understanding of the migraine–stroke overlap, it is not recommended to use migraine-specific medications (preventative or abortive) as a stroke reduction strategy. The question of whether migraine medications ameliorate the future risk of stroke is unknown and there is no evidence to support a stroke-protective effect. Minimizing concomitant stroke risk factors in migraineurs such as hypertension, smoking, or high-estrogen-content oral contraceptives should be stressed. Although there is some theoretical basis to suggest microemboli mediated by PFO contribute to stroke and migraine independently, there is no evidence supporting PFO closure as a treatment for migraine. The use of triptans and ergot derivatives for migraine and their risk of stroke are discussed in the section below.

DRUGS AND STROKES

Estrogens

Estrogens have been shown to increase serum levels of several coagulation cascade proteins, including fibrinogen, factors II, VII, IX, X, and XII, and protein C. Exogenous use of estrogen in contraceptive formulations and postmenopausal hormonal replacement is associated with an increased risk of ischemic stroke. The risk of estrogens in gender-affirming hormone supplementation for transwomen is largely unmeasured but has been extrapolated from nontransgender individuals.

The belief in a protective effect of estrogen against stroke originates from the view that the increase in incidence of stroke and cardiovascular disease in postmenopausal women parallels the decline in endogenous estrogen. Research from the Women's Health Initiative and others found, in fact, that hormone replacement therapy with estrogen is actually associated with an increased risk of stroke.[12] This risk of stroke does not appear to be modifiable with respect to a woman's age upon initiation of therapy, temporal proximity to menopause, or whether formulations contain opposing hormones.

The association between oral contraceptive pill (OCP) use and stroke has been known for decades. Early studies demonstrated a much higher risk of stroke associated with estrogen-containing pills, which has been attributed to the higher dose of estrogen in earlier formulations. When OCPs were first available in the 1960s, the estrogen dose was approximately 150 μg compared to 20 to 50 μg in current formulations. The current risk of stroke associated with modern, estrogen-containing OCPs is overall small, but certain conditions appear to elevate the associated risk including comorbid hypertension, tobacco use, a history of migraine with aura, and factor V Leiden mutation or other inherited thrombophilias. Alternatives to estrogen-containing OCPs should be considered in women with other vascular risk factors. It is recommended to screen for other underlying thrombophilias (e.g., protein C and protein S deficiency, antithrombin III deficiency, the factor V Leiden mutation) in women who have a stroke while taking oral contraceptives, since contraceptive use may simply unmask previously latent clotting abnormalities.

Anabolic Androgenic Steroids

Anabolic androgenic steroids are used in the treatment of hypogonadism. Abuse of anabolic steroids is most often associated with performance enhancement in athletes, and dosages can far exceed those used for therapeutic purposes. The relatively low levels of testosterone used in therapeutic supplementation have not been definitively linked with an increased risk of stroke, but elevated testosterone levels in the setting of androgenic steroid abuse do seem to increase the risk of atherothrombotic events including ischemic stroke and venous thromboembolism, as well as cerebral venous sinus thrombosis.[13] The effect of high doses of testosterone on unfavorable lipid profiles, platelet aggregation, production of procoagulant factors, erythrocyte overproduction, and hypertrophic cardiomyopathy serve a theoretical basis for the pathophysiologic mechanism that may underlie the association.

Alcohol

Alcohol has long been recognized for its broad range of effects on the CNS. Heavy alcohol use is linked to an increased risk of ischemic, hemorrhagic strokes, and subarachnoid hemorrhage. Low to moderate alcohol use may be associated with a decreased risk of ischemic stroke compared to no alcohol use (Fig. 11-4), although the causality of this association has been questioned and will require further exploration. This potentially protective association with low to moderate alcohol use is not seen in relation to intraparenchymal or subarachnoid hemorrhage.

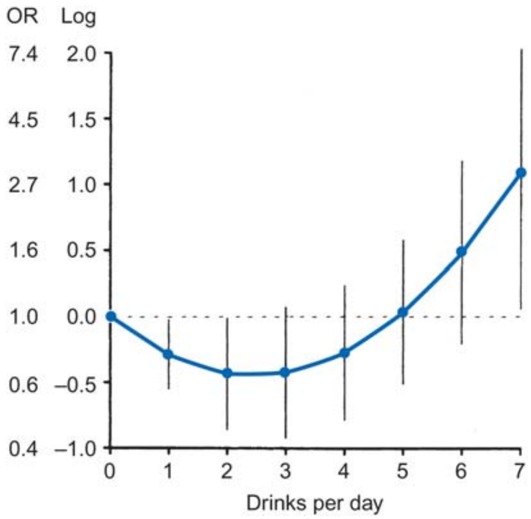

FIGURE 11-4 ■ Relationship between alcohol and the risk of ischemic stroke. OR denotes odds ratio for ischemic stroke. (From Sacco RL, Elkind M, Boden-Albala B, et al: The protective effect of moderate alcohol consumption on ischemic stroke. JAMA 281:57, 1999, with permission. © 1999, American Medical Association.)

Several pathophysiologic relationships may exist between alcohol and stroke. Alcohol may induce atrial fibrillation, alcoholic cardiomyopathy, and global cardiac akinesis, thereby predisposing to cardioembolism. Alcohol has also been linked to hypertension, increased platelet aggregation, abnormal activity of the clotting cascade, and reduced fibrinogen levels. Alcohol consumption contributes to systolic hypertension along with a decrease in the production of circulating clotting factors by the liver, both of which may contribute to the development of hemorrhagic stroke.

Tobacco

Tobacco use remains a leading preventable cause of stroke and death worldwide. Although the reduction in tobacco smoking in the United States represents a major public health accomplishment, the percentage of Americans who smoke remains high. Second-hand smoke exposure, including among children, remains a continued risk factor for stroke. Tobacco use in the form of E-cigarettes has also become highly popular particularly in young adults and adolescents.

The effects of tobacco smoking lead to chronic inflammation, insulin resistance, proatherogenic lipid profiles, and endothelial injury from oxidizing chemicals and nicotine. These chemicals promote atherosclerotic plaque formation in coronary and peripheral arteries.[14] The multisystemic effects of tobacco smoking are now well-known and include cardiovascular and cerebrovascular disease, respiratory conditions, and cancer. Importantly, smokers who abstain from smoking seem to eventually resume a lifetime risk of stroke similar to that of nonsmokers.

Amphetamines

Amphetamines and amphetamine derivatives constitute a class of drugs used for weight loss and as stimulants. The route of administration can be intravenous, oral, intranasal, or inhaled. The estimated prevalence of amphetamine abuse worldwide is nearly double that of cocaine.[13] Amphetamines are synthetic sympathomimetics that have been causally linked to ischemic and hemorrhagic strokes through a variety of mechanisms including cardiac arrhythmia with cardioembolism, cerebral vasculitis, vasoconstriction, and acute hypertension. Amphetamines may also lead to aneurysm formation and rupture due to frequent bouts of acute hypertension.

Cocaine

Cocaine is a synthetic sympathomimetic that is associated with an increased risk of stroke in users regardless of the route of exposure. Ischemic stroke, hemorrhagic stroke, and subarachnoid hemorrhages have been described in association with acute cocaine use, but long-term users may also experience accelerated vascular disease which causes stroke through more traditional intermediate phenotypes (e.g., large-vessel atherosclerosis). Arterial dissection has also been described.

Cannabis and Cannabinoids

Cannabis is the most widely used psychoactive substance in the world and has now been made legal in several countries around the world for therapeutic and recreational use. An increased risk of ischemic stroke associated with cannabis has been reported, and mechanisms include cerebral vasospasm and the prothrombotic effect of tetrahydrocannabinol (THC) on platelet aggregation. Synthetic cannabinoids represent a growing public health concern because of numerous safety issues and availability for legal purchase; this class of drugs contains highly active metabolites with a higher potency compared to THC. Case reports have highlighted an association with ischemic stroke, severe cardiac events, cerebral vasospasm, and hemorrhagic stroke. Since synthetic cannabinoids are not detected in routine toxicology, complete epidemiologic data are lacking.

Migraine Medications

Triptans and ergot alkaloid derivatives are two major classes of migraine abortive therapy with vasoconstrictive effects that have been linked with stroke. Because of the long-recognized association between migraine and ischemic stroke, a causal relationship has not been confirmed. In patients with a history of cardiovascular or cerebrovascular disease, triptans and ergot alkaloids are not relatively contraindicated.

GENETICS OF STROKE

Stroke remains a leading cause of death and permanent disability in the United States and worldwide. Primary and secondary stroke prevention strategies make up a limited armamentarium that is often bluntly applied. The application of genomic studies that would allow for individualized stroke risk prediction and novel drug development will have substantial implications in stroke prevention and public health.

Most strokes are a result of multiple intersecting genetic pathways and environmental exposures. The heritability of stroke calculated from genome-wide association studies (GWAS) is estimated at 30 to 40 percent.[15] To date, various GWAS have identified at least 35 variants (mainly single nucleotide polymorphisms) with links to stroke. Risk loci have been identified for all major ischemic stroke subtypes and hemorrhagic stroke.[15] Most of these loci have a minor allele frequency in the population and individually attribute only modest increases in stroke risk. Many are in nonprotein-coding DNA. Some of these genetic variants may be mediated by known stroke risk factors such as hypertension, but a substantial portion are not yet confirmed to be related to any known stroke pathway. The association of some variants exclusively with one stroke subtype suggests the possibility of novel pathophysiologic discovery in the future.

Although the majority of sporadic strokes arise through complex genetics and exposures, a small minority of strokes are caused by single-gene mutations with Mendelian inheritance. In some of these conditions, stroke is the defining complication and systemic symptoms are not appreciated. These conditions include the heritable small-vessel diseases CADASIL (i.e., cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; *Notch 3*), CARASIL (cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy; *HTRA1*), and PADMAL (pontine autosomal dominant microangiopathy with leukoencephalopathy; *COL4A1*). Among these, CADASIL is the most common hereditary stroke disorder.

However, there are several monogenetic diseases that are predominantly characterized by their systemic manifestations but also increase the risk for ischemic stroke. These include: sickle cell disease (*HBB*), a common cause of stroke in children; Fabry disease (*GLA*), discussed later; Marfan syndrome (*FBN1*), in which there may be skeletal, cardiac, aortic, and ocular abnormalities; and Ehlers–Danlos type IV, vascular subtype (*COL3A1*), in which there are characteristic facial features (acrogeria), thin translucent skin, easy bruising, and arterial, intestinal and uterine complications. Other such disorders include hereditary hemorrhagic telangiectasia (*ENG*, *ALK1*, others), with arteriovenous malformations that lead to bleeding in the lungs, central nervous system, and liver; homocystinuria (*CBS*, *MTHFR*, others), leading to vascular disease, cognitive and developmental disability, musculoskeletal abnormalities, and ocular manifestations; pseudoxanthoma elasticum (*ABCC6*) causing retinal changes and calcification in the skin, arteries, and heart; and retinal vasculopathy with cerebral leukoencephalopathy and systemic manifestations known as RVCL-S (*TREX1*). These conditions often affect younger patients than those affected by common strokes.

Fabry disease, for example, is an X-linked lysosomal storage disease caused by a deficiency of α-galactosidase. This results in a pathologic accumulation of unmetabolized lipids in many cell types. In hemizygous males, the condition classically presents in childhood or adolescence with skin findings (angiokeratomas), corneal opacities (cornea verticillata), and a painful neuropathy (acroparesthesias). In adulthood, additional manifestations unfold including cardiac dysfunction with left ventricular thickening, kidney disease, and systemic vasculopathy leading to stroke and transient ischemic attacks. Heterozygous females can also present with symptomatic enzyme deficiency, leading to delayed or heterogeneous phenotypes. Enzyme replacement therapy is indicated for individuals who are clinically symptomatic with a confirmatory genetic diagnosis. Enzyme replacement therapy has been shown to be beneficial for systemic complications, though the effect on stroke risk reduction has yet to be confirmed.

As outlined in this chapter, stroke can result from a variety of medical conditions, toxins, sex-related risk factors, and genetic predispositions. The majority of ischemic strokes occur due to a cumulative effect from hypertension, diabetes mellitus, hyperlipidemia, and atrial fibrillation. However, stroke can manifest in patients independent of these traditional risk factors and thus an understanding of the expanse of conditions with potentially distinct treatment options is crucial to stroke prevention.

HEPATIC ENCEPHALOPATHY

Definition

The term *hepatic encephalopathy* (HE) refers to any type of cerebral dysfunction that is due to liver insufficiency and/or portosystemic shunting and is detectable by clinical, neuropsychologic, or neurophysiologic means. Three types of HE are differentiated based on the underlying cause: type A occurs in patients with acute liver failure (ALF), type B in patients with portosystemic shunting in the absence of liver dysfunction, and type C in patients with cirrhosis. Episodic, recurrent, and chronic progressive forms have been described.[1]

Clinical Features

HE is characterized by alterations of cognition, motor function, and consciousness in various combinations.[2] The most commonly used grading system that distinguishes grades of HE (I–IV) based on the degree of alteration in consciousness is the West Haven system (Table 12-1). Motor symptoms can be detected in all grades, but with increasing frequency and severity in grades II and III (Fig. 12-1). The most characteristic motor findings are extrapyramidal and cerebellar symptoms, including hypomimia, hypo- and bradykinesia, rigidity, tremor, dysarthria, dysdiadochokinesia, and ataxia. Hyperreflexia and pyramidal signs are observed predominantly in patients with grades III and IV encephalopathy. Asterixis (flapping tremor), a form of negative myoclonus, may be present in the absence of any alteration of consciousness or cognition, but is observed most frequently in patients with grade II or III disease.

Difficulties in writing and speech disturbances are some of the first symptoms of HE in patients with liver cirrhosis. In the early phases, tremulous writing, omission of single letters, reversal of order, and misspellings are common. With later stages of HE, letters become superimposed and lines of writing converge. Patients become unable to sign their names or to move the pencil from left to right. Speech, initially monotonous and slowed, becomes slurred and unintelligible with associated dysphasia in later stages of the illness.

Personality changes and alterations of mood may be the first symptoms of HE and are generally first observed by relatives or friends. As the disease progresses, patients may become uninhibited and bizarre due to increasing difficulties in visual perception and disorientation, illusions, and hallucinations. Mood alterations including euphoria and depression are common and may exhibit rapid fluctuations.

TABLE 12-1 ■ West Haven Criteria for Grading of Clinically Overt Hepatic Encephalopathy

Grade I	Trivial lack of awareness, shortened attention span, impaired performance of addition, euphoria or anxiety
Grade II	Lethargy or apathy, minimal disorientation for time and place, inappropriate behavior
Grade III	Somnolence to semistupor but responsiveness to verbal stimuli, confusion, gross disorientation
Grade IV	Coma

CHRONIC PROGRESSIVE HEPATIC ENCEPHALOPATHY

The chronic progressive (or persistent) form of HE has predominantly been observed in patients with extensive portosystemic shunting that developed either spontaneously or after transjugular intrahepatic portosystemic stent shunting or other shunting procedures. Data regarding the prevalence of this subtype of HE are sparse. Cirrhosis-related parkinsonism and hepatic myelopathy are the best characterized manifestations of this form of HE. In a prospective study of 214 patients with cirrhosis awaiting liver transplantation, cirrhosis-related parkinsonism was found in 4 percent and hepatic myelopathy in 2 percent of patients.[3] The parkinsonian patients show hypomimia, hypokinesia, tremor, and rigidity similar to patients with idiopathic Parkinson disease (PD), but typically they do not develop the characteristic shuffling gait of PD and have predominant involvement of their upper limbs. Moreover, symptoms develop faster and are symmetric more often. Tremor occurs predominantly with action; a parkinsonian rest tremor is observed less commonly. The extrapyramidal symptoms may be associated with cerebellar and corticospinal deficits.

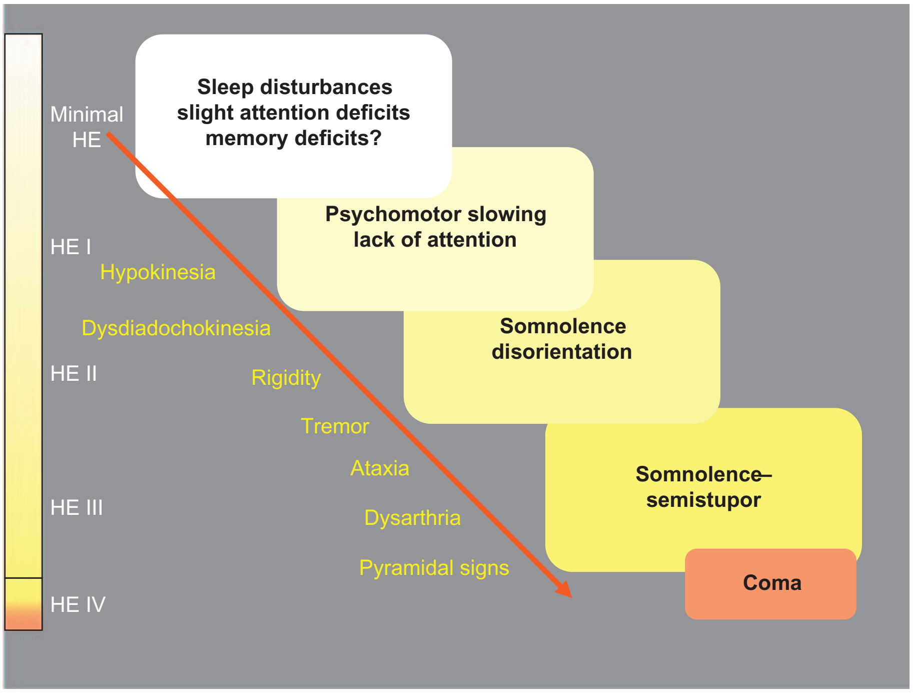

FIGURE 12-1 ■ Hepatic encephalopathy (HE) should be considered as a continuum of decreasing brain function rather than a sequence of well-defined steps of cerebral alteration. To compare different patient groups, however, grading systems such as the West Haven criteria have been developed, which subdivide patients with HE into groups depending on the extent of any alteration of consciousness. Motor symptoms of HE may be present in all grades, even in the absence of cognitive dysfunction.

Some patients present with a combination of cirrhosis-related parkinsonism and hepatic myelopathy. The myelopathy is characterized by a rapidly progressive spastic paraparesis without accompanying sensory deficits or disturbances of bladder or bowel functions.[2,3] After only a few months of progressive disability, most patients with hepatic myelopathy either depend upon an assistive device or are confined to a wheelchair. For unknown reasons most patients with hepatic myelopathy are men, whereas cirrhosis-related parkinsonism is equally prevalent in men and women.[2,3]

MINIMAL HEPATIC ENCEPHALOPATHY

Minimal HE is considered the mildest form of HE and is defined as cerebral dysfunction detectable only by neuropsychologic or neurophysiologic means in the absence of clinically overt symptoms of encephalopathy. The concept of minimal HE was developed in the 1970s when it became obvious that some patients who were considered unimpaired clinically nevertheless had significant deficits in attention, visual perception, and motor speed and accuracy on neuropsychometric tests; some only showed slowing of the electroencephalogram (EEG). These observations led to the addition of this early stage of HE to established grading systems.[1,2]

The prevalence of minimal HE ranges between 30 and 60 percent of patients with liver cirrhosis. Variations in prevalence estimates are due to differences in methods used for diagnosis and population differences regarding underlying liver diseases.

It has been suggested that minimal and grade I HE should be merged into a new class termed “covert HE” as grade I HE may only be apparent to clinicians with experience in neurologic assessment.[1] More detailed clinical examination of HE patients yields a higher number with grade I HE and fewer with minimal HE. In one study, among patients initially thought to be clinically unimpaired, bradykinesia, tremor, and hyperactive muscle stretch reflexes were detected in about 30 percent when examined in detail, and 50 percent of these patients showed eye movement abnormalities indicating cerebellar dysfunction.[2]

ENCEPHALOPATHY IN ACUTE LIVER FAILURE

The presence of HE is a prerequisite for diagnosing ALF in patients with jaundice, coagulopathy, and no pre-existing liver disease. Thus, HE is present by definition in all patients with ALF.[4] In contrast, clinically overt HE is prevalent in 10 to 14 percent of all cirrhotic patients, and in about 20 percent of patients with decompensated cirrhosis.[1] The risk of HE recurrence is 40 percent within 1 year.

In contrast to HE in patients with liver cirrhosis, HE with ALF may be complicated by significant brain edema (25 to 35% in grade III; 65 to 75% in grade IV). Currently, the prevalence of brain edema in patients with ALF seems to be decreasing, though for unclear reasons. An analysis of the case records of 3,305 patients with ALF or acute liver injury from King’s College Hospital, London, between 1973 and 2008 showed that the proportion of patients with intracranial hypertension fell from 76 percent in the period from 1984 to 1988 to 20 percent in 2004 to 2008. Multivariate analysis showed an association of intracranial hypertension with younger age, female sex, and elevated international normalized ratio.[4]

While restlessness, agitation, and irritability are characteristic of the initial phase of ALF, HE in patients with cirrhosis usually begins with psychomotor slowing. With increasing grade of HE, clinical presentations are more similar, as depressed consciousness predominates. Extrapyramidal symptoms are not typically observed in patients with ALF, but signs of corticospinal tract dysfunction are present. Seizures are a frequent complication of ALF, but occur only rarely in patients with cirrhosis.

Diagnosis of Forms of Hepatic Encephalopathy

The diagnosis of HE can only be made after exclusion of other possible causes of brain dysfunction, as the symptoms are not specific. Hyponatremia, hypo- or hyperglycemia, uremia, diabetes mellitus, and renal dysfunction are frequent in patients with cirrhosis and may resemble HE. Other important disorders to distinguish are septic encephalopathy and Wernicke encephalopathy.[1] In a neuropathologic study of the brains of 32 patients with cirrhosis who died with HE, cerebellar lesions suggestive of Wernicke encephalopathy were observed in 50 percent. The diagnosis of Wernicke encephalopathy was made in nine patients, whereas it had been made based on clinical findings in only two patients.[2]

Due to altered coagulation, intracranial hemorrhage must be considered in the differential diagnosis of HE, and brain imaging should be obtained in all patients, usually with noncontrast computed tomography (CT). Magnetic resonance imaging (MRI) requires much more cooperation than CT, and thus is not practical in agitated patients.

Cirrhosis-Related Parkinsonism

In patients with cirrhosis who develop clinical signs of extrapyramidal motor dysfunction, the differential diagnosis includes acquired hepatocerebral degeneration or an independent neurodegenerative disease. The course of the disease and the symptom combination may help to differentiate between these entities.[3]

The clinical features of cirrhosis-related parkinsonism resemble those of patients with PD. As discussed earlier, however, symptoms in PD are more often asymmetric, develop more slowly, may be associated with early gait abnormalities, are not accompanied by cerebellar or corticospinal deficits, and respond well to dopaminergic drugs.

More difficult is the distinction from multiple system atrophy (MSA), which combines extrapyramidal symptoms with cerebellar and pyramidal deficits and thereby can resemble cirrhosis-related parkinsonism. MSA likewise shows rapid progression and often a poor response to dopaminergic agents. In contrast to patients with cirrhosis-related parkinsonism, however, patients with MSA characteristically show severe autonomic dysfunction and many show alterations of the basal ganglia, midbrain, and cerebellum on MRI. Single-photon emission computed tomography (SPECT) in patients with cirrhosis-related parkinsonism shows a decreased binding capacity of striatal dopamine receptors and the dopamine transporter similar to the findings in MSA but different from those in PD, in which there is decreased availability of the transporter but not of the receptors.

Hepatic Myelopathy

A diagnosis of hepatic myelopathy can be based on the clinical findings of myelopathy and exclusion of other possible causes through MRI and cerebrospinal fluid analysis, both of which are normal in hepatic myelopathy.[3]

Minimal Hepatic Encephalopathy

The diagnosis of minimal HE depends on the results of neuropsychologic or neurophysiologic examinations in the setting of a normal clinical examination.[5–7] Debate about the most useful method for diagnosing minimal HE is ongoing. Currently the Portosystemic Encephalopathy (PSE) Syndrome Test, Inhibition Control Test, critical flicker frequency analysis, and automated EEG analysis are the most frequently used methods. A combination of the number connection tests A and B and either the digit symbol test or the block design test, or both, are used as an alternative. Working groups commissioned to elaborate an expert recommendation for diagnosing minimal HE agreed on the PSE Syndrome Test as valuable, objective, and reliable.[5] For the United States, the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) has been recommended as an alternative, because it is a valid, objective, and reliable test battery, and there are no US norms for the PSE Syndrome Test.[5] However, the RBANS has only rarely been used for diagnosing minimal HE, and thus data regarding its suitability for this purpose are sparse.

The PSE Syndrome Test is a battery of five paper-pencil tests: the number connection tests A and B, the digit symbol test, the serial dotting test, and the line-tracing test.[1,5] The latter is evaluated by measuring the time needed to perform the test and the number of errors that occur. Thus, six subtest results are scored compared to normative values. A sum score termed the portosystemic hepatic encephalopathy score (PHES) is generated ranging between +6 and −18 points; according to current German norms, scores lower than −4 are considered abnormal. Of note, local norms differ significantly, and thus must be determined for every population before the test is used for diagnosing minimal HE. The PHES correlates significantly with cerebral glucose utilization at rest in patients with minimal HE. It is a reliable predictor of the risk of both, overt HE and mortality in patients with liver cirrhosis.

The critical flicker frequency is a psychophysiologic test that has been used in the past for the assessment of central nervous system drug effects. It was recommended for diagnosing minimal HE in 2002. Light pulses are presented to the subject in decreasing frequency (usually from 60 Hz downwards), and the subject has to react as soon as the impression of fused light switches to flickering light. The critical flicker frequency depends on the experimental setting—the color and luminance of the stimuli, distance between the light source and the subject's eye, visual angle, and age. The assessment requires intact binocular vision and absence of red-green blindness. Normative data have to be elaborated for the specific equipment used. The results correlate with the PHES and can predict the development of overt HE. Of note, critical flicker frequency depends on age, and thus age-adjusted norms should be used for the evaluation of results. Moreover, scores in patients with alcoholic cirrhosis are lower than in patients with cirrhosis due to other causes. The results may also be affected by propofol given during endoscopy, though only temporarily.

The Inhibitory Control Test (ICT) has been recommended for diagnosing minimal HE as well. It is freely available online (www.hecme.tv) and is a test of attention and response inhibition. Results depend on age and education and must be compared with normative values.

The Continuous Reaction Time Test (CRT) requires a simple reaction to a series of 500-Hz tones. With developing HE, not only reaction time but especially the variability of reaction times increases. The reaction time variability is represented by the so-called CRT index, which is calculated from the fiftieth reaction time percentile/(90th − 10th percentile). Recently it was shown that the CRT index does not depend on age or sex, and is more sensitive for cerebral dysfunction in patients with liver cirrhosis than the critical flicker frequency test.

The EEG has been used for diagnosing HE for decades after it had been observed that the amount of theta and delta activity increases with increasing grade of HE. This alteration is associated initially with an increase in amplitude and the appearance of triphasic waves, followed in later stages by a decrease in amplitude, a discontinuous pattern, and finally isoelectricity in patients with coma (Fig. 12-2).[6] Occasionally the EEG is unaltered in spite of

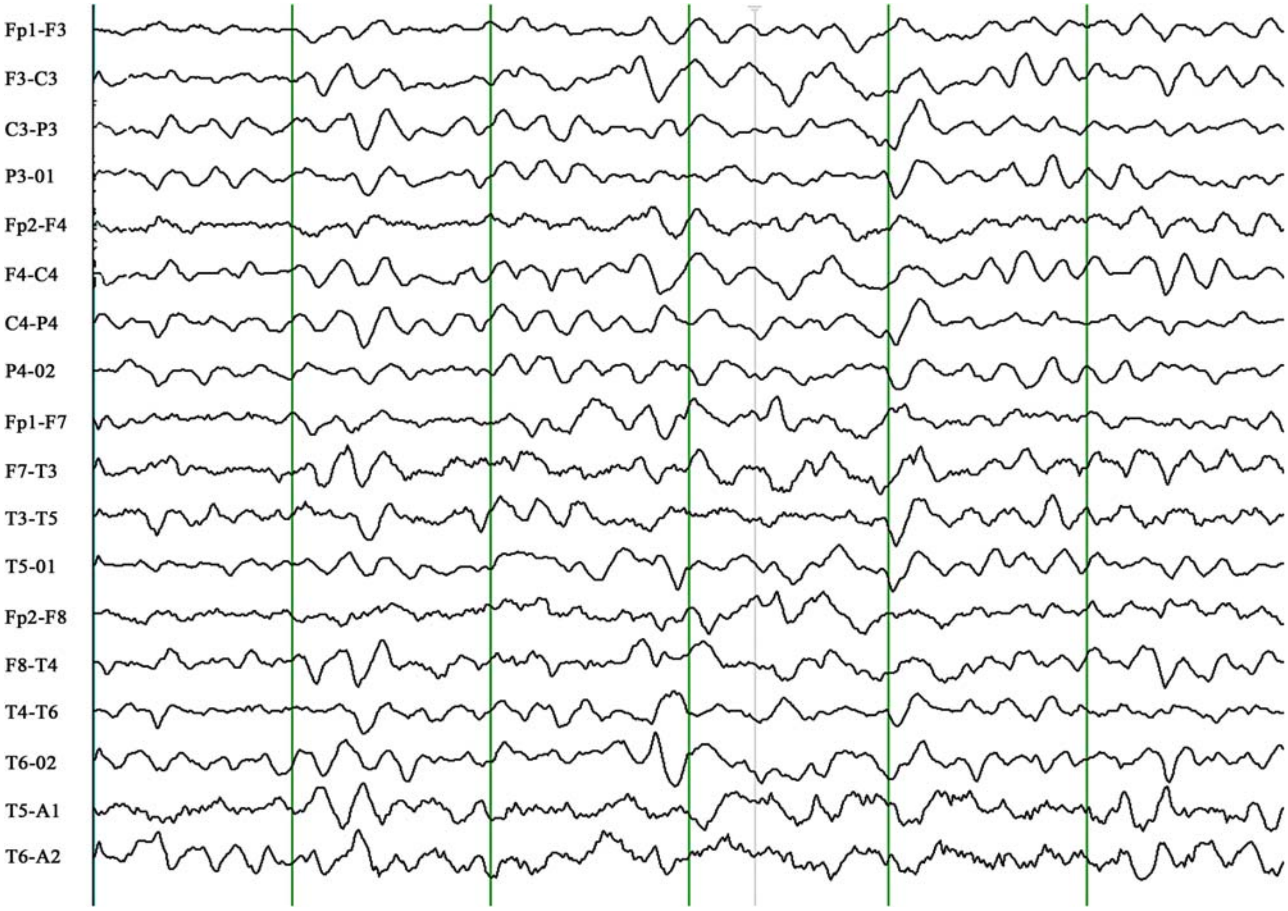

FIGURE 12-2 ▪ The EEG of a patient with hepatic encephalopathy (grade II according to the West Haven criteria). The portosystemic hepatic encephalopathy score was −17. The EEG shows diffuse slow activity (mean dominant frequency 4.49) with triphasic components. Time marker, 1 second.

clinically overt HE. Quantitative EEG analysis shows a decrease in the mean dominant frequency and an increase in theta and delta activity in only 15 to 30 percent of patients with cirrhosis having no clinical signs of HE, and in up to 40 percent of patients with clinically overt HE. Thus EEG appears more appropriate for serially following the progression of HE than for diagnosis.

Computerized EEG analysis continues to be refined, but diagnostic utility is limited at this time.

INCREASED INTRACRANIAL PRESSURE IN ACUTE LIVER FAILURE

The percentage of patients with brain edema and increased intracranial pressure (ICP) increases with more severe grades of HE in patients with ALF.[4] Since intubation and sedation are required in these patients, brain edema cannot always be detected by clinical examination. Repeated brain imaging may show the development of cerebral edema but is not feasible. Continuous monitoring of ICP is recommended by some clinicians, but the coagulopathy that accompanies ALF holds a significant risk of intracranial bleeding. As a result, ICP monitoring is not standard in the management of patients with ALF. Studies have shown no difference in mortality between patients who underwent or did not undergo ICP monitoring.

Neuroimaging

Brain imaging in HE is used to exclude other possible causes of brain dysfunction such as intracranial hemorrhage or Wernicke encephalopathy. MRI, however, may not be feasible in HE patients because of lack of cooperation due to alterations of consciousness.

Although MRI of the brain in patients with cirrhosis shows characteristic symmetric signal change with predominance in the pallidum on T1-weighted sequences, these MRI findings cannot be used to diagnose HE since some patients may show signal change with no signs of HE and others may be severely affected by HE without MRI abnormalites.[1] These MRI changes are thought to be due to deposition of manganese in the brain and correlate with serum manganese levels in patients with cirrhosis. It is still controversial whether the extent of MRI signal change is related to the extent of extrapyramidal symptoms. Of note, the MRI changes fade over about 1 year following successful liver transplantation, while the clinical symptoms of HE usually disappear immediately.

Laboratory Studies

There are no laboratory parameters that can be used for diagnosing HE. Plasma ammonia levels follow the clinical course in an individual patient, but there is no clear correlation between ammonia levels and the degree of HE.[1,2] However, if plasma ammonia is normal in a patient with liver cirrhosis and severe alteration of consciousness, the diagnosis of HE should be questioned.

Pathophysiology

The pathophysiology of HE is still incompletely understood. Currently, hyperammonemia and increased levels of inflammatory cytokines are considered to play a major role.[8,9] Blood ammonia levels may increase in patients with liver cirrhosis up to 300 μmol/L, but range between normal levels (up to 40 μmol/L) and 100 μmol/L in the majority of patients.[1,2] Although there is a correlation between plasma ammonia level and the grade of HE, there is substantial overlap, indicating that other factors besides hyperammonemia play a role in the development of HE. Increased blood ammonia levels are accompanied by an increase in cerebral ammonia concentration; in the brain, ammonia is detoxified in astrocytes by glutamine synthesis. Increased cerebral ammonia levels induce glutamine synthase activity, glutamate uptake, and glutamine production leading to osmotic pressure and water uptake. Inhibition of glutamine release from astrocytes due to a downregulation of glutamine transporters adds to cell swelling unless other osmolytes such as *myo*-inositol are released in compensation.

Astrocyte swelling is considered the key factor in the pathogenesis of HE as it triggers multiple alterations of cell function and gene expression.[8,9] Astrocyte swelling induces the formation of reactive oxygen and nitrogen oxide species, including nitric oxide (NO), which in turn induce further astrocyte swelling. Part of this cycle leads to a collapse of the mitochondrial inner membrane potential, swelling of the mitochondrial matrix, defective oxidative phosphorylation, cessation of adenosine triphosphate synthesis, and finally the generation of reactive oxygen species.

HE in patients with cirrhosis is often precipitated by electrolyte disturbances, benzodiazepines, or infection. Astrocyte swelling may be induced also by inflammatory cytokines, hyponatremia, or benzodiazepines.[8,9] The vulnerability of the brain to these precipitating factors depends on the amount of astrocytic osmolyte depletion that has taken place prior to the insult; for example, lower *myo*-inositol levels increase the risk of developing neuropsychiatric symptoms in response to a protein load.

The toxic effects of ammonia and inflammatory cytokines are amplified by intracerebral manganese deposition in patients with hepatic cirrhosis, due to impaired biliary manganese excretion. Manganese increases ammonia toxicity in astrocyte cultures and alters dopaminergic neurotransmission. Brain autopsy examinations show that manganese deposition causes cell loss and gliosis in the globus pallidus, caudate, putamen, and subthalamic nucleus.

HE in its episodic form is not accompanied by significant neuronal alterations, but the size and number of Alzheimer type II astrocytes increases. The extent of this astrocytosis correlates with the severity of HE and blood ammonia levels. Neuronal cell death is considerably less than would be expected considering the numerous cell death mechanisms present in this condition, such as NMDA receptor-mediated excitotoxicity, oxidative/nitrosative stress, and the presence of proinflammatory cytokines. It has been hypothesized that the extent of neuronal damage in liver failure may be attenuated by compensatory mechanisms including downregulation of NMDA receptors or the presence of neuroprotective steroids such as allopregnanolone. In contrast to patients with episodic HE, patients with acquired hepatocerebral degeneration show neuronal degeneration in the deep layers of cerebral cortex and subcortical white matter, particularly in the parieto-occipital cortex, basal ganglia, and cerebellum. The reason that some patients are more susceptible than others to progressive neuronal degeneration is unknown.

In patients with ALF, blood ammonia levels are markedly increased and correlate with high ICP, severity of clinical presentation, and death due to cerebral herniation.[4] However, ammonia-lowering strategies working in type C HE have not been shown to be effective in treating HE and brain edema in ALF.[4] Additional mechanisms of injury may involve proinflammatory cytokines; serum levels of tumor necrosis factor-α (TNF-α) and interleukin 6 are invariably increased in ALF patients and relate to the severity of HE. The presence of a systemic inflammatory response syndrome (SIRS) has been identified as a predictor of HE progression in patients with ALF due to acetaminophen overdose. Current models explaining brain dysfunction in ALF suggest a simultaneous reaction between systemic proinflammatory cytokines and a neuroinflammatory response to the increase of cerebral ammonia, with a corresponding increase in cerebral lactate level. The cause of the increased lactate level is not known—it was previously thought to be the consequence of an alteration of energy metabolism but currently is attributed to an altered astrocyte–neuron lactate shuttle, as high-energy phosphate levels are unaltered in animal models of ALF.

The reasons for the development of increased ICP in ALF are still unclear. Cytotoxic cerebral edema occurs in ALF, but the occurrence of vasogenic edema is controversial. Pathologic studies of patients who died with ALF have not shown evidence of a breakdown of the blood–brain barrier. However, in patients with ALF and a concomitant infection or sepsis, blood–brain barrier breakdown may occur as it does in many forms of septic encephalopathy. An increase in cerebral blood flow due to an alteration of cerebrovascular autoregulation may also play a role in the development of increased ICP in ALF.

Treatment

Hepatic Encephalopathy in Cirrhosis

Most HE episodes in patients with cirrhosis are precipitated by medications such as diuretics or sedatives, excessive protein intake, gastrointestinal bleeding, or infection. Correction of these precipitating factors is the basis of any initial therapy in these patients. In addition, treatment with drugs that reduce gut ammonia production and absorption is recommended. The most frequently administered medication for this purpose is lactulose. Its use has been supported in a recent meta-analysis of randomized controlled trials of nonabsorbable disaccharides (lactulose/lactitol) versus placebo/no intervention.[10] This showed a beneficial effect of nonabsorbable disaccharides on mortality and treatment as well as on prevention of HE. In addition, this meta-analysis found evidence that treatment with lactulose improves cognitive function and probably also quality of life in patients with minimal HE. The initial dose should be 50 ml of lactulose syrup every 1 to 2 hours until at least two bowel movements are produced. Thereafter, the dose should be reduced to produce two to three bowel movements per day (30 to 60 g or 45 to 90 ml daily).

When a patient's condition does not improve with lactulose, and concomitant disorders that might impair brain function have been excluded, lactulose should be combined with antibiotics, which also reduce gut ammonia production and absorption. In the past, neomycin and, alternatively, metronidazole were used predominantly, but nowadays rifaximin is used; it has minimal side effects and good efficacy in the treatment as well as secondary prevention of HE.[11]

In some countries, L-ornithine L-aspartate (LOLA) is used as second-line therapy for the treatment or prevention of overt HE, and predominantly in conjunction with lactulose. Data on its efficacy are sparse. The authors of a recent meta-analysis concluded that LOLA might have a beneficial effect on mortality, HE, and serious adverse events in comparison with placebo or no intervention, but they rated the quality of evidence as very low and recommended further trials.[12] Branched-chain amino acids (BCAA) have also been used for treating HE but have not yet found general acceptance. A meta-analysis including 16 randomized clinical trials where BCAA were compared to either placebo, no intervention, diets, lactulose, or neomycin, however, showed beneficial effects of oral BCAA treatment upon HE, while there was no effect on mortality.[13]

Prevention of Further Spells

Although lactulose is frequently used for the prevention of HE episodes, data supporting its use for this purpose are scant. A single-center, unblinded, randomized-controlled study showed less recurrence of HE with lactulose therapy than with placebo. This positive effect was also observed in cirrhotic patients with gastrointestinal bleeding. In one study, lactulose, probiotics, and no therapy were compared for prevention in 235 patients who had recovered from an HE episode. Both lactulose and probiotics were significantly more effective than no therapy in preventing a further HE episode during a 12-month follow-up period. A positive effect of lactulose for preventing HE episodes was also shown in patients with cirrhosis without a history of overt HE, supporting its use for primary prevention. Among the patients, 55 percent had minimal HE. Minimal HE responded to lactulose in 66 percent of cases, while improving spontaneously in only 25 percent. A recent review summed up the results of eight trials with lactulose for the prevention of overt HE, and showed that long-term lactulose therapy prevents recurrence of overt HE. Another six trials showed that addition of rifaximin to lactulose significantly reduced the recurrence of overt HE and rate of HE-related hospitalizations in comparison with lactulose therapy alone.[11] In clinical practice, routine long-term treatment with lactulose is jeopardized by noncompliance of patients due to gastrointestinal side effects. A switch to rifaximin monotherapy may be considered in these patients, but further research is needed to back up this strategy.

MINIMAL HEPATIC ENCEPHALOPATHY

Treatment of minimal HE is controversial, and data on the therapeutic effects of drugs are sparse. Since cognitive changes significantly impair the quality of life of patients and their relatives, many physicians consider treating these patients, and this strategy is supported by the results of a recent meta-analysis of various treatment studies in patients with minimal HE.[14] According to this analysis, lactulose is effective in treating minimal HE, preventing overt HE, lowering ammonia levels, and improving health-related quality of life. Rifaximin and lactulose were the most effective drugs for reversal of minimal HE while—compared to placebo or no treatment—LOLA, lactulose, and probiotics significantly reduced the risk of developing overt HE.

CIRRHOSIS-RELATED PARKINSONISM AND HEPATIC MYELOPATHY

Cirrhosis-related parkinsonism does not respond to ammonia-lowering therapies but may respond to dopaminergic drugs.[3] Liver transplantation is also sometimes helpful, but only a few cases have been reported. Patients unresponsive to lactulose may improve with rifaximin therapy. Hepatic myelopathy similarly fails to respond to ammonia-lowering therapies but liver transplantation may lead to an improvement in walking ability.[3]

Hepatic Encephalopathy in Acute Liver Failure

In patients with ALF, treatment of HE and brain edema is aimed at reducing levels of plasma ammonia and systemic cytokines.[4] A basic treatment strategy is the prophylactic use of antibiotics and antifungals along with early continuous renal replacement therapy to allow highly efficacious ammonia removal. Persistent hyperammonemia above 122 μmol/L for more than 3 days is associated with an increased risk of developing brain edema, seizures, and death. Drugs that are used for the reduction of plasma ammonia levels in patients with cirrhosis such as lactulose or LOLA have not shown a significant beneficial effect in ALF. Lactulose treatment is discouraged because gaseous distension of the bowel may impede liver transplantation surgery.

Hyponatremia is one of the causes of brain edema and intracranial hypertension in patients with ALF. Therefore normalization and even a slight elevation of plasma sodium levels up to 155 mEq/L (mmol/L) is recommended. ICP has been shown to decrease significantly in patients in whom serum sodium levels were maintained in a range of 145 to 155 mEq/L (mmol/L).

Moderate hypothermia (32° to 34°C) has been demonstrated to reduce plasma levels of proinflammatory cytokines and elevated ICP in patients awaiting emergency liver transplantation, and thus may be considered as bridging therapy in patients with uncontrolled intracranial hypertension before transplantation. Considering the negative results of a randomized controlled study, induction of moderate hypothermia for prevention of intracranial hypertension is not recommended.[4]

Brain edema in patients with ALF is currently treated with mannitol infusion every 6 hours (1 g mannitol/kg body weight) or, in cases with ICP monitoring, in response to ICP increases above 20 to 25 mmHg; mannitol should be held if serum osmolality exceeds 320 mOsm/L or in patients with oliguric renal dysfunction. ICP monitoring is often not feasible due to severe coagulopathy.

To maintain a sufficient cerebral perfusion pressure of 60 to 80 mmHg, mean arterial blood pressure should be raised in patients with hypotension to greater than 75 mmHg through repletion of intravascular volume with normal saline and the use of vasopressors (e.g., vasopressin and norepinephrine). One of the most important tasks in the treatment of patients with ALF is the identification of those who will need liver transplantation; the King's College criteria are frequently used for this purpose.[4]

PANCREATIC ENCEPHALOPATHY

Definition and Clinical Features

Pancreatic encephalopathy is a controversial entity consisting of a confusional state due to acute pancreatitis. The underlying pathophysiology remains unclear. Since acute pancreatitis is accompanied by the SIRS, electrolyte abnormalities, hypotension, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, and hyperglycemia, all of which can induce brain dysfunction, the delineation of a discrete disease is difficult.[15] There is some evidence that pancreatic enzymes themselves are involved in the development of a metabolic encepalopathy. The activation of phospholipase A by trypsin and bile acid likely plays a key role in the pathophysiology of pancreatic encephalopathy. Activated phospholipase A converts lecithin and cephalin into their hemolytic forms. Phospholipase A and hemolytic lecithin then may destroy the blood–brain barrier, resulting in demyelination, hemorrhage, and edema due to increased vascular permeability. Neuropathologic studies of patients who died with pancreatic encephalopathy show capillary necrosis with diffuse petechial hemorrhages, encephalomalacia, and perivascular demyelination.

Pancreatic encephalopathy usually begins within 2 weeks after the onset of acute pancreatitis, most often between the second and fifth days. Clinical symptoms, which may fluctuate, include disorientation, confusion, agitation, anxiety, irritability, delirium, hallucinations, dysarthria, ataxia, akinetic mutism, rigidity, hemiparesis, hyperreflexia, and seizures. Patients may develop stupor and coma. In a 7-year follow-up case report, recurrence of neurologic symptoms occurred with each relapse of pancreatitis, and a close relationship was found between serum amylase levels and the occurrence of neurologic symptoms. Neuropsychiatric symptoms do not correlate in severity with the pancreatitis, and improvement of these symptoms may lag behind recovery from pancreatitis. The mortality rate from pancreatic encephalopathy is estimated to be as high as 50 percent.

Diagnosis

Pancreatic encephalopathy should be suspected in any patient with severe abdominal pain and altered consciousness. Since neither symptoms nor laboratory or imaging results are specific for the disorder, the diagnosis can only be made after exclusion of other possible causes of brain dysfunction. The EEG typically shows generalized slowing. The cerebrospinal fluid may show a mild increase in protein and glucose concentration, but is normal in most cases. In a few cases, lipase concentrations in the cerebrospinal fluid have been assessed and were slightly elevated. There are only a few reports of brain MRI findings in patients with pancreatic encephalopathy and these describe predominantly diffuse or scattered white matter abnormalities. Abnormalities of the pons and cerebellar peduncles have been seen on diffusion-weighted and fluid-attenuated inversion recovery sequences. A case of pancreatic encephalopathy associated with pontine and extrapontine myelinolysis involving the brain and spinal cord has been described.

Treatment

There are no standard recommendations for the treatment of pancreatic encephalopathy other than supportive therapy along with treatment of the underlying pancreatitis. In one study, a significant decrease was found in the frequency of pancreatic encephalopathy in patients with acute pancreatitis treated with low-molecular-weight heparin compared to a control group. This effect may result from a reduction in pancreatitis-associated microvascular disturbances and hemorrhagic necrosis.

Patients with pancreatitis are also at risk of developing Wernicke encephalopathy due to hyperemesis, anorexia, and the necessity of prolonged total parenteral nutrition. Thiamine deficiency should be considered in these patients and treated prophylactically.

  - *Treatment*

The presence of gastrointestinal (GI) dysfunction in the setting of neurologic disease has received increasing attention in recent years, particularly in disorders such as Parkinson disease. Much less attention has been devoted to the occurrence of neurologic dysfunction in primary GI disease processes. The enteric nervous system (ENS), which lines virtually the entire GI tract, contains approximately the same number of neurons as the spinal cord and is capable of generating and controlling many functions entirely independently of the central nervous system (CNS). It should not be surprising, then, that processes affecting the GI system, including the ENS, also may affect the CNS or systems controlled by the CNS.

GASTROINTESTINAL DISORDERS

Bariatric Surgery

The increasing prevalence of obesity worldwide has led to immense growth in bariatric surgery, which typically is performed after behavioral modification, medical nutrition therapy, and physical activity enhancement strategies have failed. The number of bariatric operations performed in the United States has increased over the past three decades, and the American Society for Metabolic and Bariatric Surgery estimates that up to 228,000 procedures were performed in 2017 alone.[1] Different methods of surgical intervention, including gastric restriction procedures (e.g., laparoscopic adjustable gastric banding, sleeve gastrectomy, vertical banded gastroplasty), malabsorptive procedures (e.g., biliopancreatic diversion, jejunoileal bypass), and combined restrictive and malabsorptive procedures (e.g., Roux-en-Y gastric bypass, duodenal switch with biliopancreatic diversion) have been performed frequently, but sleeve gastrectomy, in which approximately 75 to 85 percent of the stomach is removed along the greater curvature, is particularly growing in popularity. Neurologic complications may occur following all of these procedures, both in the immediate perioperative period and months to years after the surgery.

Aminoff's Neurology and General Medicine, Sixth Edition.

Neurologic complications occur in a range of 3 to 16 percent following these procedures. Although peripheral nervous system disorders appear to be the most frequent neurologic complications, encephalopathy, myelopathy, and optic neuropathy all have been reported. The mechanisms of neural injury following bariatric surgery include both mechanical compression and entrapment leading to mononeuropathies as well as nutritional deficiencies. Rapid weight loss can lead to loss of protective fat pad and compression through loss of subcutaneous tissue. Injury from mechanical retractors or malpositioning during surgery can lead to immediate complications after bariatric surgery. The most important factors in the pathogenesis of neurologic complications are nutritional deficiencies, often due to malabsorption or prolonged emesis.

Three patterns of peripheral neuropathy have been described following bariatric surgery: sensory-predominant polyneuropathy, mononeuropathy, and radicular or plexus neuropathy. Peripheral neuropathy is reported in over 15 percent of patients following bariatric surgery, compared with only 3 percent of patients undergoing cholecystectomy. In a subsequent cohort drawn from a single tertiary referral center, investigators noted peripheral neuropathy in only 7 percent but did not report on the frequency of other types of neurologic complications.[2] Peripheral neuropathy typically is chronic, although acute inflammatory demyelinating polyneuropathy also has been reported. Carpal tunnel syndrome is the most frequent mononeuropathy, accounting for 80 percent of cases. Lateral femoral cutaneous neuropathy (meralgia paresthetica) develops in only around 1 percent of individuals despite recent weight loss being a well-known risk factor for its development. Peroneal neuropathy leading to numbness and weakness in the affected leg can manifest as "foot drop" and pose functional limitations to the patient. Risk factors include marked weight loss, rapid rate of weight loss, and postoperative complications.

Nutritional deficiencies (see Chapter 15) due to malabsorption are responsible for the development of neuropathy in many, although not all, instances. Deficiencies of riboflavin, pyridoxine, vitamin B_{12}, folate, vitamin D, vitamin E, and copper all have been described. Thiamine deficiency, one of the most common and serious complications of bariatric surgery, can lead to Wernicke encephalopathy and may appear within days to weeks following the surgery.

Optic neuropathy after bariatric surgery can be caused by copper, vitamin B_{12}, and thiamine deficiency. Other neuro-ophthalmic presentations are nyctalopia (the inability to see in dim light or at night) due to vitamin A or zinc deficiency and ophthalmoparesis due to vitamin E deficiency.

Muscle weakness has been reported in around 7 percent of patients after bariatric surgery, primarily in patients with hypokalemia or with global protein, vitamin D, or copper deficiencies. Postoperative rhabdomyolysis may occur and is especially frequent in patients undergoing Roux-en-Y gastric bypass; small series suggest up to three-quarters of patients may experience this complication which presents with muscle pain, typically in the gluteal region, accompanied by an increase in serum creatine kinase (CK) levels. The development of surface and deep tissue pressure during surgery may be responsible. The risk of rhabdomyolysis is greatest when the BMI of the patient is greater than $56\,\mathrm{kg/m^2}$ and the duration of the surgery is more than 230 minutes. CK testing should be performed in all patients after bariatric surgery to make an early diagnosis and promptly start fluids and diuretics. Osteomalacia and associated osteomalacic myopathy may also develop postoperatively. An acquired myotonic syndrome also has been reported.

Spinal cord dysfunction is another potential complication of bariatric surgery. Symptoms often start insidiously and may not become apparent until 5 to 10 years later. These symptoms may include gait ataxia and spasticity with pyramidal signs, paresthesias, loss of proprioception and vibratory sensation, and limb weakness often restricted to the legs. Many of these patients are found to have low serum vitamin B_{12}, vitamin E, or copper levels.

Cortical dysfunction bearing the characteristics of Wernicke encephalopathy, also known as "bariatric beriberi," complicated bariatric surgery in approximately one-quarter of patients in one study but was noted much less frequently in larger prospective investigations. Current guidelines for bariatric surgery recommend preventive thiamine supplementation (12 mg) in multivitamin treatment for all patients undergoing surgery, with higher doses for patients with suspected deficiency.[3]

Celiac Disease

Celiac disease (CD) is characterized by the constellation of diarrhea, malabsorption, weight loss, and gaseous distension that develops as a consequence of damage to the mucosa of the small intestine, triggered by an immune-mediated response to gluten. The prevalence of CD in American and European populations has been estimated to be approximately 1 percent, but because the number of undiagnosed patients may be considerable, its prevalence is probably much higher. Genetic factors play a role, and almost all patients with celiac disease possess specific variants of the HLA class II genes *HLA-DQA1* and *HLA-DQB1* that, together, encode the two chains (α and β) of the celiac-associated heterodimer proteins DQ2 and DQ8 that are expressed on the surface of antigen-presenting cells.

In recent years there has been a rise in the overall prevalence of CD in Western countries, but the reason for this "epidemic" remains unclear. The increased rate of diagnosis seems to be due to a true rise in incidence rather than merely increased awareness and detection. Approximately 30 percent of the general population carry the *HLA-DQ2/8* celiac disease susceptibility genes; however, only 2 to 5 percent of these individuals will go on to develop celiac disease, suggesting that additional environmental factors contribute to disease development. Epidemiologic, clinical, and animal studies suggest that exposure to nonpathogenic microorganisms early in life is associated with a reduced risk of developing CD. Several studies have shown an association between alteration in gut microbiota composition and function and CD, some of which can precede the onset of disease and persist when patients are on a gluten-free diet.

Individuals with classic CD have serum antigliadin antibodies along with additional gliadin-related antibodies (e.g., antiendomysial, antitransglutaminase). The pathology of CD extends beyond the GI tract, leading to proposals that the term *gluten sensitivity* be used for individuals displaying more widespread involvement, with the label CD reserved for those with evidence of enteropathy on small bowel biopsy.

Neurologic dysfunction has been reported in 6 to 12 percent of patients with CD. A systematic review reported the prevalence of neuropathy in CD patients to be up to 39 percent, with an increased risk in older and female patients.[4] In studies of CD patients with neurologic manifestations, gluten ataxia was reported in 20 to 40 percent of patients. Neurologic dysfunction in CD often is ascribed to nutritional deficiency secondary to malabsorption, although immunologic mechanisms may be an alternative explanation in some instances.

ATAXIA

Gluten ataxia has no uniquely distinguishing clinical characteristics and remains a controversial entity. Gait ataxia is present in all individuals by definition; limb ataxia, dysarthria, and ocular signs are present in most. Individuals with gluten ataxia may display cerebellar atrophy, which may be irreversible. Other neurologic symptoms may include encephalopathy, myopathy, myelopathy, and ataxia with myoclonus and chorea. Gluten ataxia usually has an insidious onset with a mean age at onset of 53 years. The classic GI symptoms of CD are present in less than 10 percent of individuals with gluten ataxia and evidence of classic CD is found on duodenal biopsy in only 25 to 33 percent. Diagnostic delays are frequent and can result in permanent neurologic disability.[4] CD patients with gluten ataxia often have oligoclonal bands in their cerebrospinal fluid, evidence of perivascular inflammation in the cerebellum, and anti-Purkinje cell antibodies. Cerebellar atrophy and white matter abnormalities may be evident on magnetic resonance imaging (MRI).

In the initial reports, antigliadin antibodies (IgG, IgA, or both) were found in 41 percent of patients with sporadic idiopathic ataxia, compared with only 15 percent of those with clinically probable multiple system atrophy (MSA), 14 percent with familial ataxia, and 12 percent of normal controls. In a follow-up study, 148 out of 635 (23%) patients with sporadic ataxia evaluated at the same clinic were noted to have evidence of gluten sensitivity.[5] Individuals with gluten ataxia, independent of intestinal involvement, demonstrate antitransglutaminase 6 IgG and IgA antibodies, whereas antitransglutaminase 2 IgA antibodies are present in persons with GI disease. The cerebellar damage has been attributed to a chronic, immune-mediated inflammatory process. Autopsy examination in several affected individuals has demonstrated Purkinje cell loss and lymphocytic infiltration within the cerebellum as well as the posterior columns of the spinal cord. Cerebellar IgA deposits containing transglutaminase 6 also have been found. Gluten ataxia sometimes responds to a gluten-free diet. Studies suggest that the presence or absence of enteropathy does not influence the beneficial response to a gluten-free diet and, therefore, patients with positive serology and negative duodenal biopsy should still be placed on a strict gluten-free diet. Intravenous immunoglobulin therapy reportedly ameliorates the ataxia in some patients.

Screening has been suggested for all individuals who present with adult-onset ataxia without any other obvious cause, but this recommendation remains controversial.

PERIPHERAL NEUROPATHY

Peripheral neuropathy accounts for around 20 percent of the neurologic abnormalities in patients with CD. Sural nerve biopsy demonstrates axonal injury in patients with chronic axonal sensorimotor neuropathy. In one study, 167 patients with CD without any symptoms of neuropathy were tested electrophysiologically. These tests did not show any evidence for subclinical neuropathy and the investigators concluded that in asymptomatic cases with celiac disease, electrophysiologic studies are not necessary. The etiology of the neuropathy is uncertain; both nutritional and autoimmune mechanisms have been proposed.

As with sporadic ataxia, some studies suggest that the prevalence of CD or of antigliadin antibodies is higher in individuals with peripheral neuropathy than in the general population. This has led to the use of the term *gluten neuropathy* for individuals with idiopathic neuropathy and serologic evidence of gluten sensitivity. Improvement with a gluten-free diet has been reported by some, but other studies have failed to demonstrate improvement.

MYOPATHY

CD is more prevalent in patients with inflammatory myopathies, particularly inclusion-body myositis. Immunologic mechanisms probably are responsible in most instances, but in one patient with CD and a myopathy resembling inclusion-body myopathy, reversal of both clinical and pathologic abnormalities was documented upon treatment with vitamin E and institution of a gluten-free diet.

EPILEPSY

An association between CD and epilepsy is controversial. The reported prevalence of epilepsy in CD has ranged from 1 to 7 percent and that of CD in individuals with epilepsy from 1 to 8 percent. A population-based study showed a moderately increased risk of epilepsy in individuals with CD. In other large studies, the presence of CD-associated antibodies did not differ between patients with epilepsy and individuals without epilepsy. A specific syndrome of epilepsy, bilateral occipital lobe calcifications, and CD has been described, largely in Italians. The mechanism for such an association is obscure. Even in CD patients without calcifications, seizures originate most frequently in the occipital lobe. A gluten-free diet may improve seizure control, especially when started early.

OTHER MANIFESTATIONS

A number of other neurologic manifestations of CD have been reported but less extensively evaluated, including migraine, sensorineural hearing loss, depression, learning disabilities, autonomic neuropathy, and neuromyelitis optica. The significance of these associations is uncertain.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a group of diseases characterized by chronic or relapsing immune activation in the GI tract resulting in inflammation. Ulcerative colitis and Crohn disease are two major forms of IBD. These two conditions share many clinical and even pathologic features, but also display important differences (Table 13-1). An autoimmune etiology in genetically susceptible individuals, characterized by a dysregulated mucosal immune response to antigens normally present within the intestinal lumen, is suspected in both.

In Europe and North America, the incidence of ulcerative colitis is in the range of 8 to 23 per 100,000 persons. Incidence rates of 6 to 23 per

TABLE 13-1 ■ Gastrointestinal Features of Inflammatory Bowel Disease

Feature	Crohn Disease	Ulcerative Colitis
Diarrhea	Common, nonbloody, less urgent	Common, bloody, urgent
Rectal bleeding	Occasional	Very common
Weight loss	Common	Uncommon
Abdominal pain	Prominent	Not prominent
Stricture formation	Common	Rare
Fistula formation	Common	Very rare

TABLE 13-2 ■ Nervous System Involvement in Inflammatory Bowel Disease

Peripheral
- Generalized
  - Sensorimotor neuropathy

  - Lacunar
  - Venous sinus thrombosis
- Demyelinating
- Myelopathic
- Seizures
- Encephalopathy
  - Nutritional
  - Vasculitis

100,000 have been reported for Crohn disease in the same regions, but in other parts of the world, such as Asia, a previously low incidence appears to be increasing.[6]

IBD should be considered a systemic disease and involvement outside the GI tract is well described. Neurologic dysfunction appears to be relatively infrequent, with wide-ranging estimates from less than 1 to 33 percent of patients. Neurologic dysfunction may precede the appearance of GI symptoms, and both peripheral and CNS involvement occurs (Table 13-2). Autoimmune mechanisms are primarily responsible for the development of neurologic involvement in IBD; however, nutritional deficiency (vitamin B_{12} and selenium), iatrogenic (e.g., metronidazole neurotoxicity), infection, and other processes such as thromboembolic complications may secondarily involve the nervous system. Treatment for both Crohn disease and ulcerative colitis involves potent medications, including antitumor necrosis factor α (anti-TNF-α) agents, monoclonal antibodies, and immunosuppressive medications (such as cyclosporine and sulfasalazine) that can produce neurologic complications.

Peripheral Neuropathy

Peripheral neuropathy is the most frequent neurologic complication of both Crohn disease and ulcerative colitis. The reported frequency of peripheral neuropathy in IBD varies greatly among published studies, with estimates ranging from 0 to 39 percent depending on the study population characteristics and neuropathy criteria. The etiology of peripheral nerve involvement in IBD appears to be multifactorial, including nutritional deficiency, medication side effects, and an autoimmune mechanism as part of the primary disease. The phenotype of peripheral neuropathy in IBD is diverse, but peripheral neuropathy is usually more severe in patients with Crohn disease than in patients with ulcerative colitis. Involvement may take the form of focal (e.g., mononeuropathy, cranial neuropathy, brachial plexopathy), multifocal (e.g., mononeuritis multiplex, multifocal motor neuropathy), and generalized (acute or chronic inflammatory demyelinating polyneuropathy, small- or large-fiber axonal sensorimotor neuropathy) neuropathic processes. However, it also frequently includes ataxic and demyelinating forms.

Peripheral neuropathy occurs late in the course of the disease and mainly during periods of bowel disease inactivity. The common phenotypes of peripheral neuropathy are a mild, chronic, large-fiber, sensory-predominant polyneuropathy and a moderately severe immune radiculoplexus neuropathy. Carpal tunnel syndrome appears to be the most frequently occurring isolated mononeuropathy in IBD. Axonal neuropathy occurs more frequently than demyelinating neuropathy.

Two specific patterns of cranial nerve involvement have been described in IBD. Acute sensorineural hearing loss or chronic subclinical hearing impairment has been described in ulcerative colitis. In contrast, Melkersson–Rosenthal syndrome, characterized by recurrent facial nerve palsy along with intermittent orofacial swelling and fissuring of the tongue, has been reported in patients with Crohn disease.

DEMYELINATING DISEASE

An association between IBD, especially ulcerative colitis, and multiple sclerosis (MS) has been reported. In a systematic review, it was suggested that both IBD and MS patients have a 50 percent increased risk of MS or IBD comorbidity, respectively, with no apparent difference between patients with Crohn disease or ulcerative colitis.[7] The odds ratio for MS in patients with IBD is around 1.5. White matter lesions may be present on MRI in patients with IBD; whether these represent MS or another ischemic or demyelinating process is unclear. The development of demyelination within the CNS as an adverse effect of anti-TNF-α agents has been reported.

CEREBROVASCULAR DISEASE

Vascular complications are rare, but well-documented, extraintestinal manifestations of IBD. A large population-based case-control study demonstrated an increased risk of ischemic stroke only in younger individuals (age <50 years) with Crohn disease. It is estimated that 1 to 6 percent of adults with IBD and 3 percent of children with IBD develop cerebrovascular complications at some point during the course of their disease. Responses to both immunosuppressive therapy (e.g., corticosteroids and azathioprine) and anticoagulation have been reported, suggesting that both hypercoagulable and autoimmune processes may play a role.

A variety of cerebrovascular events has been reported in Crohn disease and ulcerative colitis, including both large-artery and lacunar infarcts. Cerebral venous sinus thrombosis in IBD occurs more frequently in ulcerative colitis; individuals with active disease are at greater risk. Thrombocytosis due to enhanced platelet aggregation and platelet activation in patients with IBD can cause stroke. Once activated, platelets release inflammatory mediators and increase the likelihood of cerebral venous sinus or arterial thrombosis. The lateral and superior sagittal sinuses are involved most frequently. Severe iron-deficiency anemia may be a significant risk factor for thrombosis.

MYOPATHY

Myopathy is relatively rare in IBD, occurring in 0.5 percent of patients. Symptoms may precede the appearance of GI dysfunction, but this is unusual.

Both generalized inflammatory muscle disease and focal muscle involvement have been described, primarily in Crohn disease. Abscess formation in the psoas or other muscles is an important potential complication; psoas muscle abscess is characterized by flank, pelvic, or abdominal pain, usually associated with fever and leukocytosis. The diagnosis is confirmed by ultrasound or computerized tomography (CT). Focal myositis involving the gastrocnemius and other muscles has been reported.

MYELOPATHY

A slowly progressive myelopathy may develop in the setting of IBD and may account for approximately 25 percent of patients with neurologic involvement. It is more likely to occur in patients with Crohn disease, who may develop vitamin B_{12} deficiency as a consequence of surgical resection of the terminal ileum. Patients with Crohn disease also may develop a more acute myelopathy or cauda equina syndrome due to empyema from extension of a fistula to the epidural or subdural space.

OTHER MANIFESTATIONS

Seizures may occur as a complication of the surgical management of IBD, precipitated by fluid overload, electrolyte imbalance, hypoxia, and corticosteroid administration or withdrawal. They may occur also as a complication of cyclosporine treatment.

In one prospective multicenter study in patients with Crohn disease, the incidence of restless legs syndrome (RLS) was 43 percent and prevalence was 30 percent. In this population, symptoms of RLS started during or after the onset of Crohn disease symptoms in most patients, suggesting a link between these disorders.[8]

Diffuse encephalopathy and acute disseminated encephalomyelitis also have been reported. Both Wernicke encephalopathy and possible selenium-induced encephalopathy have been described in individuals with Crohn disease receiving total parenteral nutrition. Autonomic neuropathy has been reported rarely in both Crohn disease and ulcerative colitis. Both ocular and generalized forms of myasthenia gravis (MG) have been reported with both disorders. Case reports of patients with MG and IBD describe improvement of symptoms following surgical interventions (one with thymectomy and one with protocolectomy), suggesting an immunologic link between MG and IBD.

Whipple Disease

Although originally described as a GI disease, with symptoms of diarrhea, weight loss, and abdominal pain, Whipple disease is a multisystem disorder that also may be characterized by joint, dermatologic, lymphatic, cardiac, pulmonary, ocular, and neurologic dysfunction. The average age of symptom onset is approximately 50 years, and males are affected much more frequently than females. Over two-thirds of patients are either farmers or have occupational exposure to soil. This disease was initially thought to be related to an uncultured bacteria, but DNA sequencing has demonstrated *Tropheryma whipplei* to be responsible.

Neurologic dysfunction is the presenting feature in approximately 5 percent of persons with Whipple disease. Symptoms of CNS involvement eventually develop in 10 to 40 percent of patients, and postmortem examinations demonstrate CNS lesions in over 90 percent of individuals (Table 13-3). Cognitive impairment, such as dementia, is the most frequently observed neurologic manifestation, occurring in around 70 percent of patients, often accompanied by psychiatric symptoms such as depression and personality or behavioral changes. Peripheral neuropathy is very rare in Whipple disease and usually is due to micronutrient or vitamin deficiency caused by malabsorption. Cerebellar dysfunction with gait and balance impairment occurs in approximately 20 percent of persons; pyramidal tract abnormalities also may occur. Symptoms indicative of hypothalamic involvement, such as insomnia, hypersomnia, hyperphagia, polyuria, and polydipsia, are uncommon. Myopathy has been reported in a small number of patients; in these cases muscle biopsy shows muscle fiber atrophy and intrafascicular macrophages which are PCR positive for *Tropheryma whipplei*.

TABLE 13-3 ■ Neurologic Features of Whipple Disease

- Cognitive impairment
- Psychiatric dysfunction
  - Depression
  - Personality change
- Hypothalamic manifestations
  - Insomnia
  - Hypersomnia
  - Hyperphagia
  - Polydipsia and polyuria
- Oculomasticatory myorhythmia
- Oculofacial-skeletal myorhythmia
- Vertical gaze impairment
- Seizures
- Ataxia
- Peripheral neuropathy

Oculomasticatory myorhythmia, characterized by the combination of pendular convergence nystagmus and concurrent slow, rhythmic synchronous contractions of the masticatory muscles, develops in approximately 20 percent of individuals with CNS manifestations of Whipple disease. These movements invariably are accompanied by a supranuclear vertical gaze paresis. Sometimes the muscle contractions also involve the extremities, prompting use of the term oculofacial-skeletal myorhythmia. These two movement disorders are considered by some to be pathognomonic of Whipple disease. Other ophthalmologic abnormalities, such as ptosis, internuclear ophthalmoplegia, and pupillary dysfunction, also may occur. Whipple disease can present without its classic manifestations, but with prominent parkinsonism and with slowing and curved trajectory of vertical saccades.

Prompt diagnosis of Whipple disease is important because effective treatment is available. Cerebrospinal fluid (CSF) PCR analysis appears to be a more sensitive method of diagnosis than identification of PAS-positive inclusions in macrophages in duodenal biopsy specimens, but there is some evidence that *Tropheryma whipplei* DNA may be present in healthy individuals without the disorder. In individuals with CNS symptomatology, brain biopsy is positive in 80 percent of instances. CSF analysis may show an inflammatory response that sometimes contains PAS-positive macrophages. CSF PCR is positive in 80 percent of patients with Whipple disease and neurologic symptoms.

The rarity of the disorder has precluded formal clinical trials, but an initial 2-week course of parenteral therapy with either a combination of penicillin G and streptomycin or with a third-generation cephalosporin (e.g., ceftriaxone) is recommended, followed by a 1-year course of oral trimethoprim-sulfamethoxazole.[9] The prolonged course of trimethoprim-sulfamethoxazole, which crosses the blood–brain barrier, is intended to treat CNS involvement. A combination of doxycycline and hydroxychloroquine, supplemented by sulfadiazine, is an alternative regimen. It is important to treat the disease adequately when first identified, because CNS relapses have a poor prognosis and high mortality rate.

Malabsorption Syndromes

Historically, maldigestion is defined as defective breakdown of nutrients, and malabsorption is defined as defective mucosal absorption. However, the digestive process is more complex and factors such as solubilization, intestinal motility, and hormone secretion contribute to the normal absorption of nutrients, vitamins, and minerals. Malabsorption can be caused by many diseases of the small intestine and also by diseases of the pancreas, liver, biliary tract, and the stomach. Abdominal distension and pain, flatulence, diarrhea, weight loss, and ascites are the classic GI features of malabsorption. Systemic involvement may be characterized by dermatologic, musculoskeletal, renal, hematologic, reproductive, and neurologic dysfunction. These and other nutritional disorders are discussed further in Chapter 15.

VITAMIN E DEFICIENCY

Neurologic dysfunction in the setting of vitamin E deficiency can be genetic in origin, due to a mutation in the α-tocopherol transfer protein gene, with a clinical presentation that can mimic Friedreich ataxia. In most instances, however, it is the consequence of fat malabsorption, which can occur in a variety of circumstances.

Neurologic symptoms and signs of vitamin E deficiency may include ataxia, dysarthria, and nystagmus. Symptoms and signs of peripheral neuropathy, including paresthesias, impaired proprioception and vibration, and hyporeflexia are common. Proximal muscle weakness from myopathy, pigmentary retinopathy, action tremor, limb dysmetria, and dystonia also have been described.

Somatosensory evoked potentials may demonstrate abnormalities indicative of posterior column dysfunction. Diffuse white matter changes have been described in patients with vitamin E deficiency, in both the cerebrum and spinal cord; some of these patients present with upper motor neuron signs.

The appearance of symptoms of vitamin E deficiency can be strikingly delayed. In post-gastrectomy patients, it may take up to 50 months for evidence of vitamin E deficiency to appear. Vitamin E supplementation in high doses (800 mg daily) helps to prevent progression and may even reverse some of the neurologic signs.

FAMILIAL HYPOCHOLESTEROLEMIA

Three distinct genetic disorders—familial hypobetalipoproteinemia, abetalipoproteinemia, and chylomicron retention disease—have been identified as causes of chronic diarrhea, malabsorption, malnutrition, growth retardation, and vitamin E deficiency. Of the three, neurologists are most familiar with abetalipoproteinemia, previously known as Bassen–Kornzweig syndrome.

Abetalipoproteinemia is an autosomal recessive disorder due to a mutation in the microsomal triglyceride transfer protein (*MTP*) gene on chromosome 4, which leads to impaired biogenesis of chylomicrons and very-low-density lipoprotein (VLDL) along with an inability to absorb fats and fat-soluble vitamins including vitamin E. The clinical features of abetalipoproteinemia include steatorrhea, diarrhea, retinitis pigmentosa, acanthocytosis, and a variety of neurologic features. Blood lipid analysis demonstrates extremely low plasma levels of total cholesterol, VLDL, and low-density lipoproteins (LDL); apolipoprotein B, triglycerides, and chylomicrons are virtually absent. GI symptoms usually are evident during infancy, but neurologic dysfunction may not appear until individuals are in their teens or even older. Neurologic symptoms include progressive cerebellar ataxia and sometimes a sensorimotor neuropathy. Both the ataxia and the peripheral neuropathy probably are due to vitamin E deficiency. Additional neurologic abnormalities that have been described include upper motor neuron signs and both resting and postural tremor. Treatment of neurologic dysfunction with both vitamin E and vitamin A has been advocated, but results have been mixed.

TROPICAL SPRUE

Tropical sprue remains a significant cause of malabsorption in both indigenous residents of tropical countries and travelers visiting the tropics. The etiology remains obscure but possibly is the consequence of small intestinal mucosal damage inflicted by protozoa, helminths, bacteria, viruses, or a variety of other disease processes of inflammatory, autoimmune, or neoplastic origin. Diagnosis requires the demonstration of malabsorption and the exclusion of other specific pathologies including celiac disease, chronic pancreatitis, and parasitic infections.

Infrequently encountered in North America, tropical sprue has been reported to account for approximately 40 percent of malabsorption in children and adults in some portions of south Asia. The usual presentation includes chronic diarrhea, steatorrhea, glossitis, abdominal distention, and weight loss. Tropical sprue typically involves the entire length of the small intestine, in contrast to celiac disease, which usually spares the terminal ileum. Mucosal damage results in malabsorption of fat, carbohydrates, and multiple vitamins, including folate and vitamins A, E, and B_{12}.

Neurologic symptoms are present in approximately two-thirds of individuals with tropical sprue. Proximal muscle weakness and peripheral neuropathy are most common. Night blindness, presumably due to vitamin A deficiency, and combined system degeneration, presumably the result of vitamin B_{12} deficiency, have been described. The peripheral neuropathy has been attributed to vitamin E deficiency.

Antibiotic therapy, typically with tetracycline or doxycycline for 6 months, and a high-calorie, high-protein, fat-restricted diet are the standard treatments for tropical sprue, but abnormal small intestine permeability may remain following treatment.

WERNICKE ENCEPHALOPATHY

Wernicke encephalopathy (WE) is an acute neuropsychiatric syndrome that is most closely linked to chronic alcoholism with nutritional thiamine deficiency, but also can result from malabsorption of thiamine (see Chapters 15 and 33). In nonalcoholic patients, the full classic triad of neurologic features—mental status changes, ophthalmoplegia, and ataxia—develops in only 10 to 16 percent of individuals.

Thiamine is absorbed primarily in the duodenum, but the stomach also plays a role. As a result, Wernicke encephalopathy has been documented following bariatric surgery. Oudman and colleagues reviewed all published cases after bariatric surgery between 1985 and 2017 and reported that the latency between bariatric surgery and onset of symptoms was not significantly different between the three most reported surgical procedures (gastroplasty, gastric bypass, and sleeve gastrectomy).[3] Wernicke encephalopathy developed as early as the first month and as late as the 425th month after surgery. Although a large majority of cases (79.1%) developed in the first 6 months, 4 to 12 weeks postoperatively was the most frequent time frame. Gastric bypass or a restrictive procedure is the most common operation that predisposes to it. Repeated vomiting, presumably with decreased thiamine absorption as a result, is a frequent risk factor. Individuals undergoing Roux-en-Y gastric bypass have an additional risk since thiamine is predominantly absorbed in the duodenum, which is bypassed following this procedure.

Werrnicke encephalopathy also has been described in individuals with other causes of malabsorption. In one patient with a history of neonatal necrotizing enterocolitis and subsequent bowel resection, it developed as an adult during pregnancy and was attributed to long-standing chronic malabsorption exacerbated by the pregnancy.

PELLAGRA

Pellagra often is considered to be extinct in developed countries, but it still occurs in rare instances. It is caused by niacin deficiency, but can also develop secondary to deficiency of tryptophan, a precursor of niacin. Pellagra most often is diagnosed in individuals with chronic alcoholism and inadequate nutritional intake, but also may develop in patients with HIV infection, anorexia, and malabsorption syndromes.

The classic clinical features of pellagra include the triad of dermatitis, diarrhea, and dementia, although most individuals do not have all three features. In addition to dementia, neurologic abnormalities may include headache, irritability, poor concentration, apathy and confusion, vertigo, myoclonus, tremor, rigidity, weakness, dysphagia, seizures, and various psychiatric symptoms. As pellagra advances, patients first become disoriented, confused, and delirious, then become stuporous and comatose, and finally die.

Pellagra may develop in persons with Crohn disease as a consequence of niacin deficiency due to malabsorption and tryptophan wastage with increased urinary excretion of 5-hydroxyindoleacetic acid. Pellagra has been reported in infectious colitis and with intestinal bacterial overgrowth resulting in malabsorption.

Copper Deficiency

Copper deficiency is best recognized in Menkes disease, in which there is a genetically based inability to transport copper across the intestinal barrier due to a mutation in the *ATP7A* gene. However, impairment of intestinal copper absorption also may occur in the setting of various acquired malabsorptive processes.

Copper is absorbed in the proximal small intestine, primarily in the duodenum but also to a lesser extent in the stomach and more distal small intestine. Processes that remove or impair these absorptive sites may result in eventual copper deficiency; thus, copper malabsorption has been identified in individuals who have previously undergone gastric or intestinal surgery. Although malabsorption is the most frequent cause, copper deficiency also may follow excessive zinc ingestion.

The clinical features of copper deficiency myelopathy closely mimic those of subacute combined degeneration due to vitamin B_{12} deficiency. The combination of posterior column dysfunction with sensory ataxia and associated corticospinal tract abnormalities is common to both; peripheral neuropathy also may be present, although it is not as common in copper deficiency as it is with vitamin B_{12} deficiency. Hematologic manifestations frequently are present in both; anemia and neutropenia are characteristic in copper deficiency and the anemia may be microcytic, macrocytic, or normocytic. Optic neuropathy also may be present. T2 hyperintensities within the dorsal columns of the cervical spinal cord may be seen on MRI in both copper deficiency myelopathy and vitamin B_{12} deficiency.

The response to copper replacement therapy is inconsistent. Although the hematologic abnormalities typically respond fully over the course of 4 to 12 weeks of therapy, neurologic dysfunction may only be partially reversible. In a retrospective study in which 16 copper-deficient patients were followed for 5 years, 93 percent of hematologic abnormalities resolved with copper supplementation, but only 25 percent of neurologic symptoms improved.[10]

HEPATIC DISORDERS

When hepatic disease, regardless of its cause, progresses to a point that the liver becomes incapable of effectively eliminating toxic substances, neurologic dysfunction can ensue as these toxins, notably ammonia, cross the blood–brain barrier. Hepatic failure most often evolves slowly, over a period of many months. However, in acute liver failure, erupting over a period of days to weeks, neurologic symptoms often predominate. The cerebral dysfunction that is due to liver insufficiency or portosystemic shunting is discussed in Chapter 12.

The most widely recognized neurologic complications of serious hepatocellular failure include hepatic encephalopathy, diffuse cerebral edema, Wilson disease, hepatic myelopathy, acquired hepatocerebral degeneration, cirrhosis-related parkinsonism, and osmotic demyelination syndrome. A predominantly axonal, length-dependent peripheral neuropathy may occur in patients with chronic liver disease. It is often subclinical or oligosymptomatic, but distal sensory loss and areflexia are sometimes found on examination, and quantitative studies may reveal abnormalities of small-fiber function. Median neuropathy at the wrist (carpal tunnel syndrome) is common. Autonomic neuropathy also is frequent, regardless of whether there is a concomitant somatic neuropathy, and tends to involve parasympathetic (vagal) more often than sympathetic components; its severity relates to the severity, but not the cause, of the hepatic dysfunction. The presence of vagal dysfunction in patients with well-compensated chronic liver disease indicates a substantially worse prognosis for survival.

Various disorders causing hepatic dysfunction—such as alcohol-induced cirrhosis, porphyria, polyarteritis nodosa, and primary biliary cirrhosis—may independently cause peripheral nerve dysfunction.

However, because the severity of neuropathy correlates with that of the liver disease regardless of its etiology, it seems likely that the peripheral neuropathy is caused by hepatocellular damage.

Patients infected with hepatitis C virus may develop various neuromuscular complications. A fulminant vasculitic syndrome and progressive mononeuropathy multiplex may occur in those with cryoglobulinemia, but a length-dependent oligosymptomatic distal peripheral neuropathy may occur without cryoglobulinemia. Acute or chronic demyelinating neuropathies have been reported in the setting of viral hepatitis. Muscle disease also occurs. Myalgia is common but of uncertain cause; muscle weakness is uncommon. There have been several case reports of polymyositis or dermatomyositis occurring in patients with hepatitis C. In addition, interferon therapy for hepatitis C infection may precipitate or aggravate the myopathy.

Patients with primary biliary cirrhosis form a separate group in which a pure sensory neuropathy may develop, with or without xanthomatous infiltration of the nerves. Autonomic involvement also may occur.

Wilson Disease

Wilson disease is an autosomal recessive disorder caused by a mutation in the *ATB7P* gene on chromosome 13. More than 700 mutations have been identified, and most affected patients are compound heterozygotes.[11] The prevalence rate most often has been quoted as between 1:30,000 and 1:40,000, although recent studies suggest that this may be an underestimate. Missense and nonsense *ATP7B* mutations have been most frequently identified, followed by insertions/deletions and splice site and point mutations; exonic mutations causing exon skipping also have been identified.[12]

PATHOPHYSIOLOGY

The defective ATP7B protein cannot carry out its transport functions within the hepatocyte. As a result, copper is neither delivered for ceruloplasmin formation nor transported into the bile canaliculus for excretion. The defect in biliary excretion of copper results in a slow accumulation of copper within the liver. Eventually, the ability of the liver to store the copper is exceeded and unbound copper escapes from the liver and accumulates in other sites, including the nervous system.

CLINICAL PRESENTATION

Hepatic Manifestations

Approximately 40 to 50 percent of patients with Wilson disease experience hepatic symptoms as their initial manifestation. These individuals tend to present at an earlier age (average 11.4 to 15.5 years) than those with a primary neurologic or psychiatric presentation. Onset of symptoms before age 6 is rare; presentation with hepatic dysfunction has been reported as late as age 74.

The most frequent hepatic presentation is that of slowly progressive liver failure with cirrhosis, ascites, esophageal varices, and splenomegaly. A clinical picture similar to autoimmune (chronic active) hepatitis is evident in 10 to 30 percent; acute fulminant hepatic failure occurs in approximately 5 percent. The pattern of liver enzyme abnormalities in the setting of fulminant hepatic failure may provide clues to the diagnosis as hemolysis may produce disproportionate elevation of the total bilirubin. The combination of an alkaline phosphatase to total bilirubin ratio of less than 4 and an aspartate aminotransferase to alanine aminotransferase ratio of greater than 2.2 is highly suggestive of Wilson disease, especially if the serum hemoglobin level also is reduced.

Neurologic Manifestations

Neurologic dysfunction is the second most frequent initial clinical manifestation of Wilson disease, with estimates that range from 35 to 60 percent. The average age of symptom onset (around 20 years) is later than when the initial presentation is hepatic in nature, but ages from 6 to 72 years have been reported.

Tremor is the initial symptom of neurologic involvement in around one-half of patients. The tremor typically is asymmetric and may be resting, postural, kinetic, or a combination of these. Dystonia may be as frequent as tremor. Chorea occurs relatively infrequently, but may be present at the time of diagnosis in around 15 percent of patients. Athetosis also has been described. Parkinsonism frequently is present, with one case series finding 45 percent of patients with neurologic dysfunction having parkinsonian symptoms or signs. Although unusual, myoclonus also has been reported.

Cerebellar dysfunction develops in 25 to 50 percent of individuals. It may take the form of ataxia, dysarthria, kinetic tremor, or incoordination. Dysarthria in one study was evident in 91 percent of patients at diagnosis. Several patterns of dysarthria have been described including a hypokinetic form with difficulty in initiating speech, reduced volume, phonation, and intonation; inadequate tongue movements; and imprecise articulation along with a tendency for speech to accelerate as it proceeds. Dysarthria of cerebellar or brainstem origin also has been described. Dysphagia may develop during the course of the illness. An unusual laugh, in which most of the sound is generated during inspiration, also may occur.

Gait abnormalities are another common neurologic feature, present in 45 to 75 percent of patients at diagnosis. Gait impairment ranges from parkinsonian, with small shuffling steps and difficulty initiating gait, to cerebellar, with a wide-based and unsteady appearance.

Sleep disorders also may occur. Insomnia, restless legs syndrome, cataplexy, daytime sleepiness, and REM sleep behavior disorder all have been described; the latter two may precede the actual diagnosis.[13]

Psychiatric Manifestations

Psychiatric symptoms are the presenting feature in approximately 15 to 20 percent of patients with Wilson disease and may result in delays in diagnosis. Most individuals will experience psychiatric dysfunction at some point during their illness. This may range from subtle personality changes to mania and frank psychosis. Major depression develops in around one-quarter of patients. Suicidal behavior has been described in some.

Ophthalmologic Manifestations

The ophthalmologic hallmark of the disease is the formation of Kayser–Fleischer rings within the cornea (Fig. 13-1). They are virtually always bilateral, but unilateral Kayser–Fleischer rings have been described, possibly as a consequence of reduced intraocular pressure in the eye without the ring. Because of their dark color, Kayser–Fleischer rings often can be identified easily in patients with blue eyes, but only with difficulty in brown-eyed persons without the benefit of slit-lamp examination. Kayser–Fleischer rings first appear in the superior aspect of the cornea, followed by the inferior aspect; the medial and lateral portions of the ring then subsequently fill in. Because of this pattern of ring evolution, it is important to lift the eyelid during the examination so that incomplete ring formation is not overlooked.

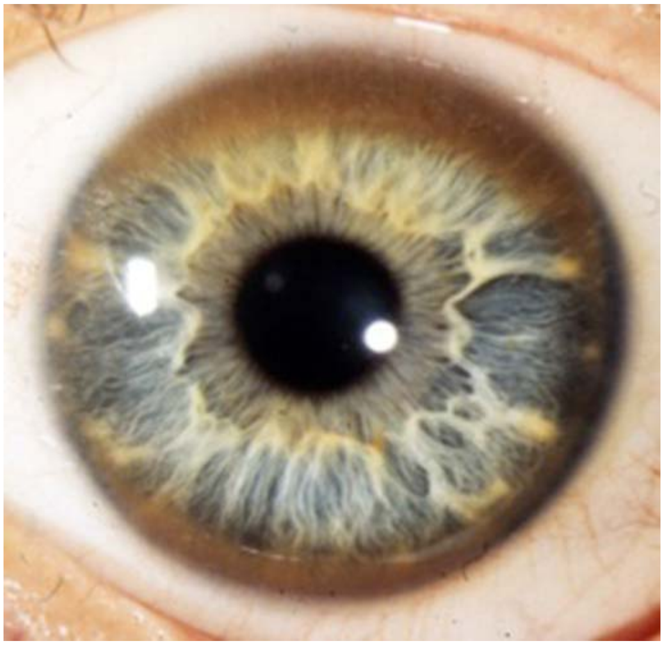

FIGURE 13-1 ■ Kayser–Fleischer ring. (Courtesy of Wayne Cornblath, MD, University of Michigan, Kellogg Eye Center, Ann Arbor, Michigan.)

Kayser–Fleischer rings virtually always are present in patients with neurologic or psychiatric symptoms, but they may not yet have formed in persons who present with isolated hepatic involvement.

Other Manifestations

Radiographic evidence of osteoporosis is common. Coombs-negative hemolytic anemia may present initially in 10 to 15 percent of cases. Renal impairment is the initial symptom in nearly 10 percent of children in some studies. Myocardial involvement in Wilson disease, presumably due to copper deposition within the heart, is underrecognized. Autonomic dysfunction, most often asymptomatic and evident only upon neurophysiologic testing, has been noted in almost 40 percent of persons, predominantly those with neurologic involvement. Skin changes, including hyperpigmentation of the legs and a dark complexion, may occur and be mistaken for Addison disease. Bluish discoloration of the lunulae of the nails and acanthosis nigricans also have been reported.

DIAGNOSIS

The presence of over 700 different mutations has made genetic testing difficult. However, it has been suggested that *ATP7B* gene sequencing should now be standard practice in the diagnosis of Wilson disease.

Determination of hepatic copper content via liver biopsy is currently the single most sensitive and specific test for the diagnosis. Hepatic copper elevation is typically quite striking, with levels greater than 250 μg/g dry tissue, compared with normal values of 15 to 55 μg/g. In patients with neurologic or psychiatric dysfunction, liver biopsy is generally unnecessary since other tests will provide the diagnosis; it is, however, usually required in individuals presenting with hepatic dysfunction.

The visualization of Kayser—Fleischer rings is an invaluable aid in diagnosis. Slit-lamp examination by a neuroophthalmologist or experienced ophthalmologist should be part of the diagnostic evaluation, particularly in persons displaying neurologic or psychiatric dysfunction. Individuals with only hepatic dysfunction may not display Kayser—Fleischer rings because copper accumulation may not yet have exceeded the liver's capacity to store the excess. Anterior segment optical coherence tomography (AS-OCT) may offer improved objectivity and accuracy over slit-lamp examination in identifying Kayser—Fleischer rings.[14]

Serum ceruloplasmin determination cannot be relied upon as the sole screening study in patients with possible Wilson disease. Ceruloplasmin may be normal or only slightly lower than normal in 5 to 15 percent of persons with the disease. Since ceruloplasmin is an acute-phase reactant, it may increase and reach normal levels during pregnancy, with estrogen or steroid administration, in the setting of infections, or with various inflammatory processes including hepatitis. As many as 10 to 20 percent of heterozygotes for Wilson disease have subnormal ceruloplasmin levels.

A 24-hour urinary copper determination is generally considered to be the single best screening test in symptomatic patients, although a recent analysis suggests that measuring copper in the first morning urine may be just as accurate and much easier to reliably collect.[15] Urinary copper levels in symptomatic patients typically exceed 100 μg/day. However, in individuals who are asymptomatic, 24-hour urinary copper excretion may be within the normal range because the ability of the liver to store the accumulating copper has not yet been exceeded.

Although serum copper levels, which measure total serum copper, are characteristically low in patients with Wilson disease, they are of little diagnostic value. Total serum copper largely reflects ceruloplasmin concentrations and is low simply because of the marked reduction in ceruloplasmin. In a patient with fulminant hepatic failure, however, serum copper levels become markedly elevated due to the sudden release of copper from tissue stores.

A variety of neuroimaging changes may occur. The most characteristic brain MRI changes include the presence of increased signal intensity in the basal ganglia on T2-weighted sequences and reduced signal intensity on T1-weighted sequences. The T2 sequence has a higher sensitivity than the T1 and FLAIR sequences in detecting brain lesions in Wilson disease. Several distinctive neuroimaging abnormalities, such as the "face of the giant panda" sign in the midbrain, the "face of the miniature panda" sign in the pons, and the "bright claustrum sign," have been described, but they are present in only a relatively small percentage of patients, limiting their diagnostic utility.

Measurement of the incorporation of radioactive copper (^{64}Cu) into ceruloplasmin also has been employed for diagnostic evaluation. However, difficulty obtaining the radioactive isotope limits its availability, and an overlap of values between individuals with Wilson disease and heterozygous carriers limits the procedure's specificity.

CSF copper levels are elevated in persons with neurologic dysfunction and decline with successful symptomatic treatment, but measurement is not performed in routine clinical practice.

TREATMENT

Dietary restriction of copper has, in general, not been a successful treatment approach. When administered orally, zinc is absorbed by intestinal enterocytes and induces metallothionein formation, which then binds both zinc and copper and inhibits their intestinal absorption. The use of zinc as "maintenance" therapy following initial treatment of neurologically symptomatic individuals with other, more potent, decoppering agents has become common.

Some investigators now even consider zinc to be first-line therapy. Zinc generally is well tolerated, with very little toxicity.

Penicillamine avidly chelates copper and holds it until the complexed copper is excreted in the urine. Improvement in function following initiation of penicillamine therapy typically does not become evident for 2 to 3 months, and then may extend gradually over 1 to 2 years. Acute sensitivity reactions and a variety of other potential adverse effects may complicate chronic penicillamine therapy. Penicillamine has the propensity to produce an initial deterioration in neurologic function when initiated, perhaps in as many as 50 percent of patients. The risk that penicillamine might induce irreversible neurologic deterioration following its initiation has led to a divergence in opinion as to the proper role of the drug in treatment. Some authors suggest continuing to use penicillamine but with low initial doses; others recommend treatment induction with other, ostensibly safer, medications.

Trientine is a copper-chelating agent with a mechanism of action similar to that of penicillamine but with a somewhat gentler decoppering effect that may make it less prone to trigger deterioration in neurologic function. Adverse effects from trientine are less frequent than with penicillamine.

Tetrathiomolybdate remains an experimental treatment modality, unavailable for general use. It has a distinct, dual mechanism of action that separates it from other available treatment modalities. It functions both to inhibit copper absorption from the GI tract and to complex with copper in the bloodstream, reducing the copper load both systemically and in the gut lumen.

Deep brain stimulation (DBS) targeting the posterior subthalamic area has been reported to improve both tremor and dystonia in Wilson disease, but further work is still needed to confirm this benefit.

Orthotopic liver transplantation is essentially the one effective treatment for fulminant hepatic failure in Wilson disease. Its potential utility in treating the patient with stable liver function but severe, progressive neurologic abnormalities despite optimal medical management has been considered but is not routine standard of care.

In an individual who is asymptomatic, therapy should be initiated with zinc alone. In a patient with hepatic but not neurologic or psychiatric dysfunction, introduction of both a chelating agent and zinc simultaneously may be ideal. Trientine has gained favor over penicillamine in recent years. Some might opt for zinc monotherapy in this setting.

No unequivocally clear consensus has yet developed for treating patients with established neurologic or psychiatric dysfunction. The primary choice is whether to initiate therapy with penicillamine or trientine. Both have their advocates, but a growing preference for trientine seems evident. Zinc is usually reserved for maintenance therapy following initial employment of a chelating agent.

Guidelines for the diagnosis and treatment of Wilson disease have been published by the European Association for the Study of the Liver (EASL).

CONCLUDING COMMENTS

INTERACTIONS BETWEEN THE EXTRINSIC NERVOUS SYSTEM AND THE GUT

The major functions of the gastrointestinal tract (motor, fluid and electrolyte transport, secretory, storage, and excretory functions) result from an intricately balanced series of control mechanisms (Fig. 14-1): the electrical and contractile properties of the smooth muscle cell that result from transmembrane fluxes of ions. Control is by the enteric nervous system through chemical transmitters such as acetylcholine, biogenic amines such as serotonin, neuropeptides released within the gut, and nitric oxide. These transmitters may act as circulating hormones or at the site of release (paracrine or neurocrine function). Regulation by extrinsic pathways (sympathetic and parasympathetic nervous systems) modifies the functions that are intrinsically controlled by the enteric mechanisms. Disorders of the nervous system affecting gastrointestinal tract function are manifested primarily as abnormalities in motor (rather than sensory, absorptive, or secretory) functions of the gut.

FIGURE 14-1 ■ Control of gut motility: interactions between extrinsic neural pathways and the intrinsic nervous system ("enteric brain" or enteric nervous system plexuses) modulate contractions of gastrointestinal smooth muscle. Interactions between transmitters (e.g., peptides and amines) and receptors alter muscle membrane potentials by stimulating bidirectional ion fluxes. In turn, membrane characteristics dictate whether the muscle cell contracts. (Adapted from Camilleri M, Phillips SF: Disorders of small intestinal motility. Gastroenterol Clin North Am 18:405, 1989, by permission of Mayo Foundation.)

Enteric and Extrinsic Nervous Supply to the Digestive Tract

In the mammalian digestive tract, the intrinsic (or enteric) nervous system (ENS) contains about 100 million neurons, approximately the number present in the spinal cord. This integrative system is organized in ganglionated plexuses (Fig. 14-2), which include the interstitial cells of Cajal (positive for ckit or tyrosine kinase) and fibroblast-like cells (positive for platelet-derived growth factor receptor α [PDGFRα]). Together, these cells constitute the *electrical syncytium* or the gastrointestinal pacemakers, integrating neuromuscular activity controlled by the ENS. The ENS is distinct and separate from the autonomic nervous system. It has several components: sensory mechanoreceptors and chemoreceptors, interneurons that process sensory input and control effector (motor and sensory) units, and effector secretor or motor neurons involved in secretory or motor functions of the gut.

Neural tissue in the gastrointestinal tract consists of nerve cell bodies and plexuses found in classically recognized plexuses, including the myenteric (Auerbach) plexus between the two muscular layers of the muscularis externa, and the submucosal (Meissner) plexus.

The myenteric plexus contains a large number of closely spaced ganglia interlinked by nerve-fiber bundles and extending from the pharyngoesophageal junction to the internal anal sphincter. Each ganglion contains a variable number of nerve cell bodies (up to 100). The submucosal plexus is confined to the small and large intestines and is composed of either large or small ganglia that are interlinked by internodal strands containing hundreds of axons.

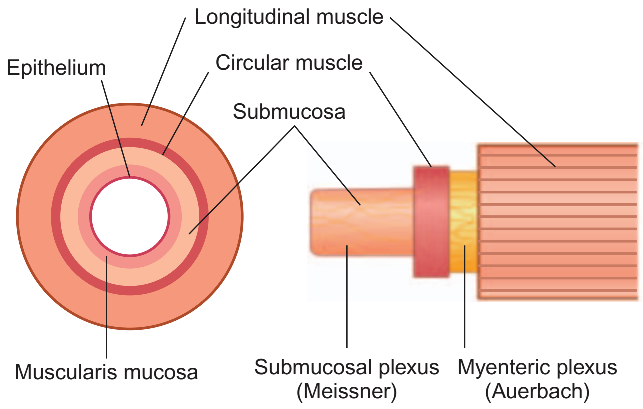

FIGURE 14-2 ■ The enteric plexuses in the intestinal layers. The chief neural plexuses are in the submucosal and intermuscular layers.

Preprogrammed neural circuits integrate motor function within and between different regions to coordinate gut functions. These functions include the peristaltic reflex and the interdigestive migrating motor complex (Fig. 14-1). The synaptic pathways in the gut wall respond to sensory input (e.g., by intraluminal content), and they can also be modulated by vagal and sacral (S2–4) preganglionic fibers (generally excitatory), and by sympathetic (T5–L2) postganglionic nerves (generally inhibitory to muscle layers, and excitatory to sphincters). There are approximately 40,000 preganglionic vagal fibers (many of which are afferent) at the level of the diaphragm. Loss of the sympathetic inhibitory control ("the brake") may manifest with gut motor overactivity, including diarrhea. Table 14-1 summarizes the wiring and functions of the extrinsic neural pathways to the digestive tract.

The Layers of the Gut

There are four layers (mucosa, submucosa, muscularis, and serosa) in the gut, with neural components between several layers. The mucosa is responsible for digestion and absorption and consists of the surface epithelium and the lamina propria. It is separated from the submucosa by the specialized, circumferential muscularis mucosae, which functions to allow surface absorptive cells to be in close contact with the intraluminal content. The submucosa consists of connective, lymphatic, and vascular tissue. The muscularis propria (or externa) is composed of an inner, thicker circular layer and an outer, thinner longitudinal layer. The longitudinal layer covers the entire circumference in the esophagus, small intestine, and rectum; in the colon, it is separated into three taeniae coli. In addition to these two layers, the stomach has a third oblique smooth muscle layer. The spindle-shaped smooth muscle cells are 40–100 μm long and 2–8 μm in diameter and are tightly packed with little connective tissue and with special contacts to allow for electrical coupling with the *electrical syncytium.* The gap junctions between the smooth muscle cells are essential, allowing sheets of muscle to be controlled by a few cells at the nerve–muscle interface. The serosa, which is the outermost layer, is composed of a thin sheet of mesothelial cells and connective tissue.

The literature on this topic is extensive. Older reference citations for specific statements made in this chapter can be found in prior editions.[1]

COMMON GASTROINTESTINAL SYMPTOMS IN NEUROLOGIC DISORDERS

Dysphagia

Dysphagia is the sensation of difficulty in swallowing. Oropharyngeal, or transfer, dysphagia is the inability to initiate a swallow or propel food from the mouth to the esophagus. The hold-up occurs high in the pharynx or esophagus and generally results from neurologic lesions affecting the swallow pathway rather than from a process affecting the oropharyngeal mucosa. Stroke and Parkinson disease are common causes; less commonly, other brainstem diseases (e.g., bulbar polio, Arnold–Chiari malformations, tumors) or muscle diseases (e.g., dystrophies and mitochondrial cytopathies) are responsible. Esophageal dysphagia is caused by abnormal esophageal peristalsis unrelated to the extrinsic neural supply, or to smooth muscle disorders (e.g., polymyositis).

Neuromuscular dysphagia typically results in dysphagia to both liquids and solids, and aspiration into the upper airways.

Physical examination shows evidence of the coexisting neurologic disease, such as abnormal palatal or pharyngeal movements or a brisk jaw jerk, suggesting pseudobulbar palsy. Barium videofluoroscopy or a fiberoptic endoscopic evaluation of swallowing can identify the motor and sensory disturbances, and may

TABLE 14-1 ■ Wiring and Functions of Extrinsic Neural Control

	Parasympathetic		Sympathetic		
Region	**Wiring**	**Function**	**Wiring**	**Function**	**Central Mechanism**
Esophagus					
Cervical	Vagus nerve; Recurrent laryngeal branch	Peristalsis in response to burst of spike activity	Superior cervical ganglion	Stimulation of UES tone	*Motor:* nucleus ambiguus, corticobulbar pathways
	Glossopharyngeal and vagus nerve	Sensation			*Sensory:* nucleus of tractus solitarius
Thoracic	Vagus nerve	Peristalsis by successive firing of vagal fibers	Celiac ganglion T6–9 spinal cord	Stimulation of LES tone	*Motor:* dorsal motor nucleus of vagus, corticobulbar pathways *Swallowing*: afferent modulation of central program
	Vagus nerve to nodose ganglia	Sensation			
Stomach	Vagus nerve	Peristalsis (cholinergic), inhibitory (nonadrenergic, e.g., receptive relaxation)	Celiac ganglion T6–9 spinal cord	Inhibition and relaxation (e.g., antrofundal reflex)	*Motor and sensory:* Dorsal motor nucleus of vagus, thoracic spinal cord; nucleus ambiguus
	Vagus nerve	Stretch and chemosensation	Spinal root ganglia T7–11	Mechanosensation (e.g., gastrogastric or enterogastric distention or nutrient reflexes)	
Small and large intestines	Vagus nerve	Small bowel and proximal colon peristalsis and sensation	Celiac ganglion to duodenum; superior and inferior mesenteric ganglia via splanchnic nerves to small bowel and via lumbar colonic nerves to colon; T9–10 spinal cord	Motor inhibition; distention reflexes	Nucleus of tractus solitarius (*sensory*), dorsal motor nucleus of vagus (*sensory and motor*); thoracic spinal cord; spinal cord base of dorsal horn (*motor parasympathetic*); parasympathetic nucleus (*sensory*)
	Sacral S2–4	Distal colon peristalsis and sensation			
Ileocecal sphincter	Vagus nerve	Sphincter contraction	Splanchnic and lumbar colonic nerves	Sphincter contraction (α effect); possibly also inhibitory β effect	T9–10 spinal cord; vagal nucleus (*motor*)
Anal sphincter					
Internal	S2–4	Sphincter relaxation	Lumbar splanchnic nerves; inferior mesenteric ganglia via hypogastric nerves	Sphincter contraction (α effect); possibly inhibitory β effect; ? participates in rectoanal inhibitory reflex; mediation of vesico-anal reflex	T9–10 spinal cord; spinal cord base of dorsal horn (*parasympathetic*)
External	S2–4 via pudendal nerves	Voluntary control; sensation			Lateral part of ventral horn of spinal cord (*motor and sensory*)

T, thoracic; S, sacral; UES, upper esophageal sphincter; LES, lower esophageal sphincter.

help stratify the risk of aspiration in patients with pharyngeal weakness. Pharyngoesophageal motility studies using solid-state pressure transducers also complement the diagnosis. Re-education of the swallowing process is feasible in many patients, often in a program that incorporates speech therapy. Nutritional support and prevention of bronchial aspiration are essential for those with more severe dysphagia not responding to conservative measures. This may require a gastrostomy feeding tube, which facilitates discharge from hospital, physical therapy, and rehabilitation. Since swallowing may improve considerably in the first 2 weeks after a stroke, long-term decisions should be delayed for that period.

Gastroparesis

Gastric motor dysfunction resulting in delayed gastric emptying is a common gastrointestinal manifestation of autonomic neuropathies, such as those associated with diabetes mellitus,[2,3] surgical vagotomy (e.g., laparoscopic fundoplication), and numerous medications, most commonly narcotic analgesics, tricyclic antidepressants, and dopamine agonists. Typical symptoms are recurrent postprandial nausea, emesis, and bloating, and pain resulting in weight loss and malnutrition. In diabetes mellitus, delayed gastric emptying may often be asymptomatic. Other stomach dysfunctions such as impaired gastric accommodation or gastric hypersensitivity may contribute to symptoms of gastroparesis (e.g., in diabetic patients). There may be a succussion splash on physical examination. It is essential to exclude gastric outlet obstruction by imaging the stomach or by endoscopy. Scintigraphic or stable isotope gastric emptying tests confirm delayed gastric emptying.[3] Gastric stasis in neurologic diseases may result from abnormal motility of the stomach or small bowel; studies of pressure profiles by manometry or solid-state pressure transducers (Fig. 14-3*A*) are rarely required to differentiate neuropathic from myopathic processes (Fig. 14-3*B*). Gastroparesis management includes the use of prokinetic agents, antiemetics, nutritional support, and interventions such as laparoscopic or endoscopic pyloroplasty.[3]

Chronic Intestinal Pseudo-Obstruction

Chronic intestinal pseudo-obstruction is a syndrome characterized by nausea, vomiting, early satiety, abdominal discomfort, weight loss, and altered bowel movements suggestive of intestinal obstruction in the absence of a mechanical obstruction. These symptoms are the consequence of abnormal intestinal motility, including from neurologic diseases extrinsic to the gut (e.g., disorders at any level of the neural axis), dysfunction of neurons in the myenteric plexus, or degeneration or malfunction of gut smooth muscle (Table 14-2). Use of narcotics, phenothiazines, dopaminergic agents, antihypertensive agents such as clonidine, and tricyclic antidepressants having anticholinergic effects may cause intestinal or colonic dysmotility.

The clinical features may suggest an underlying disease process. For example, postural dizziness, difficulties in visual accommodation in bright lights, sweating abnormalities, recurrent urinary infections, and problems with bladder voiding suggest an autonomic neuropathy. However, urinary manifestations are more commonly the result of the pelvic floor dysfunction that accompanies constipation, independent of any neurologic disease. Examination should evaluate pupillary reflexes to light and accommodation and the blood pressure and pulse in lying and standing positions; referral for autonomic reflex evaluation is important.

The combination of external ophthalmoplegia, high dysphagia, peripheral neuromyopathy (e.g., increased serum creatine kinase) and acidosis (e.g., increased lactate, pyruvate) suggests mitochondrial cytopathy, a rare disorder associated with small bowel pseudo-obstruction and diverticulosis.[4]

Plain radiographs and barium follow-through or computed tomographic (CT) or magnetic resonance (MR) enterography usually show nonspecific findings; dilatation of the small intestine is more frequent in later stages of myopathic than neuropathic disorders. The presence of small intestinal diverticula in a patient under 40 years should raise suspicion for mitochondrial cytopathy. Motility studies (Fig. 14-3) help differentiate myopathic and neuropathic processes. When a neuropathic process is identified, autonomic, radiologic, and serologic tests should be performed to identify the cause of the autonomic neuropathy or cerebrospinal disease (see later).

The goals of treatment of chronic intestinal pseudo-obstruction include the restoration of hydration and nutrition, stimulation of normal intestinal propulsion, and suppression of bacterial overgrowth when present (typically in myopathic disorders or in the presence of small bowel diverticula).

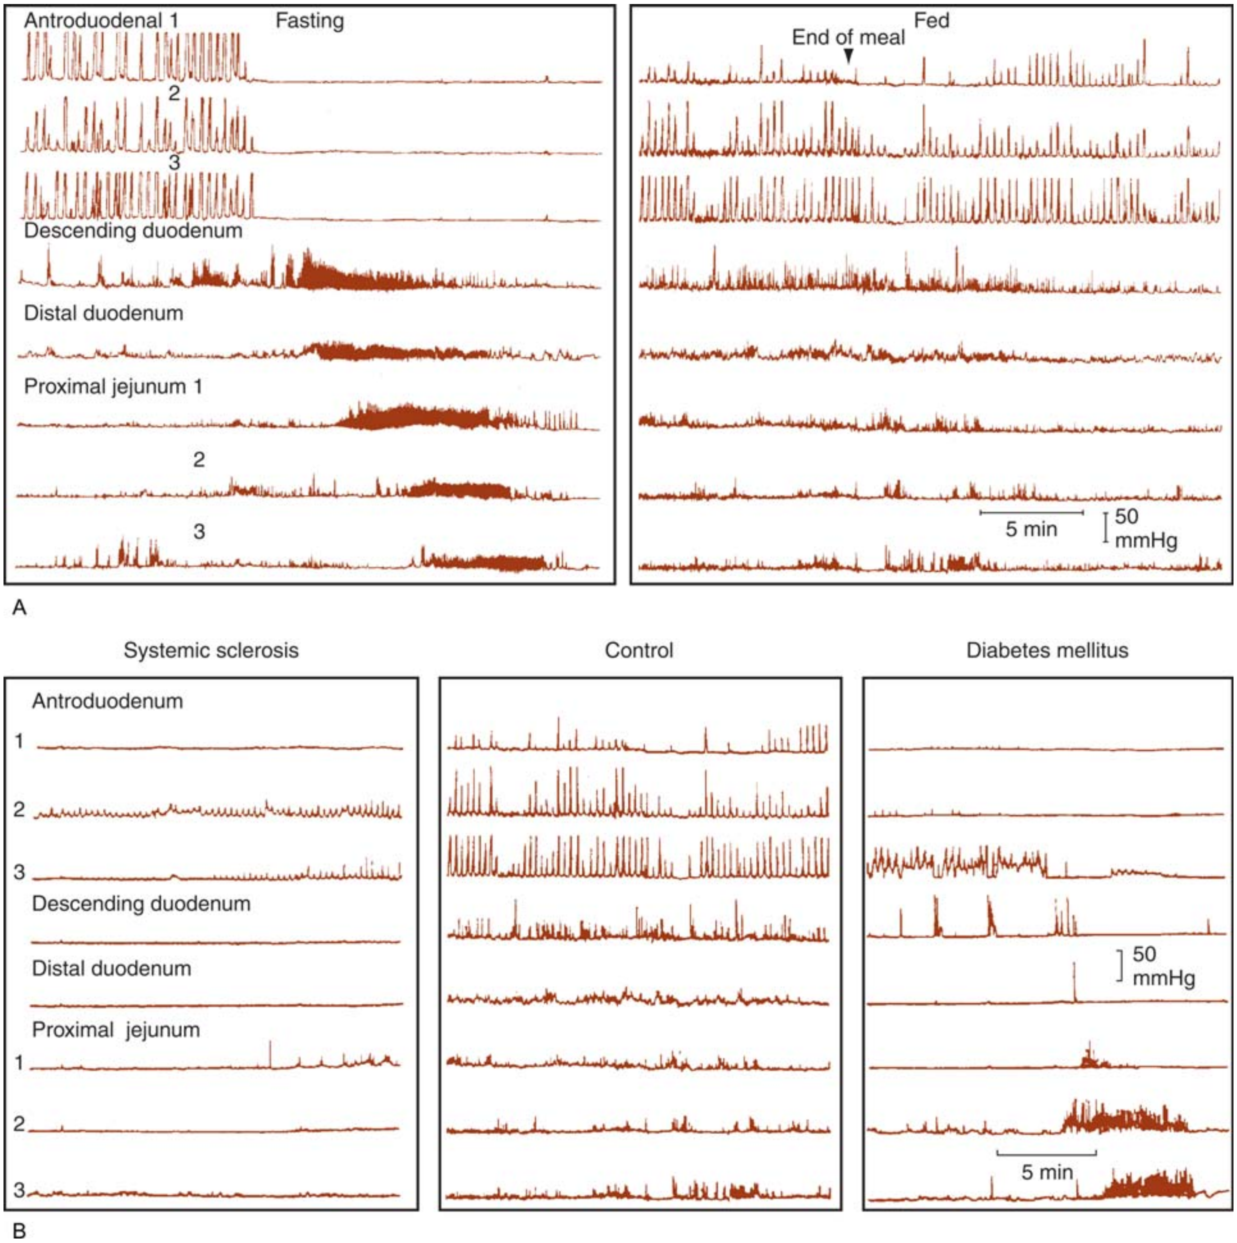

FIGURE 14-3 ■ *A*, Tracing showing normal upper gastrointestinal motility in the fasting and fed states. The fasting tracing shows phase III of the interdigestive migrating motor complex. *B*, Manometric tracings showing the myopathic pattern of intestinal pseudo-obstruction due to systemic sclerosis (*left panel*). Note the low amplitude of phasic pressure activity compared with control (*middle panel*). A manometric example of neuropathic intestinal pseudo-obstruction in diabetes mellitus shows the absence of antral contractions and persistence of cyclical fasting-type motility in the postprandial period (*right panel*). (*A*, From Malagelada J-R, Camilleri M, Stanghellini V: Manometric Diagnosis of Gastrointestinal Motility Disorders. Thieme, New York, 1986, by permission of Mayo Foundation. *B*, From Camilleri M: Medical treatment of chronic intestinal pseudo-obstruction. Pract Gastroenterol 15:10, 1991, with permission.)

Constipation

Constipation is a common complaint and may be perceived by the patient as infrequent bowel movements, excessively hard stools, the need to strain excessively during defecation, or a sense of incomplete evacuation after defecation. The need for enemas or finger evacuation to expel the stool from the lower rectum suggests a disturbance of the pelvic floor or anorectum. The co-existence of

TABLE 14-2 ■ Causes of Chronic Intestinal Pseudo-Obstruction

Cause	Myopathic	Neuropathic
Infiltrative	Progressive systemic sclerosis (PSS) Amyloidosis	Early PSS Amyloidosis
Familial	Familial visceral myopathies, including metabolic myopathies	Familial visceral neuropathies
General neurologic diseases	Myotonic and other dystrophies Mitochondrial cytopathies	Diabetes mellitus Porphyria Heavy metal poisoning Brainstem tumor Parkinson disease Multiple sclerosis Spinal cord transection
Infectious		Chagas disease Cytomegalovirus infection
Drug-induced		Tricyclic antidepressants Narcotic bowel syndrome
Neoplastic		Paraneoplastic (bronchial small cell carcinoma or carcinoid)
Idiopathic	Hollow visceral myopathy	Chronic intestinal pseudo-obstruction (possibly myenteric plexopathy)

incontinence and lack of rectal sensation suggests a neuropathy and is common among patients with diabetic neuropathy or disease affecting the lower thoracic cord (e.g., multiple sclerosis). The presence of blood in the stool with constipation necessitates further tests to exclude colonic mucosal lesions such as polyps, or perianal conditions such as hemorrhoids.

Broadly, constipation in neurologic disorders may be caused by potentially reversible factors (e.g., inadequate dietary fiber intake, lack of exercise, medications), slow colonic transit or pelvic floor dysfunction (i.e., a defecatory disorder) that may be related to the neurologic disorder, or another disease (e.g., colon cancer), or it may be a manifestation of functional disorder in patients who have a neurologic disease (Fig. 14-4). Many neurologic diseases (e.g., Parkinson disease, multiple sclerosis, spinal cord injury, and autonomic neuropathies) can affect colonic transit and pelvic floor functions or lead to diminished rectal sensation (e.g., due to a neuropathy or spinal cord injury).

The diagnosis and management of constipation in patients with neuromuscular disease include assessment of colonic anatomy, transit, and rectal evacuation.[5,6] Slow colonic transit occurs frequently in wheelchair- or bed-bound patients and may require, in addition, stimulant cathartics or prokinetic medications and scheduled rectal stimulation or enemas daily. In patients with paraplegia, computer-assisted sacral anterior root stimulation has been used to evoke sigmoid and rectal contraction coordinated with sphincter relaxation, which resembles normal defecation. This procedure reduces the time for defecation and the interval between defecations. A dorsal rhizotomy must be performed in such patients in order to avoid general stimulation of autonomic responses (autonomic dysreflexia), characterized by uncontrolled hypertension and bradycardia or tachycardia. This treatment is available at specialized centers. An alternative treatment for colonic inertia (severe neuromuscular dysfunction with absent response to food ingestion or intravenous neostigmine) may be subtotal colectomy with ileorectal anastomosis; however, if sphincter function is deficient and cannot be rehabilitated with physical therapy, a colostomy or ileostomy may be necessary. Other surgical procedures may correct a rectal prolapse or a rectocele.

Diarrhea

Diarrhea is defined as passage of abnormally liquid or unformed stools at an increased frequency, and is termed “chronic” if more than 4 weeks in duration. Acute diarrhea in neurologic patients is most frequently caused by infectious agents or medications. The differential diagnosis of chronic diarrhea is discussed in detail elsewhere.[7] In autonomic neuropathies, as in patients with diabetic neuropathy, chronic diarrhea is often multifactorial and may be associated with intake of osmotic agents (e.g., artificial sweeteners), secretion, malabsorption secondary to rapid transit (possibly due to sympathetic denervation), small bowel bacterial overgrowth, bile acid diarrhea, and high-amplitude propulsive contractions in the colon that result in urgency and sometimes incontinence of stool.

Generally, the aid of a gastroenterologist is necessary to evaluate patients and guide diagnostic tests. Features of fat malabsorption (e.g., greasy, difficult-to-flush stools, weight loss) should prompt measurement of 48-hour stool fat and total stool bile acids. The

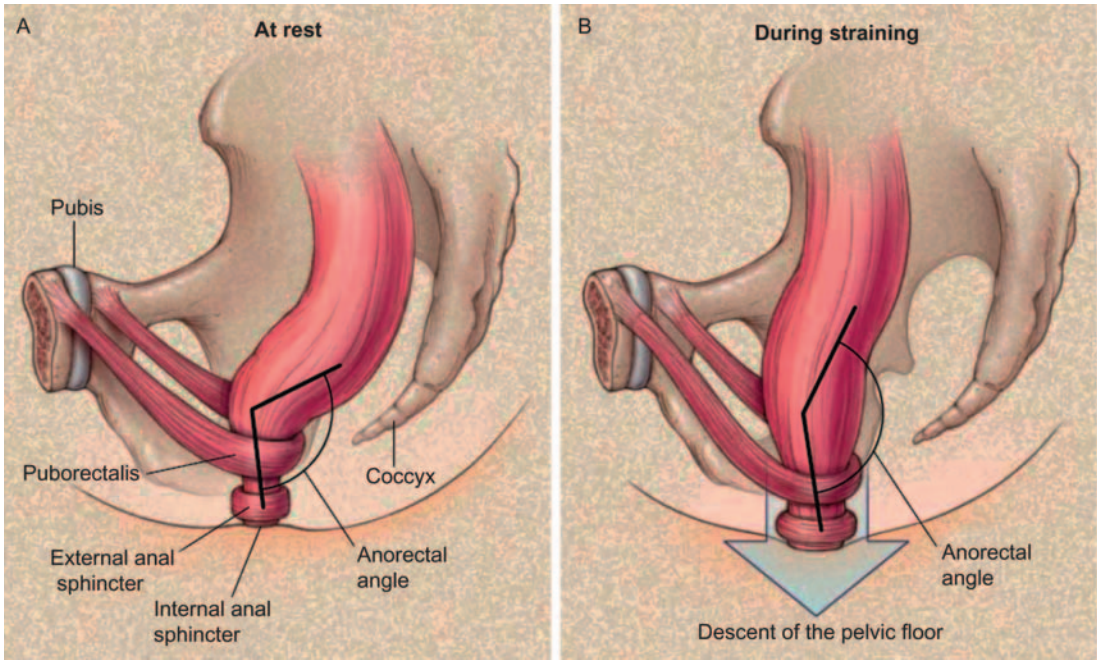

FIGURE 14-4 ■ Schema showing pelvic floor, rectoanal angle, and sphincters at rest (*A*) and normal alterations during defecation (*B*). (From Lembo T, Camilleri M: Chronic constipation. N Engl J Med 349:1360, 2003, with permission.)

co-existence of diarrhea and neurologic manifestations may be explained by autonomic dysfunction (e.g., in diabetic neuropathy), the neurologic consequences of malabsorption (e.g., myopathy or neuropathy in celiac disease or bacterial overgrowth), and rare diseases with neurologic manifestations (e.g., Whipple disease). After excluding a structural cause (e.g., inflammatory bowel disease) and malabsorption, most patients with diarrhea due to disordered motility can be treated effectively with the peripheral μ-opioid receptor agonist, loperamide, beginning with 2 mg taken 30 minutes before meals, and titrated to control symptoms up to a maximum of 16 mg daily. The α_2-adrenergic agonist, clonidine, reduces diarrhea by improving intestinal absorption, inhibiting intestinal and colonic motility, and enhancing resting anal sphincter tone; however, it aggravates postural hypotension, even when administered by transdermal patch. Other agents to be considered are oral bile acid sequestrants (e.g., cholestyramine and colesevelam) and subcutaneous octreotide.

Fecal Incontinence

Fecal incontinence may result from multiple sclerosis, Parkinson disease, multiple system atrophy, Alzheimer disease, stroke, diabetic neuropathy, and spinal cord lesions. In addition to generalized neuropathies (e.g., diabetes), obstetric trauma and stretch-induced pudendal nerve injury related to excessive straining in constipated patients are other causes of a pudendal neuropathy.[8–11] Incontinence occurring only at night suggests internal anal sphincter dysfunction (e.g., progressive systemic sclerosis, diabetic neuropathy); stress incontinence during coughing, sneezing, or laughing suggests loss of external sphincter control, typically from pudendal nerve or S2, S3, and S4 root lesions. Leakage of formed stool suggests more severe sphincter weakness than leakage of liquid stool alone.

Examination of the incontinent patient should include inspection of the anus with and without straining to detect rectal prolapse, a digital rectal examination, and proctoscopy to exclude impaction or mucosal disease. Anal examination may disclose normal (e.g., multiple sclerosis) or reduced (e.g., diabetes mellitus, scleroderma) anal resting tone. The external sphincter and puborectalis contractile responses during squeeze are reduced, and the perianal wink reflex is absent in conditions affecting the lower spinal cord or pudendal nerves. Perineal weakness is often manifested by excessive perineal descent (> 4 cm) on straining.

In evaluating such patients, it is important first to exclude overflow incontinence due to fecal impaction;

overuse of laxatives or magnesium-containing antacids may also be responsible. If these are not identified, further tests may be necessary: anorectal manometry, rectal sensation, ability to expel a balloon from the rectum, endoanal ultrasound or MRI to identify anal sphincter defects, and dynamic barium or MR defecography to identify rectal evacuation and anatomic abnormalities (e.g., rectocele, rectal intussusception). EMG of the anal sphincter is rarely required, usually to prove evidence of denervation (fibrillation potentials), myopathic damage (small polyphasic motor unit potentials), neurogenic damage (large polyphasic motor unit potentials), or mixed injury.[12,13]

Medical management includes perianal hygiene, protective devices to maintain skin integrity, and restoration of regular bowel habits. Biofeedback therapy has little impact in patients with weak anal sphincters or poor rectal sensation. Clonidine may help some patients by increasing consistency of stool and increasing resting anal sphincter tone, if it is tolerated. A colostomy may be necessary in patients with medically refractory fecal incontinence. Before resorting to this, it is important to exclude mucosal prolapse in association with incontinence, since surgical correction of the prolapse may temporarily improve continence by permitting better function of the external sphincter.[14] More complex surgical procedures (i.e., artificial anal sphincter, dynamic graciloplasty) are not routinely performed. Injection of bulking agents such as silicone biomaterial (PTQ) or carbon-coated beads (Durasphere) for fecal incontinence is used following obstetric anal sphincter injury, but has not been extensively tested in primary neurologic disease. Sacral nerve stimulation can improve symptoms, anal pressures, and rectal sensation, even in patients with neurogenic fecal incontinence. In the future, it is hoped that stem cells combined with normal cells on bioengineered scaffolds may result in successful creation and implantation of intrinsically innervated anal sphincter constructs.

EXTRINSIC NEUROLOGIC DISORDERS CAUSING GUT DYSMOTILITY

Certain diseases affect both intrinsic and extrinsic neural control. This review concentrates on diseases of extrinsic neural control and smooth muscle. Diseases affecting the enteric nervous system are reviewed elsewhere.

Brain Diseases

STROKE

Dysphagia may result from cranial nerve involvement and may cause malnutrition or aspiration pneumonia. Videofluoroscopy of the pharynx and upper esophagus typically shows transfer dysphagia or tracheal aspiration. Colonic pseudo-obstruction occurs rarely. Percutaneous endoscopic gastrostomy is usually the most effective method to provide nutrition without interfering with rehabilitation; feedings can be given in the forms of boluses or by infusion at night. Swallowing improves in a majority of survivors over 1 week to 3 months. The severity of the initial neurologic deficit is the strongest predictor of eventual recovery. The gastrostomy tube can be removed when oral intake is shown to be sufficient to maintain caloric requirements.

ALZHEIMER DISEASE

In a retrospective population-based study, people with Alzheimer disease, aged 65 years and older, had a higher incidence of serious upper and lower gastrointestinal (GI) events including ulceration, perforation, and bleeding than a well-matched random sample of people without Alzheimer disease. The association was also present in participants without a history of GI bleeding. Treatment of Alzheimer disease with the acetylcholinesterase medications, such as donepezil or rivastigmine, is associated with gastrointestinal symptoms, such as nausea, vomiting, and diarrhea. These may be dose related and may be reduced by using transdermal preparations.

PARKINSONISM

Patients with Parkinson disease experience several gastrointestinal manifestations. These include salivary drooling (sialorrhea) which is often associated with speech and eating impairment; dysphagia; gastroparesis; constipation; and anorectal dysfunction including incontinence. The prevalence of gastrointestinal symptoms is related to disease duration and severity, rather than to diet or treatment. Constipation may precede by several years the development of motor symptoms.

Excessive salivary drooling may respond to systemic or topical anticholinergic agents that reduce production of saliva.

Abnormal swallowing results mainly from impaired pharyngeal and upper esophageal muscle function.

It is associated frequently with choking, disordered salivation, and variable degrees of malnutrition. Moderate dysphagia may be diagnosed by videofluoroscopy (oropharyngeal and esophageal) or esophageal manometry. Conservative treatment includes attention to the consistency of food (thickened liquids) and to adequate caloric content of meals. With more severe dysphagia, expiratory muscle strength training and video-assisted swallowing therapy may be effective alone or with dopaminergic therapy, and a percutaneous gastrostomy may be necessary.

Delayed gastric emptying can influence levodopa pharmacokinetics and may itself be aggravated by levodopa. Domperidone, a D2 receptor antagonist, does not cross the blood–brain barrier and may help gastroparesis, but it is not widely available and increases the risk of cardiac arrhythmia. To reduce levodopa pharmacokinetic derangements, options include liquid formulations of the medication, intestinal gels, and dopamine agonist skin patches. The bioavailability of other medications can be altered considerably by the effects of parkinsonism on gut transit and delivery of medications to the small bowel for absorption.

Several factors lead to constipation in Parkinson disease: generalized hypokinesia, gut hypomotility, anal sphincter or defecatory dysfunction, and effects of anticholinergic and dopamine agonists. Constipation manifests as decreased stool frequency, disturbed stool consistency, and excessive straining. Constipation may precede the development of somatic motor symptoms by several years. Patients with Parkinson disease or progressive supranuclear palsy may also have oropharyngeal dysfunction with impaired swallowing.

The gut is a portal of entry for prions leading to neurologic diseases such as Alzheimer and Parkinson disease and transmissible spongiform encephalopathies. Neuropathologic studies have shown early accumulation of abnormal inclusions containing α-synuclein (Lewy neurites) in the enteric nervous system and dorsal motor nucleus of the vagus, in both Parkinson and incidental Lewy body disease. Colonic biopsies may show accumulation of α-synuclein immunoreactive Lewy neurites in the submucosal plexus of patients with Parkinson disease. However, α-synuclein is abundantly expressed in all nerve plexuses of the human ENS, especially with increasing age and therefore may not be regarded as a pathologic correlate.

HEAD INJURY

Immediately following moderate to severe head injury, most patients develop transient delays in gastric emptying. The underlying mechanism is unknown, although a correlation exists between the severity of injury, increased intracranial pressure, and severity of the gastric stasis. These patients are frequently intolerant of enteral feeding and may require parenteral nutrition temporarily. Enteral nutrition can often be reintroduced within a few weeks.

AUTONOMIC EPILEPSY AND MIGRAINE

Autonomic epilepsy and migraine are infrequent causes of upper abdominal symptoms, such as nausea and vomiting. Treatment is of the underlying neurologic disorder.

AMYOTROPHIC LATERAL SCLEROSIS

Patients with amyotrophic lateral sclerosis and progressive bulbar palsy have predominant weakness of the muscles supplied by the glossopharyngeal and vagus nerves. Dysphagia is a frequent complaint, and patients may have respiratory difficulty while eating as a result of aspiration or respiratory muscle fatigue. Rarely, patients with vagal dysfunction develop chronic intestinal pseudo-obstruction.

Physical examination reveals cranial nerve palsies, muscle fasciculations, or an exaggerated jaw jerk. Videofluoroscopic barium swallow of liquids and solids is employed to evaluate swallowing, determine whether aspiration occurs, and guide decisions about the route to use for nutritional support (oral feeding or a percutaneous gastrostomy). Cervical esophagostomy or cricopharyngeal myotomy have been performed in selected cases for significant cricopharyngeal muscle dysfunction.

POSTPOLIO DYSPHAGIA

Patients with postpolio syndrome frequently have dysphagia and aspiration, especially if there was bulbar involvement during the initial attack. Videofluoroscopy is useful for screening and monitoring progression of disease. Attention to the position of the patient's head during swallowing and alteration of food consistency to a semisolid state can decrease the prevalence of choking and aspiration.

BRAINSTEM LESIONS

Brainstem lesions can present with isolated gastrointestinal motor dysfunction. Compression of the brainstem and lower cranial nerves can cause potentially life-threatening neurogenic dysphagia in patients with Arnold–Chiari malformations. In the absence of increased intracranial pressure, gastrointestinal symptoms in association with brain tumors typically result from distortion of the vomiting center on the floor of the fourth ventricle, which leads to delay in gastric emptying. Although vomiting is the most common symptom, colonic and anorectal dysfunctions have also been described. The presence of more widespread autonomic dysfunction, particularly if preganglionic sympathetic nerves are involved (as shown on a thermoregulatory sweat test), necessitates a search for a structural lesion in the central nervous system.

Autonomic System Degenerations

PANDYSAUTONOMIAS OR SELECTIVE DYSAUTONOMIAS

Pandysautonomias are characterized by preganglionic or postganglionic lesions affecting both the sympathetic and parasympathetic nervous systems. Vomiting, paralytic ileus, constipation, and a chronic pseudo-obstruction syndrome have been reported in acute, subacute, and congenital pandysautonomia. Selective cholinergic dysautonomia may also impair upper and lower gastrointestinal motor activity. This picture usually follows a viral infection such as infectious mononucleosis or influenza A.

IDIOPATHIC ORTHOSTATIC HYPOTENSION

Idiopathic orthostatic hypotension is sometimes associated with motor dysfunction of the gut, such as esophageal dysmotility, gastric stasis, alteration in bowel movements, and fecal incontinence. Cardiovascular and sudomotor abnormalities usually precede gut involvement. The precise site of the lesion causing the gut dysmotility is unknown.

POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME

About one-third of patients with postural orthostatic tachycardia syndrome have gastrointestinal manifestations, including pseudo-obstruction syndrome. It is important to exclude dehydration, deconditioning, and functional gastrointestinal disorders that produce similar clinical features.

MULTIPLE SYSTEM ATROPHY

In the original description of this disorder, constipation and fecal incontinence were included among its classic features. Abnormal esophageal motility was demonstrated by videofluoroscopy and by the occurrence of frequent, simultaneous, low-amplitude peristaltic waves on esophageal manometry. Fasting and postprandial antral and small bowel motility may be reduced.

Spinal Cord Lesions

SPINAL CORD INJURY

Dysphagia after acute cervical spinal cord injury (SCI) generally improves during the initial hospitalization.

Ileus is a frequent finding soon after spinal cord injury, but it is rarely prolonged. Acalculous cholecystitis occurs in 3.7 percent of patients with acute SCI.

Bowel problems occur in 27 to 62 percent of patients with SCI, most commonly constipation, distention, abdominal pain, rectal bleeding, hemorrhoids, fecal incontinence, and autonomic hyperreflexia; gallstones occur in 17 to 31 percent of patients. In the chronic phase after injury, disorders of upper gastrointestinal motility are uncommon, whereas colonic and anorectal dysfunctions are common. The latter probably result from interruption of supraspinal control of the sacral parasympathetic supply to the colon, pelvic floor, and anal sphincters. After thoracic SCI, colonic compliance and postprandial colonic motor responses may be reduced. The loss of voluntary control of defecation may be the most significant disturbance in patients who rely on reflex rectal stimulation for stool evacuation. Fecal impaction may present with anorexia and nausea. Diverticula, internal hemorrhoids, and polyps in veterans with SCI were associated with time elapsed since SCI; however, in a small study, these complications were not more prevalent than in non-SCI veterans matched for age, sex, and race/ethnicity.

Loss of control of the external anal sphincter commonly results in fecal incontinence after SCI.

The usual management for irregular bowel function is a combination of laxatives, bulking agents, anal massage, manual evacuation, and scheduled enemas, which may contain chemical stimulants such as bisacodyl (10 mg in a 30 ml enema). Randomized, double-blind studies demonstrated the effectiveness of neostigmine, which increases cholinergic tone, combined with glycopyrrolate, an anticholinergic agent with minimal activity in the colon that reduces extracolonic side effects. Computerized stimulation of the sacral anterior roots may restore normal function to the pelvic colon and anorectal sphincters; this anterior sacral root stimulation may be combined with S2 to S4 posterior sacral rhizotomy in order to interrupt the spasticity-causing sensory nerves and avoid autonomic dysreflexia. If these measures are unavailable or ineffective and severe constipation persists, a colostomy reduces time for bowel care and avoidance or healing of decubitus ulcers.

The acute abdomen may be a significant challenge in SCI, with mortality of 9.5 percent in one series. In SCI patients, acute abdominal conditions do not present with rigidity or absent bowel sounds, but with dull or poorly localized pain, vomiting, or restlessness, with tenderness, fever, and leukocytosis in up to 50 percent of patients.

MULTIPLE SCLEROSIS

Severe constipation (typically slow transit) frequently accompanies urinary bladder dysfunction in patients with advanced multiple sclerosis; there may be fecal incontinence even in patients with constipation. Impaired function of the supraspinal or descending pathways that control the sacral parasympathetic outflow may impair colonic motor dysfunction or affect defecation. Motility disturbances are more frequent in the lower than in the upper gut.

Constipation and fecal incontinence may co-exist and alternate, impacting on the patient's quality of life and social interactions. Anorectal manometry is helpful to differentiate anal sphincter hypotonia, rectal hyposensitivity (both causes of incontinence), and pelvic floor dyssynergia as the cause of constipation, which may be complicated by "overflow" incontinence. Rectal compliance correlates with overall disability from multiple sclerosis, and observed alterations in rectal properties are secondary to spinal cord involvement. Transanal irrigation or lower bowel stimulation (with stimulant agents, as for SCI patients) may be required to relieve the constipation and clear the lower bowel to avoid incontinence episodes.

NEUROMYELITIS OPTICA

Area postrema (including morphologic evidence of aquaporin-4 [AQP4] autoimmunity) may be a selective target of the disease process in neuromyelitis optica. These findings are compatible with clinical reports of nausea and vomiting preceding episodes of optic neuritis and transverse myelitis or being the heralding symptom of the disorder.

Peripheral Neuropathy

ACUTE PERIPHERAL NEUROPATHY

Autonomic dysfunction associated with certain acute viral infections may result in nausea, vomiting, abdominal cramps, constipation, or a clinical picture of pseudo-obstruction. In the Guillain–Barré syndrome, visceral involvement may include gastric distention or adynamic ileus. Persistent gastrointestinal motor disturbances may also occur in association with herpes zoster, Epstein–Barr virus infection, or botulism B. The site of the neurologic lesion is uncertain. Cytomegalovirus has been identified in the myenteric plexus in some patients with chronic intestinal pseudo-obstruction. Selective cholinergic dysautonomia (with associated gastrointestinal dysfunction) has been reported to develop within a week of the onset of infectious mononucleosis. Diarrhea induced by human immunodeficiency virus (HIV) may be another manifestation of autonomic dysfunction (see later), but the data require confirmation.

CHRONIC PERIPHERAL NEUROPATHY

Chronic peripheral neuropathy is the most commonly encountered extrinsic neurologic disorder that results in gastrointestinal motor dysfunction.

Diabetes Mellitus

Diabetic autonomic neuropathy of the gut has been studied extensively and has been reviewed elsewhere. In patients with type I diabetes mellitus seen at university medical centers, gastrointestinal symptoms, particularly constipation, are quite common. A US-based study in the community showed that constipation, with or without the use of laxatives, was the only gut symptom more frequent in patients with type I diabetes mellitus than in age- and sex-matched controls. Patients with constipation tended to be taking medications that cause the symptoms or to have bladder symptoms.

Gastric emptying of digestible or nondigestible solids is abnormal in patients with diabetes mellitus and gastrointestinal symptoms ("gastroparesis"). There is a paucity of distal antral contractions during fasting and postprandially; small bowel motility may also be abnormal. These features are consistent with an "autovagotomy," or loss of the interstitial cells of Cajal (pacemaker cells) associated with an imbalance in the local macrophage cells that protect the neural elements from the effects of oxidative stress.

Constipation among community diabetics was associated equally with slow transit, normal transit, or pelvic floor dysfunction. Diarrhea or fecal incontinence (or both) may result from several mechanisms: dysfunction of the anorectal sphincter or abnormal rectal sensation, osmotic diarrhea from bacterial overgrowth due to small bowel stasis, rapid transit from uncoordinated small bowel motor activity, or the intake of artificial sweeteners such as sorbitol. Rarely, an associated gluten-sensitive enteropathy or pancreatic exocrine insufficiency is present.

Histopathologic studies of the vagus nerve have revealed a reduction in the number of unmyelinated axons; surviving axons are usually of small caliber. In patients with diabetic diarrhea, there are giant sympathetic neurons and dendritic swelling of the postganglionic neurons in prevertebral and paravertebral sympathetic ganglia as well as reduced fiber density in the splanchnic nerves.

Treatment of gastroparesis follows guidelines reviewed elsewhere, and therapeutic options have resulted in only transient relief. Pancreas transplantation is reported to restore normal gastric emptying in patients with diabetic gastroparesis. Long-term results are not available, however, and the gastric stasis and autonomic neuropathy may not be resolved with the pancreas transplant.

Paraneoplastic Neuropathy

Autonomic neuropathy and gastrointestinal symptoms may occur in association with small cell carcinoma of the lung or pulmonary carcinoid. In one series, all seven patients suffered constipation, six had gastroparesis, four had esophageal dysmotility suggestive of spasm or achalasia, and two had other evidence of autonomic neuropathy that affected bladder and blood pressure control. There are circulating IgG antibodies (e.g., ANNA-1 or anti-Hu) directed against enteric neuronal nuclei, suggesting that the enteric plexus is the major target of this paraneoplastic phenomenon. However, several patients have also had evidence of extrinsic visceral neuropathies, suggesting a more extensive neuropathologic process. The chest x-ray is frequently normal in these patients; a chest computed tomography (CT) scan is therefore indicated when the syndrome is suspected, typically in middle-aged smokers with recent onset of nausea, vomiting, or feeding intolerance. Whole-body fluorodeoxyglucose positron emission tomography (FDG-PET) or FDG-PET/computed tomography may be helpful for detecting malignancies that cannot be detected by conventional screening tests. In other reports, however, there has not been FDG uptake in the tumor or metastases.

Ganglionic receptor-binding antibodies have also been found in a subset of patients with idiopathic, paraneoplastic, or diabetic autonomic neuropathy and idiopathic gastrointestinal dysmotility; the antibody titer correlated with more severe autonomic dysfunction. This autoimmune model of gastrointestinal dysmotility has been replicated in an animal model.

Immunomodulatory treatment before, during, or after antineoplastic therapy may be of benefit for patients with paraneoplastic neuropathy and has been used even when the underlying malignancy cannot be identified.

Amyloid Neuropathy

Gastrointestinal disease in amyloidosis results from either mucosal infiltration or neuromuscular infiltration. In addition, an extrinsic autonomic neuropathy may also affect gut function. A retrospective series reported that 76 of 2,334 (3.2%) patients with amyloidosis had biopsy-proven amyloid involvement of the gastrointestinal tract. Of these 76 patients, 79 percent had systemic amyloidosis while 21 percent had GI amyloidosis without evidence of an associated plasma cell dyscrasia or other organ involvement. Amyloid neuropathy may lead to constipation, diarrhea, and steatorrhea. Patients have uncoordinated nonpropagated contractions in the small bowel.

These features are similar to the intestinal myoelectric disturbances observed in animals subjected to ganglionectomy. Familial amyloidosis may also affect the gut.

Manometric studies and monitoring of the acute effects of cholinomimetic agents can distinguish between neuropathic (uncoordinated but normal-amplitude pressure activity) and myopathic (low-amplitude pressure activity) types of amyloid gastroenteropathy. These strategies may identify patients (i.e., those with the neuropathic variant) who are more likely to respond to prokinetic agents. The effects of advanced therapies for amyloidosis (autologous or allogeneic stem cell transplantation in combination with cytotoxic therapy) on gastrointestinal dysmotility are unclear.

Chronic Sensory and Autonomic Neuropathy of Unknown Cause

This is a rare, nonfamilial form of slowly progressive neuropathy that affects a number of autonomic functions. Patients may exhibit only a chronic autonomic disturbance (e.g., abnormal sudomotor, vasomotor, or gastrointestinal function) for many years before peripheral sensory symptoms develop. Autonomic dysfunction is probably responsible for functional gastrointestinal motor disorders when these develop prior to the onset of more obvious features of dysautonomia. This may account for a subset of patients with symptoms suggestive of irritable bowel syndrome.

A high nicotinic acetylcholine receptor antibody titer with postganglionic autonomic damage and evidence of somatic nerve fiber involvement suggests that such cases may have an immune etiology, as is discussed later.

Some investigators have reported familial cases of intestinal pseudo-obstruction with degeneration of the myenteric plexus and evidence of sensory or motor neuropathies affecting peripheral or cranial nerves.

Porphyria

Acute intermittent porphyria and hereditary coproporphyria frequently present with abdominal pain, nausea, vomiting, and constipation. Porphyric polyneuropathy may lead to dilatation and impaired motor function in any part of the intestinal tract, presumably because of autonomic dysfunction. Effects of porphyria on the enteric nervous system have not been described.

Neurofibromatosis

Children with neurofibromatosis type 1 frequently have symptoms of constipation, which can be associated with enlarged rectal diameter and prolonged colonic transit time.

Human Immunodeficiency Virus Infection

Neurologic disease may manifest at any phase of HIV infection. Chronic diarrhea may result from increased extrinsic parasympathetic activity to the gut or damage to adrenergic fibers within the enteric plexuses. Further studies are needed to characterize these abnormalities; it is, of course, important to exclude gut infections and infestations in patients with HIV seropositivity and diarrhea.

Autoimmune Neuropathies

Autoimmune neuropathies are rare causes of gastrointestinal dysmotilities.

Antibodies to Ganglionic Acetylcholine Receptors

Antibodies that bind to or block ganglionic acetylcholine receptors have been identified in patients with various forms of autoimmune autonomic neuropathy. In one series, 9 percent of patients with idiopathic GI dysmotility had antibodies toward ganglionic acetylcholine receptors, and antibody titers were positively correlated with the severity of autonomic dysfunction, suggesting a pathogenic role. Moreover, passive transfer of ganglionic AChR-specific IgG impaired autonomic synaptic transmission and caused autonomic dysfunction in mice. The antibody effect was potentially reversible, suggesting that early use of immunomodulatory therapy directed at lowering IgG levels and abrogating IgG production may be therapeutically effective in patients with autoimmune autonomic neuropathy.

Antibodies to Specific Ion Channels

Autoantibodies directed against specific neural antigens, including ion channels, may be associated with gut motility disorders including esophageal dysmotility, slow transit constipation, and chronic intestinal pseudo-obstruction. Among 33 patients with ganglionitis shown on full-thickness jejunal laparoscopic biopsies, two patients with symptoms of irritable bowel syndrome had antibodies directed towards neuronal ion channels (one against voltage-gated potassium channels and the other against neuronal alpha3-AChR). The pathogenic role of such antibodies requires further determination. Similarly, in pediatric patients with suspected neurologic autoimmunity, there was a minority (<3%) with serum positive for neuronal potassium channel complex-reactive immunoglobulin G and, among these, two of seven patients had gastrointestinal dysmotility.[15]

Similar ion channel or acetylcholine receptor antibodies were reported in 24 patients with GI motility disorders (such as achalasia and delayed gastric emptying); 11 patients had associated malignancies.[16] The prevalence of these antibodies is not higher in community-based patients with irritable bowel syndrome or functional dyspepsia than in asymptomatic controls. Antibodies against voltage-gated potassium channels (particularly CASPR2-IgG-positivity) are also associated with chronic idiopathic pain and hyperexcitability of nociceptive pathways; however, there is no association with significant gastrointestinal pain.

GENERAL MUSCLE DISEASES CAUSING GUT DYSMOTILITY

At an advanced stage, progressive systemic sclerosis and amyloidosis result in an infiltrative replacement of smooth muscle cells in the digestive tract. Rarely, Duchenne or Becker muscular dystrophy and polymyositis or dermatomyositis have been associated with gastroparesis. There are a number of case or family reports of chronic intestinal pseudo-obstruction, sometimes in association with an external ophthalmoplegia, secondary to a mitochondrial myopathy. Patients with myotonic dystrophy may have megacolon; anal sphincter dysfunction also occurs and is consistent with an expression of myopathy, muscular atrophy, and neural abnormalities. The myopathic nature of these disorders is reflected by the low-amplitude contractions that occur at affected levels of the gut, as studied especially in systemic sclerosis.

Myopathic disorders may be complicated by bacterial overgrowth and small bowel diverticula; pneumatosis cystoides intestinalis and spontaneous pneumoperitoneum sometimes occur in progressive systemic sclerosis. However, it is worth noting that systemic sclerosis affects the gut from the distal two-thirds of the esophagus to the anorectum; thus, it may present with dysphagia (which may also be due to reflux esophagitis and stricture), gastric stasis, chronic intestinal pseudo-obstruction, steatorrhea due to bacterial overgrowth, constipation, incontinence (particularly at night, owing to involvement of the internal anal sphincter), and rectal prolapse. Skeletal muscle electromyography (EMG) or biopsy may be needed to establish the nature of the generalized neuromuscular disorder, as in mitochondrial myopathy. Treatment includes restoration of nutrition (which may necessitate total parenteral nutrition), suppression of bacterial overgrowth, and treatment of complications such as gastroesophageal reflux (with proton pump inhibitor) or esophageal strictures (by endoscopic dilatation). Colonic dilatation and intractable constipation may necessitate subtotal colectomy with ileorectostomy. Prokinetics are rarely effective but should at least be tried. The somatostatin analogue octreotide improves symptoms in the short term and may suppress bacterial overgrowth. However, octreotide retards postprandial small bowel transit. We use it only once per day, at least 3 hours after the last meal, to induce migrating motor activity and clear residue from the stomach and small bowel.

Allogeneic stem cell transplantation has been proposed as an early treatment for mitochondrial neurogastrointestinal encephalomyopathy while patients are still relatively healthy. In two patients, post-transplant clinical follow-up showed improvement in gastrointestinal dysmotility, abdominal cramps, and diarrhea.

IDENTIFICATION OF EXTRINSIC NEUROLOGIC DISEASE WITH GASTROINTESTINAL SYMPTOMS OF DYSMOTILITY

Patients with lesions at virtually any level of the nervous system may have symptoms of gastrointestinal motor dysfunction. Therefore, a strategy is necessary in the diagnostic evaluation of disordered gastrointestinal function (Fig. 14-5). Here there is convergence of the paths of the neurologist and gastroenterologist. Patients should undergo further testing, particularly if they have clinical features suggestive of autonomic or peripheral nerve dysfunction or a known underlying neuromuscular disorder. It is essential to record the use of all medications that influence gut motility.

Gastrointestinal motility and transit measurements help the clinician to objectively confirm the disturbance in the motor function of the gut and distinguish between neuropathic and myopathic disorders.

Tests of autonomic function (see Chapter 8) are useful for identifying the extent of involvement and localizing the anatomic level of the disturbance in extrinsic neural control. There is generally good agreement between abnormalities of abdominal vagal function, including the plasma pancreatic polypeptide response to modified sham feeding (Fig. 14-6) and cardiovagal dysfunction in patients with diabetes. When defects of the sympathetic nervous system have been identified by conventional tests, these usually reflect postganglionic dysfunction as in peripheral or autonomic neuropathy. An abnormal sweat test with normal sudomotor axon reflex test suggests a disturbance of preganglionic nerves and should be further investigated, for example, by imaging brain and spinal cord.

Once visceral autonomic neuropathy is identified, further tests are needed to identify any occult causes of the neuropathy; examples include lung tumors (CT of the chest), porphyria (uroporphyrinogen-1-synthase and coproporphyrinogen oxidase in erythrocytes), and amyloidosis (special protein studies in blood and urine, fat, or a rectal biopsy specimen).

MANAGEMENT OF GASTROINTESTINAL MOTILITY DISORDERS

The principles of management of any gastrointestinal motility disorder are restoration of hydration and nutrition by the oral, enteral, or parenteral route; suppression of bacterial overgrowth (e.g., with oral tetracycline); use of prokinetic agents or stimulant laxatives; and resection of localized disease. An update of pharmacotherapy is provided elsewhere.

Pyridostigmine (usually 30 to 60 mg taken four times daily, with escalation up to maximum 360 mg per day) has been used to treat autoimmune neuropathy causing dysmotility or diabetic neuropathy with constipation. Oral pyridostigmine accelerates colonic transit and improves bowel function in diabetic patients with chronic constipation and is also used (liquid formula) for gastroparesis.

The role of surgery for motility disorders due to neurologic disease is restricted to those patients with intractable colonic or rectal symptoms, particularly incontinence. There is no good rationale for vagotomy or for partial or total gastrectomy in patients with chronic neuropathies causing gastric stasis. In patients with severe colonic inertia, subtotal colectomy with ileorectostomy is usually successful, but this treatment has been used only rarely in patients with neurologic or muscle disease. Surgery for local complications of severe constipation may be necessary, as in patients with rectal intussusception or prolapse.

A Cochrane systematic review of the management of fecal incontinence and constipation in adults with central neurologic diseases12 concluded that it was not possible to make any recommendations, and bowel management remains empirical.

CONCLUDING COMMENTS

Gastrointestinal motor abnormalities result when extrinsic nerves are disturbed and are unable to modulate the motor functions of the digestive tract, which depend on the enteric nervous system and the automaticity of the smooth muscles. Disorders at all anatomic levels of the extrinsic neural control system and degenerations of gut smooth muscle have been reported in association with gut motor dysfunction and illustrate the important role of the nervous system in the etiology of gastrointestinal symptoms. Although much emphasis in the literature is placed on dysphagia and constipation in neurologic disorders, more recent studies have highlighted incontinence, vomiting, and abdominal distention in the symptomatology of such patients. Strategies that evaluate the physiologic functions of the digestive tract and the function and structure of the autonomic nervous system are available and aid in the selection of rational therapies for patients, including physical and biofeedback training (e.g., for dysphagia or incontinence), prokinetic agents (for neuropathic forms of gastroparesis, intestinal pseudo-obstruction, or slow-transit colonic disorders), and nutritional support using the enteral or parenteral route. Electric or magnetic stimulation of lumbar sacral roots may alleviate certain symptoms, such as constipation in paraplegics.

Maintenance of medical and neurologic health requires adequate ingestion, absorption, and storage of vitamins and minerals. Nutritional deficiencies may result from inadequate intake or malabsorption of critical vitamins and micronutrients. Individuals at risk for deficient nutrient intake include the impoverished in developed and underdeveloped countries (where certain nutritional disorders may be endemic), individuals with eating disorders or engaging in fad or restrictive diets, those suffering from chronic alcoholism, and patients with chronic medical conditions that result in malabsorption or require prolonged parenteral nutrition. Malabsorption may result from gastrointestinal surgery, including bariatric surgery for obesity, and from chronic gastrointestinal disorders such as celiac disease, Whipple disease, bacterial overgrowth, and inflammatory bowel disease. Excessive ingestion of certain substances, including vitamins and micronutrients, may result in neurologic impairment directly (vitamin B_6 excess) or indirectly by interfering with absorption of certain vitamins (copper deficiency induced by hyperzincemia). Awareness of the characteristic clinical features of the various nutritional disorders and conditions associated with them facilitates more timely recognition and treatment, and directly impacts prognosis (Table 15-1).

TABLE 15-1 ■ Nutritional Disorders–Diagnosis and Treatment

Vitamin	Diagnosis	Treatment
Vitamin B_{12} deficiency	Serum cobalamin Serum methylmalonic acid Serum homocysteine	Intramuscular vitamin B_{12} 1000 μg × 5 days; once monthly thereafter or vitamin B_{12} 1,000 μg daily orally
Nitrous oxide	Serum cobalamin (rendered inactive by N_2O)	Cessation of nitrous oxide exposure; Intramuscular vitamin B_{12}; Oral methionine considered
Folate deficiency	Serum folate, homocysteine	Oral folate 1 mg tid initially; then 1 mg daily thereafter
Copper deficiency	Serum copper, ceruloplasmin; urinary copper	Discontinue zinc; oral copper 8 mg daily for 1 week; 6 mg daily for 1 week; 4 mg daily for 1 week; 2 mg daily thereafter
Vitamin E	Serum vitamin E; ratio serum vitamin E to serum lipids Cholesterol, triglycerides	Vitamin E–dose range 200 mg–200 mg/kg/day oral or intramuscular
Thiamine	Clinical diagnosis; brain MRI	Thiamine 100 mg IV followed by 50–100 mg IV/IM until nutritional status stable
Pyridoxine	Serum pyridoxal phosphate	Pyridoxine 50–100 mg daily
Niacin	Urinary excretion niacin metabolites	Nicotinic acid 25–50 mg oral/IM

As is true with the evaluation of all suspected neurologic disorders, the identification of nutritional deficiencies requires a careful neurologic history and examination. A meticulous review of medication history, including prescription and over-the-counter medications, is necessary. Certain prescription and nonprescription medications may increase an individual's risk of developing a vitamin deficiency (e.g., histamine H2 blockers and vitamin B_{12} deficiency), and excessive ingestion of particular supplement medications may result in vitamin malabsorption (e.g., zinc-induced copper deficiency) and deficiency. A careful review of past medical and surgical history is critical, as a prior history of gastric bypass surgery, inflammatory bowel disease, celiac disease, and other medical and surgical conditions may compromise nutritional status. It is also essential in the evaluation of such patients to understand the time course over which various vitamin deficiencies may develop. For example, body stores of thiamine are limited, and thiamine deficiency may develop within weeks, whereas cobalamin (vitamin B_{12}) deficiency develops over years. Additionally, the identification of a particular vitamin deficiency should prompt a thorough laboratory evaluation for other vitamin deficiencies, as multiple vitamin deficiencies may occur in the same patient.

VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} (cobalamin) deficiency is a common condition, with estimated prevalence rates ranging from 2 to 15 percent of the elderly, depending upon the population studied and diagnostic criteria used. Despite these high prevalence rates, there remains no consensus on how to diagnose and evaluate patients with suspected vitamin B_{12} deficiency. Recognition of vitamin B_{12} deficiency is critical, as the hematologic and neurologic manifestations are potentially reversible if diagnosed and treated in a timely manner. However, if treatment is initiated too late, the neurologic impairment resulting from vitamin B_{12} deficiency may be irreversible.

Vitamin B_{12} is a cofactor for the enzymes methionine synthase and L-methylmalonyl-coenzyme A mutase and is required for proper red blood cell formation, normal neurologic function, and DNA synthesis. Vitamin B_{12} is necessary for the initial myelination, development, and maintenance of myelination within the central nervous system. Classically, vitamin B_{12} deficiency results in a myelopathy, or "subacute combined degeneration," which results from demyelination of the posterolateral columns of the cervical and thoracic spinal cord.[1] Demyelination of cranial nerves, peripheral nerves, and brain may also occur and has been referred to as "combined-systems disease." Vitamin B_{12} deficiency may result in megaloblastic anemia, with macrocytosis, anisocytosis, hypersegmented neutrophils, leukopenia, thrombocytopenia, or pancytopenia.

Etiology

Vitamin B_{12} is a water-soluble vitamin that exists in several forms, all of which contain cobalt, and are collectively referred to as cobalamins. Methylcobalamin and 5-deoxyadensoylcobalamin are the forms of

Dietary restriction

vitamin B_{12} that are active in human metabolism. Vitamin B_{12} is contained in a number of animal proteins, in fortified breakfast cereals, and in some nutritional yeast products. Daily losses of vitamin B_{12} are minimal, and even in cases of severe malabsorption, it may take 5 years or more to develop symptomatic vitamin B_{12} deficiency.

Vitamin B_{12} deficiency in elderly patients most commonly results from pernicious anemia, atrophic gastritis, and achlorhydria-induced cobalamin malabsorption[2,3] (Table 15-2). The incidence of atrophic gastritis increases with age and may at least partially explain the increased frequency of vitamin B_{12} deficiency with aging. Achlorhydria results in impaired extraction of vitamin B_{12} from food sources. Partial gastrectomy, bariatric surgery, and ileal resection may result in the malabsorption of vitamin B_{12}, and partial gastrectomy has been associated with loss of intrinsic factor. Gastroenterologic disorders such as celiac disease, Crohn disease, ileitis, pancreatic disease, and bacterial overgrowth may also result in vitamin B_{12} deficiency. Certain medications, such as histamine (H2) blocking agents, proton pump inhibitors, and glucophage may also increase one's risk of developing vitamin B_{12} deficiency. Vitamin B_{12} deficiency rarely results from inadequate intake in vegetarians and would be expected to develop only after many years.

Nitrous oxide alters the cobalt core of cobalamin, converting it into an inactive, oxidized form. Hence, nitrous oxide abuse may result in cobalamin deficiency, with most reported cases associated with low or borderline-low vitamin B_{12} levels. A single exposure to nitrous oxide may be enough to precipitate neurologic impairment in an individual with unsuspected vitamin B_{12} deficiency, with time to symptom onset ranging from immediate postexposure up to 2 months. Nitrous oxide remains one of the more commonly used anesthetic agents worldwide, and can also be obtained for abuse in the form of whipped cream canisters, and as "whippets," which are small bulbs containing nitrous oxide.

Clinical Manifestations

Neurologic signs and symptoms of vitamin B_{12} deficiency may be the initial manifestation of this condition. Paresthesias and ataxia are the most common initial symptoms in patients with vitamin B_{12} deficiency. Classically, vitamin B_{12} deficiency results in a myelopathy, which may be accompanied by a peripheral neuropathy. The myelopathy results from impairment in posterior column and lateral spinothalamic tract function, with a combination of pyramidal signs and posterior column sensory loss evident on examination. The peripheral neuropathy associated with vitamin B_{12} deficiency is typically mild and is predominantly axonal on electrodiagnostic testing.

Neuropsychiatric manifestations range from memory impairment, change in personality, delirium, and even psychosis. Optic neuropathy, resulting in diminished visual acuity, optic atrophy, and centrocecal scotomas may be seen. Symptoms of orthostatic intolerance, resulting from orthostatic hypotension, are an uncommon manifestation of vitamin B_{12} deficiency. Other much less commonly encountered neurologic conditions attributed to vitamin B_{12} deficiency include cerebellar ataxia, orthostatic tremor, ophthalmoplegia, and vocal cord paralysis. A number of constitutional symptoms may accompany the neurologic signs and symptoms, including fatigue, weight loss, fever, dyspnea, and gastrointestinal symptoms.

Diagnosis

Serum cobalamin is the initial screening test in patients with suspected vitamin B_{12} deficiency (Table 15-1), however limitations in cobalamin sensitivity must be recognized. Some patients with vitamin B_{12} deficiency will have normal cobalamin levels. In patients with borderline low cobalamin levels, and particularly in those patients strongly suspected of vitamin B_{12} deficiency, methylmalonic acid and homocysteine levels should be checked. Methylmalonic acid and homocysteine levels are increased in as many as one-third of patients with low-normal serum cobalamin levels and vitamin B_{12} deficiency. However, these tests, particularly homocysteine, lack specificity (Table 15-2).

Once a diagnosis of vitamin B_{12} deficiency is established, diagnostic testing may be pursued in order to determine the cause. Antibodies to intrinsic factor are seen in only 50 to 70 percent of patients with pernicious anemia, but are highly specific. Antiparietal cell antibodies lack sensitivity and specificity and have limited utility. Gastrin antibodies are 70 percent sensitive and specific for pernicious anemia. Elevated serum gastrin and decreased pepsinogen I levels have been reported to be abnormal in 80 to 90 percent of patients with pernicious anemia, but the specificity of these tests may be limited. The Schilling test is rarely utilized presently due to concerns about radiation exposure, cost, and diagnostic accuracy.

Nerve conduction studies (NCSs) and needle electromyography (EMG) may confirm the presence of an axonal sensorimotor peripheral neuropathy. Somatosensory evoked potentials (SEPs) may show slowing in central proprioceptive pathways. Brain and spinal cord magnetic resonance imaging (MRI) studies may show signal change in subcortical white matter and in posterolateral columns.

Treatment

Treatment of neurologic impairment due to vitamin B_{12} deficiency involves the administration of high-dose oral, sublingual, or intramuscular cobalamin. With malabsorption, 1000 μg of cobalamin is administered intramuscularly for 5 days and monthly thereafter. There is evidence to suggest that 1000 μg of oral or sublingual cobalamin, given daily, is as effective as intramuscular administration.[4] Lifelong vitamin B_{12} supplementation therapy is typically necessary, unless a potentially reversible cause is identified and treated. Hematologic recovery occurs within the first 1 to 2 months and is complete. The neurologic condition should stabilize and improvement may occur over the first 6 to 12 months following the initiation of treatment. Neurologic recovery may be incomplete, particularly in those with significant neurologic deficits prior to the initiation of therapy. Methylmalonic acid and homocysteine levels should be utilized to monitor response to therapy, and typically should normalize within 10–14 days.

Patients with pernicious anemia should undergo endoscopy, as they are at higher risk of developing gastric and carcinoid cancers. Upper endoscopy should be considered in other patients as well, including those with other gastrointestinal symptoms and those with other concomitant vitamin deficiencies.

FOLATE DEFICIENCY

The active form of folate, tetrahydrofolic acid (THFA), is essential in the transfer of one-carbon units to substrates utilized in the synthesis of purine, thymidine, and amino acids. Methyl tetrahydrofolate (THF) is required for the cobalamin-dependent remethylation of homocysteine to methionine, and methylene THF methylates deoxyuridylate to thymidylate. While folate deficiency might be expected to result in similar complications as vitamin B_{12} deficiency, neurologic manifestations of isolated folate deficiency are extremely uncommon.

Etiology

Folate is present in animal products, citrus fruits, and green, leafy vegetables. Normal body stores of folate range from 500 to 20,000 μg, and 50 to 100 μg are required daily. Serum folate falls within 3 weeks of diminished intake or malabsorption, and clinical signs of folate deficiency may occur within months. After ingestion, folate polyglutamates undergo hydrolysis to monoglutamates, which are absorbed in the proximal small intestine and ileum. Absorbed folate monoglutamates are then metabolized by the liver to 5-methyl-tetrahydrofolate (MTHF), the principal circulating form of folate. The cellular uptake of MHTF is mediated by four different carrier systems: a proton-coupled folate transporter, low-affinity high-capacity reduced folate carrier, and two high-affinity folate receptors.

Folate deficiency is one of the more common nutritional disorders worldwide. Risk factors for folate deficiency include malnutrition, conditions associated with increased folate requirements (e.g., pregnancy, lactation, and chronic hemolytic anemia), gastroenterologic disorders, and certain medications (Table 15-3). Gastroenterologic conditions that affect folate absorption in the small bowel may result in folate deficiency, including tropical sprue, celiac disease, bacterial overgrowth syndrome, inflammatory bowel disease, and pancreatic insufficiency. Gastric surgeries or medications that reduce gastric secretions may also result in folate deficiency. A number of other medications, such as methotrexate, aminopterin, pyrimethamine, trimethoprim, and triamterene, inhibit dihydrofolate reductase and may result in folate deficiency. Mechanisms by which other medications such as anticonvulsants, sulfasalazine, oral contraceptives, and antituberculous drugs affect folate levels have not been established.

Eight inborn errors of folate absorption have been described, including hereditary folate malabsorption, cerebral folate transporter deficiency, glutamate formiminotransferase deficiency, severe methylenetetrahydrofolate reductase (MTHFR) deficiency, dihydrofolate reductase deficiency, methylenetetrahydrofolate dehydrogenase 1 (MTHFD1) protein deficiency, and functional methionine synthase deficiency. Clinical manifestations of these disorders may include megaloblastic anemia, mental retardation, seizures, movement disorders, and peripheral neuropathy. Early identification and treatment with folate may result in clinical improvement in certain forms of these disorders. Methylenetetrahydrofolate deficiency is the most common of these disorders, with variable neurologic and vascular manifestations, including mental retardation, seizures, motor and gait disorders, schizophrenia, and thromboses, with laboratory studies showing hyperhomocysteinemia and homocystinuria.

TABLE 15-3 ■ Causes of Folate Deficiency

Malnutrition (e.g., in alcoholism, premature infants, adolescents)
Increased folate requirement (e.g., pregnancy, lactation, chronic hemolytic anemia)
Dietary restriction (e.g., phenylketonuria)
Malabsorption (e.g., tropical sprue, celiac disease, bacterial overgrowth, inflammatory bowel disease, giardiasis)
States of reduced gastric secretions (e.g., gastric surgery, atrophic gastritis, H2 receptor antagonists, proton pump inhibitors, treatment of pancreatic insufficiency)
Medications that inhibit dihydrofolate reductase (e.g., aminopterin, trimethoprim, methotrexate, pyrimethamine, triamterene)
Medications with unclear mechanism (e.g., anticonvulsants, antituberculous drugs, sulfasalazine, oral contraceptive agents)
Inborn errors of folate metabolism (e.g., hereditary folate malabsorption, cerebral folate transporter deficiency, glutamate formiminotransferase deficiency, severe methylenetetrahydrofolate reductase (MTHFR) deficiency, dihydrofolate reductase deficiency, methylenetetrahydrofolate dehydrogenase 1 (MTHFD1) protein deficiency, functional methionine synthase deficiency)

Clinical Manifestations

Maternal folate deficiency during or around the time of conception has been reported to result in more than 50 percent of neural tube defects.[5] Myeloneuropathy, peripheral neuropathy, and megaloblastic anemia have been associated with folate deficiency. These potential manifestations of folate deficiency are clinically indistinguishable from those of vitamin B_{12} deficiency, although as previously mentioned they are much less common. Preliminary reports suggest that folate deficiency may be associated with an increased risk of peripheral vascular disease, coronary artery disease, cerebrovascular disease, and cognitive impairment, although these preliminary reports await further confirmatory research.

Diagnosis

Serum folate, red blood cell folate, and homocysteine levels may be used to evaluate an individual with suspected folate deficiency. Results depend upon methods and laboratories where these studies are performed. Serum folate levels fluctuate considerably and do not always accurately reflect tissue stores. Red blood cell folate levels may more accurately predict tissue stores, but there is considerable laboratory assay variability. Homocysteine levels have been demonstrated to be elevated in 86 percent of patients with clinically significant folate deficiency. Typically, a serum folate level of 2.5 μg/L has been utilized as the cutoff for folate deficiency; however, it has been suggested that a range of 2.5 to 5 ng/mL may reflect mildly compromised folate status.[6]

Treatment

Vitamin B_{12} levels should also be assessed with suspected folate deficiency, and if low, vitamin B_{12} supplementation should be initiated immediately. Oral administration of folic acid may be adequate, typically 1 mg three times daily followed by maintenance dosing of 1 mg daily. Parenteral administration of folic acid may be considered in acutely ill patients, and particularly in patients with malabsorption. Folate supplementation, 0.4 mg daily, is recommended in women of childbearing age with epilepsy.

COPPER DEFICIENCY

Copper is a trace element involved in a number of metalloenzymes, critical in the development and maintenance of nervous system structure and function. These enzymes include cytochrome c-oxidase (electron transport, oxidative phosphorylation), copper/zinc superoxide dismutase (antioxidant defense), tyrosinase (melanin synthesis), dopamine β-hydroxylase (catecholamine synthesis), lysl oxidase (cross-linking collagen and elastin), and others.

Copper deficiency in animals was first recognized in sheep in 1937, manifesting as an enzootic ataxia (also known as swayback), and then subsequently was noted to affect other animals similarly.[7] Hematologic abnormalities were the first signs of acquired copper deficiency recognized in humans, with anemia, neutropenia, and sideroblastic anemia evident in some but not all patients with copper deficiency. The neurologic manifestations of acquired copper deficiency have been defined over the past several years.

Etiology

Copper is present in a wide variety of foods, with shellfish, oysters, legumes, organ meats, chocolate, nuts, and whole-grain products being particularly rich in copper. The estimated daily requirement for copper is 0.70 mg, and the estimated total body copper content is 50 to 120 mg. Copper absorption occurs in the stomach and proximal small intestine via active and passive transport processes. The Menkes P-type ATPase (ATP7A) is responsible for copper efflux from enterocytes.

Malabsorption following prior gastric surgery and excessive, exogenous zinc ingestion are the most frequently identified causes of symptomatic copper deficiency. Copper deficiency may also occur in premature, low-birthweight, and malnourished infants, and may occur as a complication of total parenteral or enteral nutrition. Chronic gastrointestinal conditions such as celiac disease, cystic fibrosis, inflammatory bowel disease, and bacterial overgrowth may result in copper malabsorption. Patients should be queried about the use of zinc supplements, including denture creams, some of which have excessive zinc and may induce copper deficiency. Excessive zinc ingestion may also cause copper deficiency. It is hypothesized that excessive zinc ingestion upregulates intestinal enterocyte metallothionein production, which has a higher affinity for copper than zinc, resulting in retention of copper in intestinal enterocytes and loss of copper in the stool. Some patients will not have any identifiable cause for copper deficiency.

Menkes disease is a congenital disorder with clinical signs and symptoms that result from copper deficiency. This condition results from a mutation in the *ATP7A* gene, which leads to failure of intestinal copper transport across the gastrointestinal tract and subsequent copper deficiency. Wilson disease is a disorder of copper toxicity that results from an impairment in biliary copper excretion.

Clinical Manifestations

Hematologic abnormalities have been well described in copper deficiency, and include anemia and neutropenia, primarily. Failure to recognize hematologic derangements as resulting from copper deficiency has led to misdiagnoses such as myelodysplastic syndrome, aplastic anemia, and sideroblastic anemia. Patients with copper deficiency may develop a myeloneuropathy that resembles the syndrome of subacute combined degeneration associated with vitamin B_{12} deficiency. Pyramidal signs, such as brisk deep tendon reflexes at the knees, and extensor plantar responses are typically present, along with impairment in posterior column sensory modalities. Sensory loss is characteristically severe, and frequently leads to a sensory ataxia. Neuropathic extremity pain may be reported, and distal lower limb weakness and atrophy may develop suggesting peripheral nerve involvement.

Diagnosis

Low serum copper and ceruloplasmin levels establish the diagnosis of copper deficiency. Twenty-four-hour urine copper levels will often be decreased, in contrast to an elevation in urinary copper seen with Wilson disease. Serum and 24-hour urine zinc levels should also be assessed. Ceruloplasmin is an acute-phase reactant and may be increased in various conditions, including pregnancy, oral contraceptive use, liver disease, malignancy, hematologic disease, smoking, diabetes, uremia, and other inflammatory and infectious diseases. In the presence of these conditions, copper deficiency may be masked. Serum copper and ceruloplasmin may be decreased in Wilson disease, hence laboratory evidence of copper deficiency does not necessarily indicate copper deficiency in the absence of clinical features consistent with the diagnosis.

Cervical MRI studies may show T2 hyperintensity involving the dorsal columns (Fig. 15-1). Somatosensory evoked potentials often show slowing in central proprioceptive pathways, and NCS and needle EMG demonstrate findings consistent with an axonal sensorimotor peripheral neuropathy. Brain MRI studies may show diffuse T2 hyperintensities involving the subcortical white matter, suggesting demyelination.

Treatment

Treatment of copper deficiency involves discontinuation of zinc in those with excessive zinc consumption as well as copper supplementation. A recommended regimen is 8 mg of orally administered elemental copper administered daily for 1 week, followed by 6 mg daily for the next week, 4 mg daily during the third week, and 2 mg daily thereafter. Occasionally intravenous copper supplementation is necessary. Ongoing copper supplementation may not be necessary in patients with copper deficiency due to zinc excess (with cessation of zinc ingestion) or in those with a treatable gastrointestinal condition resulting in copper malabsorption (such as celiac disease). Patients without an identifiable cause of copper deficiency or those with copper malabsorption due to gastric bypass surgery typically require lifelong copper supplementation.

Similar to vitamin B_{12} deficiency, the hematologic abnormalities associated with copper deficiency normalize within 1 month of copper repletion. Neurologic deficits are expected to stabilize, but there may be little improvement in neurologic signs and symptoms, particularly in those with more severe neurologic impairment.

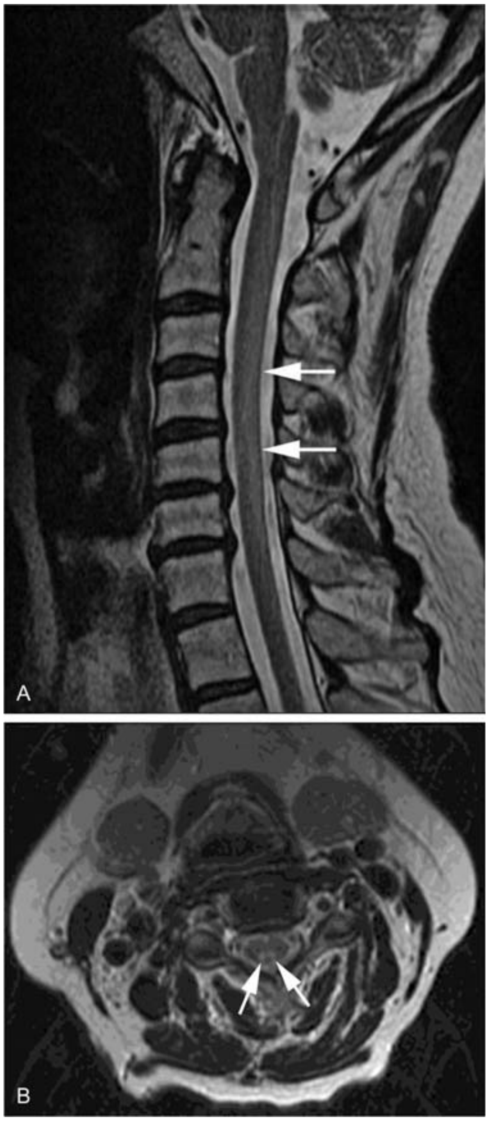

FIGURE 15-1 ■ Cervical magnetic resonance imaging (MRI) in a patient with copper deficiency myeloneuropathy. T2 hyperintensity demonstrated in posterior columns in *A*, sagittal and *B*, axial images (*arrows*). (From Goodman BP, Chong BW, Patel AC, et al: Copper deficiency myeloneuropathy resembling B_{12} deficiency: partial resolution of MR imaging findings with copper supplementation. AJNR Am J Neuroradiol 27:2112, 2006, with permission.)

VITAMIN E DEFICIENCY

Vitamin E is a fat-soluble vitamin with important antioxidant properties, providing protection against oxidative stress and inhibiting the fatty acid peroxidation of membrane phospholipids. Vitamin E refers to a family of tocopherols and tocoretinols, of which α-tocopherol is the most abundant and active biologic form of vitamin E in the human diet.

Etiology

Nut oils, sunflower seeds, whole grains, wheat germ, and spinach are foods high in vitamin E. Vitamin E absorption requires bile salts and pancreatic esterases. Vitamin E is incorporated into chylomicrons in intestinal enterocytes, and upon release into the circulation lipolysis ensues, resulting in the transfer of vitamin E to high-density and other lipoproteins. Alpha-tocopherol transfer protein in the liver is responsible for the incorporation of vitamin E into very-low-density lipoprotein (VLDL), which also delivers vitamin E to tissues.

Vitamin E absorption requires pancreatic and biliary secretions, and may therefore result from chronic cholestasis and pancreatic insufficiency. Chronic total parenteral nutrition (TPN) with inadequate vitamin E supplementation may be a cause. Other gastrointestinal disorders may result in vitamin E malabsorption, including celiac disease, inflammatory bowel disease, blind loop syndrome, bacterial overgrowth, irradiation, and cystic fibrosis. Genetic causes of vitamin E deficiency include ataxia with vitamin E deficiency resulting from α-tocopherol transport protein (α-TTP) deficiency, apolipoprotein B mutation (homozygous hypobetalipoproteinemia), or a defect in the microsomal triglyceride transfer protein (abetalipoproteinemia).

Clinical Manifestations

Numerous neurologic manifestations of vitamin E deficiency have been reported including ophthalmoplegia, retinopathy, and a spinocerebellar syndrome with an associated peripheral neuropathy, resembling Friedreich ataxia. This spinocerebellar syndrome manifests with signs of a cerebellar ataxia, posterior column sensory loss, pyramidal signs, and sensory loss on neurologic examination. A myopathy has been associated with vitamin E deficiency, with reported pathologic features including inflammatory infiltrates and rimmed vacuoles. Vitamin E deficiency has rarely been associated with a demyelinating neuropathy.

Diagnosis

Low serum vitamin E levels confirm the diagnosis of vitamin E deficiency. Serum lipids, cholesterol, and VLDL affect serum vitamin E levels, and serum vitamin E levels can be corrected for these factors by dividing serum vitamin E levels by the sum of serum triglycerides and cholesterol. Increased stool fat and decreased serum carotene levels may also be noted in patients with fat malabsorption.

Spinal MRI studies may show T2 signal change in the dorsal columns, similar to what is seen with vitamin B_{12} and copper deficiency. Median and tibial SEPs may show slowing in central proprioceptive pathways.

Treatment

Vitamin E supplementation utilizing dosages ranging from 200 mg/day to 200 mg/kg/day are administered. Parenteral administration may be necessary with some conditions, particularly those with severe malabsorption. Unless there is a reversible cause for vitamin E deficiency, lifelong supplementation may be necessary.

THIAMINE (VITAMIN B_1) DEFICIENCY

The active form of thiamine is thiamine pyrophosphate (TPP), which functions as a coenzyme in the metabolism of carbohydrates, lipids, and branched chain amino acids. It is involved in decarboxylation of α-keto acids during adenosine triphosphate (ATP) synthesis and maintenance of reduced glutathione in erythrocytes. TPP additionally is a coenzyme in myelin synthesis, and has been hypothesized to play a role in cholinergic and serotonergic neurotransmission through effects on sodium channel function.

Etiology

Thiamine, or vitamin B_1, is a water-soluble vitamin most commonly found in unrefined cereal grains, wheat germ, yeast, soybean flour, and pork. A water-soluble vitamin, storage (hepatic) of thiamine is minimal, with excess excreted in the urine. This and the 10- to 14-day half-life necessitate regular dietary supply of thiamine to prevent deficiency. The recommended daily allowance ranges from 1.0 to 1.5 mg/day, but requirements increase in proportion to carbohydrate intake and metabolic rate.

Thiamine is converted in the jejunum to TPP and absorbed throughout the small intestine, passing through the portal circulation prior to active and passive transport across the blood–brain barrier. Hepatic storage is minimal and the half-life of thiamine is short, leading to clinical manifestations of deficiency within days of depletion or reduced stores.

With thiamine supply being intake-dependent, deficiency is seen in persons with compromised nutritional status: reduced intake (e.g., alcoholism, starvation, fad dieting and dieting aids, chronic illness, inadequate parenteral nutrition, thiaminase-containing foods); malabsorption (e.g., bariatric surgery, gastrointestinal/liver/pancreatic disease, excess antacid use); and increased losses (persistent emesis or diarrhea, renal failure with dialysis) can result in clinical deficiency (Table 15-4). Deficiency is also seen from increased thiamine requirements such as in high metabolic states (e.g., pregnancy, critical illness, hyperthyroidism, malignancy, infection) and high carbohydrate intake (e.g., intravenous glucose administration, refeeding syndrome, parenteral nutrition). In the latter case, the demand for thiamine, which is needed for glucose oxidation, exceeds replacement.

In developed countries thiamine deficiency is seen most commonly with excessive alcohol use, although the rise of fad dieting and bariatric surgery has led to an increasing incidence in nonalcoholics. Inadequate intake, reduced gastrointestinal absorption, impaired conversion to active metabolite, increased demand (for carbohydrate metabolism), and reduced hepatic storage of thiamine all contribute to the development of clinical deficiency in alcoholics. Genetic polymorphisms in thiamine and alcohol metabolism may predispose to the development of a thiamine deficiency syndrome.

Clinical Manifestations

Thiamine is a key cofactor in carbohydrate metabolism, acting as a coenzyme in the tricarboxylic acid cycle and hexose monophosphate shunt. Deficiency results in a reduction of high-energy phosphates with lactic acid accumulation and impaired oxygen uptake. Cerebral tissue is dependent on glucose for energy and is particularly vulnerable to damage from impaired glucose metabolism. Neurotoxicity is thought to result from disruption in osmotic gradients, glutamate accumulation, and impaired blood–brain barrier permeability. Animal models have shown a predilection for brainstem and cerebellar involvement.

Thiamine deficiency most commonly affects the heart and both central and peripheral nervous systems. Three well-described manifestations include beriberi (dry and wet), infantile beriberi, and Wernicke encephalopathy with Korsakoff syndrome.

TABLE 15-4 ■ Causes of Thiamine Deficiency

Reduced intake
- Alcoholism
- Starvation
- Fad dieting/dieting aids
- AIDS
- Inadequate parenteral nutrition
- Thiaminase-containing foods (polished rice, overbaked bread, prolonged milk pasteurization)

Malabsorption
- Bariatric surgery
- Gastrointestinal/hepatic/pancreatic disease
- Antacids

Increased loss
- Persistent emesis
- Persistent diarrhea
- Renal failure/dialysis

High metabolic state
- Pregnancy
- Critical illness
- Hyperthyroidism
- Malignancy
- Infection
- Chemotherapy (ifosfamide)

Increased carbohydrate intake
- Intravenous glucose administration
- Refeeding syndrome
- Parenteral nutrition

AIDS, acquired immunodeficiency syndrome.

BERIBERI

Thiamine deficiency is classically described as a painful, length-dependent sensorimotor axonal neuropathy. In malnourished individuals, concomitant deficiency in other B vitamins such as pantothenic acid and pyridoxine may also contribute to the development of a nutritional polyneuropathy. Fatigue, irritability, and muscle cramps may be the earliest manifestation, presenting within days to weeks of deficiency. Symptoms can be rapidly progressive and evolve from distal sensory loss or burning dysesthesias to muscle weakness. Cranial neuropathy and recurrent laryngeal nerve palsy have been described, and an autonomic neuropathy may also be present.

Dry beriberi refers to the presence of a polyneuropathy, while wet beriberi is used when the development of high-output cardiac failure and peripheral edema predominate. They are considered clinical spectra of the same disease process, with the potential of one to evolve into the other.

Infantile beriberi is seen in infants with thiamine-deficient diets, including breast-fed children of thiamine-deficient mothers. The clinical spectrum is varied and may involve the development of cardiac, ophthalmologic, central nervous system, and systemic abnormalities. Infants can present with irritability, vomiting, diarrhea, failure to thrive, seizures, ophthalmoplegia, drowsiness, and respiratory difficulty.

WERNICKE ENCEPHALOPATHY

Wernicke encephalopathy refers to a syndrome characterized by varying degrees of subacute gait and trunk ataxia, ocular abnormalities, and mental status changes. The presentation is heterogeneous and autopsy studies suggest it often goes undiagnosed. Ataxia is caused primarily by cerebellar dysfunction and can be accompanied by other localizing abnormalities such as dysarthria and dysmetria. Vestibular dysfunction and co-existing neuropathy can contribute to the development of ataxia. Ocular manifestations are many and include nystagmus, ophthalmoparesis, pupillary abnormalities, and decreased visual acuity. Delirium, somnolence, impaired attention, and lack of orientation are prominent cognitive manifestations of this syndrome. Brainstem or hypothalamic involvement in addition to comorbid autonomic neuropathy may result in fluctuations in body temperature, blood pressure, and heart rate. Typically, pathologic changes are most prominent in the mammillary bodies.

KORSAKOFF SYNDROME

Approximately 80 percent of patients with Wernicke encephalopathy develop residual Korsakoff syndrome, an amnestic condition characterized by severe retrograde and anterograde memory loss and subsequent confabulation. The dorsal medial nucleus of the thalamus is often affected. Involvement of the limbic and frontal cortex has been implicated in the development of anterograde and retrograde amnesia, respectively. Memory impairments are often chronic and progressive.[8]

Diagnosis

Thiamine deficiency remains a clinical diagnosis; urine and serum thiamine levels are not reflective of tissue thiamine concentrations and can often be normal.[9] Surrogate measurements can include erythrocyte thiamine diphosphate levels or the transketolase activation assay, but they must be drawn prior to treatment initiation due to rapid normalization. Impaired aerobic metabolism can cause elevations in lactate and subsequent anion-gap metabolic acidosis. Brain MRI can show T2 signal abnormalities in paraventricular regions including the thalamus, hypothalamus, mammillary bodies, periaqueductal midbrain,pons, medulla, and cerebellum (Fig. 15-2). Reversible contrast enhancement of the mammillary bodies is often seen in Wernicke encephalopathy. Development of vasogenic edema may cause diffusion-weighted abnormalities, often resolving with treatment. MR spectroscopy can show elevation in cerebral lactate but is not commonly used.

Treatment

Parenteral thiamine replacement is the mainstay of treatment, but must be administered to high-risk patients prior to glucose or TPN infusion. Glucose oxidation is highly thiamine-dependent and inadequate supplementation can result in intracellular shift of already-depleted thiamine stores and resultant neurotoxicity. Ongoing poor nutritional status often necessitates oral maintenance therapy at 50 to 100 mg daily. Attention should be given to the possibly emergent underlying cause of malnutrition or increased metabolic demand such as sepsis.

Clinical manifestations of thiamine deficiency are partially reversible with treatment; heart failure, ocular abnormalities, and acute mental status changes often resolve quickly. Neuropathic symptoms and gait ataxia recover slowly and can persist. Memory impairment from Korsakoff syndrome is often permanent.

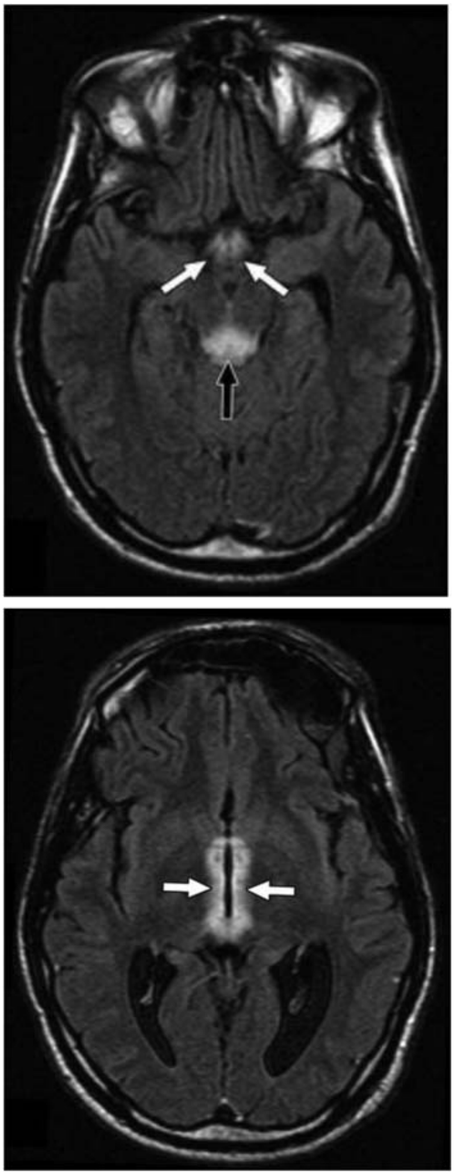

FIGURE 15-2 ■ Axial fluid-attenuated inversion recovery (FLAIR) brain MRI in a patient with Wernicke encephalopathy demonstrating hyperintensity in the periventricular region of the third ventricle, periaqueductal region, and mammillary bodies (*arrows*). PYRIDOXINE (B_6) DEFICIENCY

Pyridoxine, or vitamin B_6, is a water-soluble vitamin involved in tryptophan, methionine, and gamma aminobutyric acid (GABA) metabolism. The active form of pyridoxine is pyridoxal 5'-phosphate (PLP), a coenzyme that is critical in amino acid and sphingolipid metabolism, as well as the biosynthesis of glucose, many neurotransmitters, and heme.

Etiology

Pyridoxine is abundant in meat, fish, eggs, and dairy products. Pyridoxine must be obtained exogenously and is absorbed in the small intestine. As most adult diets provide adequate pyridoxine, clinical deficiency is predominantly seen as a side effect of pyridoxine-antagonizing medications such as isonicotinic acid hydrazide, hydralazine, and penicillamine. The elderly, pregnant and lactating women, alcoholics, those with sickle cell anemia, and patients with chronic gastrointestinal or malabsorptive conditions are additionally susceptible to pyridoxine deficiency. Genetic mutations can result in an infantile deficiency syndrome.

Clinical Manifestations

Autosomal recessive mutations in the antiquitin gene results in inactivation of PLP and can manifest with pyridoxine-responsive seizures in adequately nourished neonates. Rarely, seizures may develop in breastfeeding infants of malnourished mothers. In adults, chronic pyridoxine deficiency causes a painful sensorimotor peripheral neuropathy. Patients may additionally develop a microcytic hypochromic or sideroblastic anemia. A pellagra-type syndrome with skin, gastrointestinal, and cognitive abnormalities has been described due to abnormal tryptophan metabolism and subsequent niacin deficiency. Conversely, ingestion of pyridoxine exceeding 100 mg per day as seen with excessive vitamin intake can result in a pure sensory neuropathy or dorsal root ganglionopathy.

Diagnosis

Pyridoxine deficiency is often diagnosed clinically and confirmed through measurement of serum PLP levels. An empiric diagnostic trial of pyridoxine is indicated for neonatal seizures. Elevation of pipecolic acid and α-amino adipic semialdehyde levels is seen in infants with genetic pyridoxine-dependent seizures and can be measured in the serum, urine, and cerebrospinal fluid. In adults, serum PLP levels in excess of 20 to 30 nmol/L are considered indicative of adequate pyridoxine status. Elevated serum homocysteine levels following a methionine load can also be seen with pyridoxine deficiency but are rarely measured.

Treatment

Infantile seizures are usually responsive to high doses of pyridoxine but require years of oral maintenance therapy as seizures will recur days after treatment cessation. Drug-induced neuropathy often recovers with discontinuation of the offending agent and oral pyridoxine replacement at 50 to 100 mg/day. One must avoid excess supplementation to prevent associated toxic sensory neuropathy, which additionally is reversible. Treatment of any underlying gastrointestinal, malabsorptive, or hematologic disease is indicated.

NIACIN DEFICIENCY

Etiology

Niacin, or vitamin B_3, is an end-product of tryptophan metabolism involved in carbohydrate metabolism. Niacin deficiency results in the clinical syndrome of pellagra, and is seen primarily in developing countries where corn is the primary carbohydrate source, since corn lacks niacin and tryptophan. Several vitamins and minerals are necessary for the conversion of tryptophan to niacin, including iron, copper, vitamin B_2, and vitamin B_6. Deficiency of vitamin B_6 may result in secondary niacin deficiency. Niacin deficiency may also develop in alcoholics, those with malabsorption, and bacterial overgrowth conditions. Hartnup syndrome may also result in pellagra due to an impairment in conversion of tryptophan to niacin.

Clinical Manifestations

Niacin deficiency affects the skin, gastrointestinal tract, and the nervous system, but skin and gastrointestinal manifestations are frequently absent. Potential gastrointestinal manifestations of pellagra include stomatitis, abdominal pain, and diarrhea. A hyperkeratotic rash, preferentially involving the face, chest, and dorsum of the hands and feet may be seen. Potential neurologic manifestations include encephalopathy, coma, and peripheral neuropathy.

Diagnosis and Treatment

There are currently no reliable serologic studies to identify niacin deficiency. However, measurement of urinary excretion of the methylated niacin metabolites N^1-methylnicotinamide and N^1-methyl-2-pyridone-5-carboxamide can assess niacin status. Oral or parenteral nicotinic acid is administered three times daily.

VITAMIN A DEFICIENCY

Etiology

Vitamin A refers to a collective group of fat-soluble retinoids that includes retinol, retinal, retinoic acid, and retinyl esters. Vitamin A plays an important role in vision, reproduction, and cellular communication. Preformed vitamin A (retinol and retinyl ester) and provitamin A carotenoids are available in the diet. Preformed vitamin A is found in animal sources including dairy products, fish, and meat, while the provitamin A carotenoids (such as beta-carotene) are present in various plant sources. These forms of vitamin A are converted intracellularly into retinal and retinoic acid, the biologically active forms of vitamin A.

The various forms of vitamin A are absorbed primarily in the duodenum and stored in the liver as retinyl esters. Vitamin A deficiency may result from dietary restriction (e.g., diets lacking beta-carotene, alcoholics, the elderly), and may develop in conditions associated with fat malabsorption such as celiac disease, pancreatitis, cystic fibrosis, biliary atresia, and cholecystatic liver disease.

Clinical Manifestations

Chronic, excessive ingestion of vitamin A may lead to headache, increased intracranial pressure, nausea, dizziness, skin changes, bone and joint pain, coma, and even death. Conversely, vitamin A deficiency can cause night blindness, corneal dryness and keratinization, white foamy spots on the cornea (Bitot spots), dysgeusia, skin hyperkeratosis, and hyperkeratosis of the respiratory, gastrointestinal, and urinary tracts.

Diagnosis and Treatment

Assessment of vitamin A levels establishes states of vitamin A deficiency or toxicity. Oral vitamin A supplementation is used to treat vitamin A deficiency.

VITAMIN D DEFICIENCY

Vitamin D is a fat-soluble vitamin that promotes calcium absorption in the gut, thereby maintaining normal serum calcium and phosphate concentrations and enabling normal bone mineralization, bone growth, and remodeling. Vitamin D is also involved in cell growth modulation, neuromuscular function, immune function, and reduction of inflammation. There are two forms of vitamin D: vitamin D_2 or ergocalciferol (produced by plants) and vitamin D_3 or cholecalciferol (produced by sunlight conversion of 7-dehydrocholesterol in the skin).

Etiology

Very few foods in the human diet contain vitamin D. Fatty fish (such as tuna, salmon, mackerel) and fish liver contain the highest amounts, while smaller amounts can be found in beef liver, cheese, and egg yolk. The majority of vitamin D in the American diet comes from fortified foods such as milk, some breakfast cereals, orange juice, and various other foods. However, most people obtain most of their vitamin D needs through sun exposure.

Vitamin D is absorbed passively in the small intestine, then bound to lipoproteins and transported to the liver by chylomicrons. In the liver, vitamin D is hydroxylated to 25-(OH)-vitamin D, and subsequently hydroxylated a second time to 1,25-(OH)-vitamin D in the kidneys. 1,25-(OH)-vitamin D is the biologically active form.

Causes of vitamin D deficiency include inadequate sun exposure, dietary insufficiency, gastrectomy and gastric bypass surgery, pancreatic disease, liver disease, renal disease, and malabsorption. As is true with the other vitamin deficiencies, inflammatory bowel disease, celiac disease, extensive small intestine resection, and cholestatic liver disease may cause vitamin D deficiency. Phenobarbital and phenytoin inhibit vitamin D hydroxylation in the liver. Breastfed infants are at risk because breast milk does not have adequate levels to meet vitamin D requirements. People with dark skin are also at greater risk for developing vitamin D deficiency because melanin in the epidermis reduces the skin's ability to generate cholecalciferol. Other risk factors include older age, sunscreen use, high latitudes, and other environmental factors such as pollution, extent of cloud cover, and ozone levels.

Clinical Manifestations

Vitamin D deficiency may cause rickets in children and osteomalacia in adults due to defective bone mineralization. A proximal myopathy may develop, often associated with bone pain and osteomalacia. A multitude of other medical conditions have been associated with suboptimal vitamin D levels including hypertension, diabetes mellitus, certain types of cancers, and multiple sclerosis, but more definitive, prospective studies are necessary to establish definite risk. The role of vitamin D deficiency in multiple sclerosis risk has not been conclusively established to date. Multiple sclerosis incidence and prevalence are increased at higher latitudes, but the roles of sun exposure and vitamin D deficiency may both be factors in increased risk. Treatment with vitamin D in multiple sclerosis has not been demonstrated to be of benefit in reducing risk of relapse, brain MRI lesions, or decreasing disability.[10]

Diagnosis and Treatment

Total 25-(OH)-vitamin D is the best laboratory study to assess vitamin D body stores, and can be used to diagnose and monitor vitamin D deficiency. A frequently employed strategy to treat severe vitamin D deficiency is to give a loading dose of 50,000 IU of vitamin D once weekly for 2 to 3 months or three times weekly for 1 month. A lower dose may be utilized in mild to moderate vitamin D deficiency; a daily dose of 800 to 2,000 IU is necessary.

LATHYRISM

Lathyrism is one of the oldest known neurotoxic disorders and results from excessive consumption of *Lathyrus sativus*, a species of chickpea. Lathyrism is currently restricted to areas in Bangladesh, India, and Ethiopia, resulting in nonprogressive, but irreversible, spastic paraparesis. Neurophysiologic studies suggest anterior horn cell impairment, and neuropathologic studies have demonstrated myelin loss in pyramidal pathways and anterior horn cell involvement. It has been suggested that lathyrism results from the toxin beta-*N*-oxalyl-amino-L-alanine, an agonist of the excitatory neurotransmitter glutamate.[11]

KONZO

Konzo is a neurologic disorder confined to rural Africa, resulting from a diet of excessive cyanogen consumption from inadequately processed cassava root combined with a low-protein diet. Cassava root is drought tolerant and therefore may become the major or sole food source during agricultural crises. Konzo is characterized clinically by a symmetric, nonprogressive spastic paraparesis.

The neurologic aspects of renal disease and the neurologic complications of dialysis and renal transplantation are discussed in this chapter. The neurologic complications of renal carcinoma are not considered, but paraneoplastic complications of malignancy are considered in Chapter 27, and the neurologic consequences of radiation and chemotherapy in Chapter 28. The subject itself is complicated because many of the causes of renal failure lead to neurologic complications that also occur in uremia. Thus, collagen vascular diseases are commonly associated with encephalopathy or seizures, and diabetes with neuropathy or encephalopathy. Attention here is directed primarily to complications that are a direct consequence of the renal failure and its treatment rather than to the underlying cause of the kidney disease. In addition, however, certain hereditary disorders that affect both the nervous system and the kidneys are considered. In order to limit the size of the chapter, the bibliography has been restricted, but a more detailed list of references can be found in previous editions of this book.

UREMIC ENCEPHALOPATHY

The neurologic consequences of uremia resemble other metabolic and toxic disorders of the central nervous system (CNS). Thus, the clinical features of the encephalopathy that occurs in uremic patients include an impairment of external awareness that ranges from a mild confusional state, with diminished attention and concentration, to coma. The

Aminoff's Neurology and General Medicine, Sixth Edition.
© 2021 Elsevier Inc. All rights reserved.

presence of coma may indicate severe uremia or reflect a complication such as hypertensive encephalopathy, posterior reversible encephalopathy syndrome (PRES, discussed later), fluid and electrolyte disturbances, seizures, or sepsis. Other causes of an encephalopathy in uremic patients include dialysis, thiamine deficiency, drug toxicity, and transplant rejection. Finally, the encephalopathy and renal impairment may both relate independently to the same underlying systemic illness, such as diabetes or connective tissue diseases. All these factors complicate clinical assessment.

In addition to an alteration in external awareness, patients with uremic encephalopathy may have cognitive changes (impaired memory and executive functions), seizures, dysarthria, gait ataxia, asterixis, tremor, and multifocal myoclonus. As with all metabolic encephalopathies, symptoms and signs typically fluctuate in severity over short periods of time, such as over the course of a day or from day to day.

Pathophysiology

Uremic encephalopathy relates to a variety of metabolic abnormalities, with the accumulation of numerous metabolites, acid–base disturbances, imbalance in excitatory and inhibitory neurotransmitters, inflammatory changes, and hormonal disturbances leading to cerebral dysfunction. The European Uremic Toxin Work Group has listed 90 compounds considered to be uremic toxins; 68 have a molecular weight less than 500 Da, 12 exceed 12,000 Da, and 10 have a molecular weight between 500 and 12,000 Da.[1] A few merit brief discussion here. Retention of urea occurs; urea clearance, even in well-dialyzed patients, amounts to only one-sixth of physiologic clearance.[1] Accumulation of guanidinosuccinic acid, methylguanidine, guanidine, and creatinine, all of which are guanidine compounds, in the serum and cerebrospinal fluid (CSF) of uremic patients, may relate to uremic seizures and cognitive dysfunction. Oxidative stress, homocysteinemia, activation of *N*-methyl-D-aspartate (NMDA) receptors, and inhibition of γ-aminobutyric acid-A ($GABA_A$) transmission may be involved. It remains unclear whether low-level aluminum overload in renal failure causes gradual deterioration in cerebral function. Abnormalities of the membrane pumps for both Na^+,K^+-adenosine triphosphatase and calcium ions may be of clinical relevance, and cerebrovascular factors may be contributory.

Hormonal changes may also be important. Serum concentrations of parathyroid hormone, growth hormone, prolactin, luteinizing hormone, insulin, and glucagon are elevated in uremic patients. Parathyroid hormone levels increase with the severity of the encephalopathy, and alterations in brain calcium could influence neurotransmitter release, the sodium–potassium pump, intracellular enzyme activity, and intracellular metabolic processes, and thereby may affect cerebral function. The calcium content of the cerebral cortex is greatly increased in uremia, and this is unrelated to alterations in calcium concentration in the plasma or CSF. Both clinical and electroencephalographic (EEG) abnormalities and changes in cerebral calcium concentration are improved by parathyroidectomy.

Clinical Features

The clinical features of uremic encephalopathy do not show a good correlation with any single laboratory abnormality but can sometimes be related to the rate at which renal failure develops. Thus, stupor and coma are relatively common in acute renal failure, whereas symptoms may be less conspicuous and progression more insidious despite more marked laboratory abnormalities in chronic renal failure. Dialysis relieves or prevents some of the more severe features of this encephalopathy, but in contrast to the continuous function of normal kidneys, the removal of uremic toxins in dialysis is achieved by a one-step, membrane-based process and is intermittent.

The most reliable early indicators of uremic encephalopathy are a waxing and waning reduction in alertness and impaired external awareness. The ability to concentrate is impaired, so that patients seem preoccupied and apathetic, with a poor attention span; they become increasingly disoriented with regard to place and time and may exhibit emotional lability and sleep inversion. An impairment of higher cognitive abilities, such as of executive function, becomes evident, and patients become increasingly forgetful and apathetic. With progression, patients become more obtunded so that it may then be necessary to shout or gently shake them to engage their attention and elicit any responses, which are likely to be of variable accuracy and relevance. Delusions, illusions, and hallucinations (typically visual) often develop, and patients may become agitated and excited, with an acute delirium that eventually is replaced by stupor and a preterminal coma.

Tremulousness may be conspicuous and usually occurs before asterixis is found. A coarse postural tremor is seen in the fingers of the outstretched hands, and a kinetic tremor is also common. Asterixis is a nonspecific sign of metabolic cerebral dysfunction. An intermittent loss of postural tone produces the so-called flapping tremor of asterixis after several seconds when the upper limbs are held outstretched with the elbows and wrists hyperextended and fingers spread apart; irregular flexion–extension occurs at the wrist and of the fingers at the metacarpophalangeal joints, with flexion being the more rapid phase. There is complete electrical silence in the wrist flexors and extensors during the downward (flexor) movements, followed by electrical activity in the extensors as they restore the limb's posture. The axial structures, including the trunk or neck, may also be affected. Asterixis can also be demonstrated in the lower limbs, and flapping may even be elicited in the face by forceful eyelid closure, strong retraction of the corners of the mouth, pursing of the lips, or protrusion of the tongue, provided that some degree of voluntary muscle control persists. In obtunded or comatose patients, or others in whom voluntary effort is limited, asterixis can still be elicited, but at the hip joints. With the patient lying supine, the examiner grasps both ankles of the supine patient and moves the feet upward toward the patient's body, flexing and abducting the thighs: irregular abduction–adduction movements at the hips indicate asterixis.

Spontaneous and stimulus-sensitive myoclonus is common in uremia and in other metabolic encephalopathies and reflects increased cerebral excitability. The myoclonus is typically multifocal, irregular, and asymmetric; it may be precipitated by voluntary movement (action myoclonus). The myoclonic jerks may be especially conspicuous in the facial and proximal limb muscles. Uremic myoclonus in humans resembles the reticular reflex form of postanoxic action myoclonus. It is usually not associated with EEG spike discharges, although such discharges have sometimes been encountered with the myoclonus. The myoclonus may respond to clonazepam. Multifocal myoclonus is sometimes so intense that muscles appear to be fasciculating (*uremic twitching*). Tetany may occur.

Seizures are common. They are usually generalized convulsions, may be multiple, and are often multifactorial in etiology. In acute renal failure, convulsions commonly occur several days after onset, during the anuric or oliguric phase. In chronic renal failure, they tend to occur with advanced disease, often developing preterminally; they may relate to the uremia itself or to electrolyte disturbances, medications (such as penicillin, aminophylline, or isoniazid), or an associated *posterior reversible encephalopathy syndrome* (characterized by vasogenic white-matter edema predominantly localized to the posterior cerebral hemispheres on imaging studies, as shown in Fig. 16-1). Their incidence has declined, perhaps because of more effective treatment of renal failure and its complications. Seizures also occur in patients undergoing hemodialysis as part of the *dialysis dysequilibrium syndrome* (discussed later). Focal seizures sometimes occur. Occasionally patients develop nonconvulsive status epilepticus that may not be recognized unless an EEG is obtained.

During the early stages of uremia, patients may be clumsy or have an unsteady gait. Paratonia (*gegenhalten*), a variable, velocity-dependent resistance to passive movement, especially rapid movement, is common, and grasp and palmomental reflexes may be present, presumably as a result of a depression of frontal lobe function. As uremia advances, extensor muscle tone increases and may be asymmetric; opisthotonos or decorticate posturing of the limbs may eventually occur. Motor deficits may include transient or alternating hemiparesis that shifts sides during the course of the illness, flaccid quadriparesis related to hyperkalemia, or distal weakness from uremic neuropathy. The tendon reflexes are generally brisk unless a significant peripheral neuropathy is present and they may be asymmetric; Babinski signs are often present.

Encephalopathy may occur in uremic patients for reasons other than uremia, such as in relation to dialysis, thiamine deficiency, electrolyte imbalance, medication-related toxicity, and graft rejection. These disorders are considered in later sections of this chapter.

Investigations

Laboratory studies provide evidence of impaired renal function but are of limited utility in monitoring the course of the encephalopathy. Furthermore, abnormal renal function tests do not exclude other causes of encephalopathy. An underlying structural lesion must be excluded in uremic patients who have

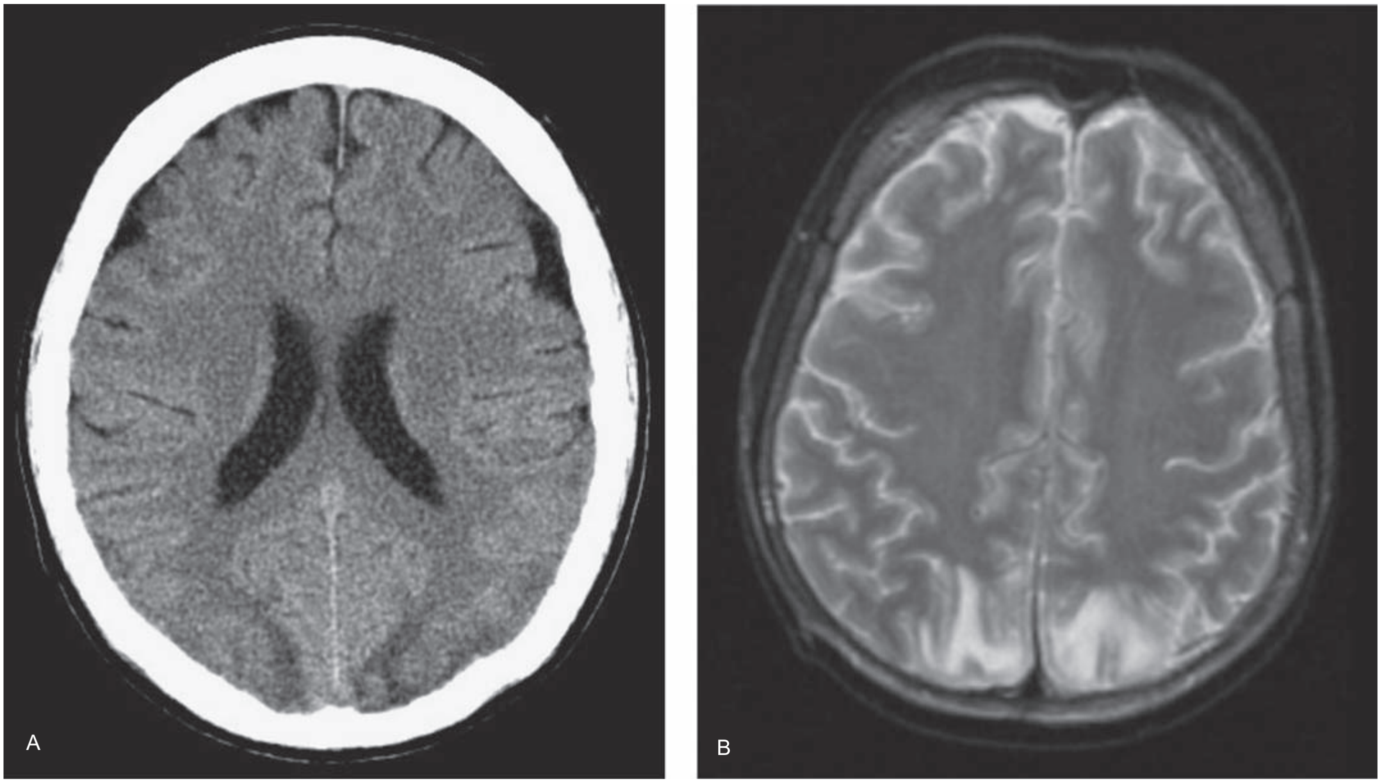

FIGURE 16-1 ■ Imaging findings of a patient with seizures who was diagnosed with posterior reversible encephalopathy syndrome. *A*, Axial computed tomography (CT) scan demonstrates bilateral low-density involvement of the occipital lobes. *B*, Axial T2-weighted magnetic resonance imaging (MRI) shows high signal intensity lesions without mass effect involving white matter bilaterally in the occipital lobes. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

had seizures, especially when focal or multiple seizures have occurred.

The CSF is commonly abnormal, with a pleocytosis that is unrelated to the degree of azotemia and an increased protein content that sometimes exceeds 100 mg/dL. The findings may thus suggest a mild aseptic meningitis.

The EEG is diffusely slowed, with an excess of intermittent or continuous theta and delta waves that may show a frontal emphasis, perhaps reflecting a decreased cerebral metabolic rate. Triphasic waves are often present, with an anterior predominance (Fig. 16-2). Bilateral spike–wave complexes may be present either in the resting EEG or with photic stimulation. The EEG becomes increasingly slowed with progression of the encephalopathy, so that delta activity becomes more continuous; the findings correlate best with the level of retained nitrogenous compounds, although no clear relationship exists between the EEG and a specific laboratory abnormality. Similarly, there are delays of visual, auditory, and somatosensory evoked cerebral potentials. Event-related potentials reveal abnormalities even in asymptomatic patients, with an increase in P3 latency. In a study involving transcranial magnetic stimulation, 36 patients with end-stage renal disease were evaluated at different stages of the disease and under different treatment.[2] Patients on conservative treatment showed a significant reduction of short-interval intracortical inhibition that could be reversed by hemodialysis, peritoneal dialysis, or renal transplantation. After hemodialysis, intracortical facilitation increased, and this was inversely correlated with the decline in plasma osmolarity induced by the dialytic procedure. In other words, patients showed alterations in cortical excitability that were reversed by treatment of the renal disease.

Cerebral imaging studies are of limited help except in excluding other, structural causes of the encephalopathy. They may reveal a reversible, predominantly posterior leukoencephalopathy, with subcortical edema without infarction. There may be multiple areas of

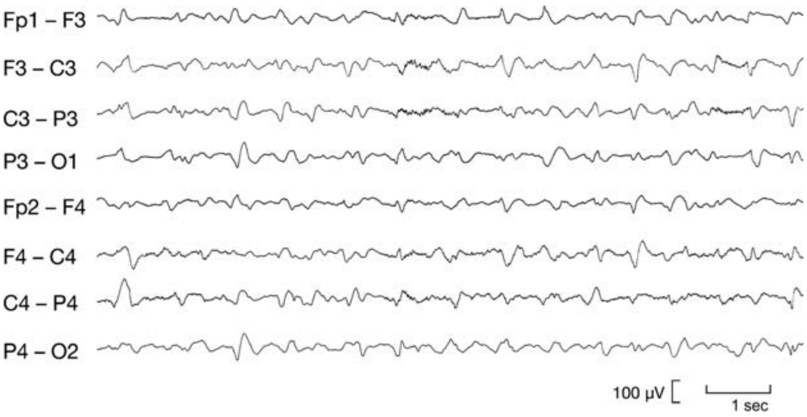

FIGURE 16-2 ■ Electroencephalogram (EEG) showing a diffusely slowed background with triphasic waves in a patient with uremic encephalopathy.

symmetric edema in the basal ganglia, brainstem, or cerebellum, with—in severe cases—focal infarcts, sometimes hemorrhagic.

Treatment of Uremic Convulsions

Treatment involves correction of renal failure and related metabolic abnormalities. In patients who have had seizures, anticonvulsant medication may be required, especially when the convulsions are of uncertain cause. If status epilepticus occurs, it is managed as in other circumstances.

Various considerations make anticonvulsant therapy difficult to manage in uremia. As discussed in Chapter 57, plasma protein binding and renal excretion are reduced, and dialysis may remove drugs from the circulation. Phenytoin was often used in the past in this context; reduced protein binding leads to a greater volume of distribution and lower serum concentrations, but the proportion of unbound (active) phenytoin increases and maintains the benefit of a given dose. Free phenytoin rather than total plasma levels are used to monitor treatment; the optimal therapeutic range is 1 to 2 μg/mL. The total daily dose generally need not be changed, but it is probably best taken divided rather than in a single dose. Dialysis does not remove phenytoin from the circulation to any significant extent. Plasma phenobarbital levels are unaffected by renal insufficiency. Lower doses of phenobarbital are used for long-term maintenance therapy, however, because the drug may accumulate; additional doses may be required after dialysis. Primidone and its metabolites may also accumulate, causing toxicity in uremic patients.

Valproic acid is helpful for treating myoclonic seizures and generalized convulsions in uremic patients. Protein binding decreases, but the free fraction remains constant. Dialysis does not necessitate additional doses.

Serum carbamazepine levels are unchanged, and dosing does not need alteration. Impaired renal function leads to decreased clearance of felbamate, gabapentin, topiramate, levetiracetam, vigabatrin, pregabalin, and oxcarbazepine. Gabapentin, pregabalin, and topiramate are excreted mainly by the kidneys, and the daily dose will need to be reduced in uremic patients; dosing of zonisamide may also need reduction. Hemodialysis necessitates additional doses of levetiracetam (typically 250 to 500 mg) and gabapentin (200 to 300 mg); supplemental doses of topiramate and pregabalin after hemodialysis may also be required. Extra doses of zonisamide may not be necessary if this drug is given in a single daily dose after dialysis sessions. Tiagabine and lamotrigine pharmacokinetics show little change even in severe uremia, and dosage adjustment is usually unnecessary.

UREMIC NEUROPATHY

Polyneuropathy

Peripheral nerve function becomes impaired at glomerular filtration rates of less than 12 mL/min, with clinical deficits developing at rates of about 6 mL/min. More than 50 percent of patients with end-stage renal disease have clinical (neuropathic symptoms or signs) or electrophysiologic abnormalities, the exact number depending on the series and diagnostic criteria utilized.

PATHOPHYSIOLOGY

Because uremic neuropathy improves with dialysis, uremic neuropathy has been attributed to the accumulation of dialyzable metabolites. Hemodialysis regimens sufficient to control urea or creatinine may nevertheless fail to prevent the development of neuropathy, and this observation led to the "middle molecule" hypothesis. In particular, the lower prevalence of neuropathy in patients on peritoneal dialysis than on hemodialysis suggested that the responsible substance was better dialyzed by the peritoneum, and it was proposed that these substances might be in the middle-molecule range (500 to 12,000 Da), which is poorly cleared by hemodialysis membranes. The adoption of dialysis strategies to improve the clearance of middle molecules reduced the rates of severe neuropathy, but the identity of the responsible neurotoxins has remained elusive.

Secondary hyperparathyroidism complicates chronic renal failure and some evidence exists for the neurotoxicity of parathyroid hormone, as discussed earlier. Studies in uremic patients of the effect of parathyroid hormone on peripheral nerves, however, have yielded both supporting and conflicting results.

It has been proposed that mild hyperkalemia has a role in the genesis of the neuropathy. Hyperkalemia typically recurs within a few hours of a dialysis session as a result of re-equilibration between intracellular and extracellular fluid compartments. Prolonged hyperkalemia may disrupt normal ionic gradients and activate Ca^{++}-mediated processes that are damaging to axons. Motor and sensory nerve excitability has been studied in relation to changes in serum levels of potential neurotoxins, including calcium and potassium ions, urea, uric acid, and certain middle molecules. Predialysis measures of nerve excitability were abnormal, consistent with axonal depolarization, and correlated strongly with serum potassium levels, suggesting that hyperkalemic depolarization did underlie the development of uremic neuropathy.[3] The severity of symptoms also correlated with excitability abnormalities. Most nerve excitability parameters were normalized by hemodialysis. The findings thus supported the belief that hyperkalemia contributes to the development of neuropathy. There was no evidence of significant Na^+/K^+ pump dysfunction.

If hyperkalemia does indeed have a role in mediating these abnormalities, measures of dialysis adequacy based solely on blood urea or creatinine concentrations may be inadequate for determining whether dialysis will prevent neurotoxicity. Monitoring the serum potassium level to ensure that it is maintained within normal limits between periods of dialysis may be more relevant in this regard. Preliminary evidence suggests that dietary potassium restriction confers some degree of neuroprotection in chronic kidney disease.[3]

CLINICAL FEATURES

Uremic neuropathy is more common in men than women and in adults than children. It is characterized by a length-dependent, symmetric, mixed sensorimotor polyneuropathy of axonal type that resembles other axonal metabolic-toxic neuropathies. Its clinical manifestations, severity, and rate of progression are variable. As with uremic encephalopathy, its severity correlates poorly with biochemical abnormalities in the blood, but neuropathy is more likely to develop in chronic or severe renal failure.

Initial symptoms commonly consist of dysesthesias distally in the legs; muscle cramps may also be troublesome. The restless legs syndrome often develops before or with the clinical onset of neuropathy, and its occurrence may therefore indicate incipient peripheral nerve involvement. As with many other neuropathies, the earliest clinical signs are of impaired vibration appreciation and depressed or absent tendon reflexes distally in the legs, indicating involvement of large-diameter myelinated fibers. Autonomic involvement may occur but is usually mild.

Progression is typically insidious over many months but occasionally is rapid, leading early to severe disability, sometimes painful. A more progressive, predominantly motor subacute neuropathy may occur in uremic patients with diabetes and lead to severe weakness over a few weeks or months; nerve conduction studies typically demonstrate features of an axonal neuropathy but may show demyelination features, and the neuropathy may respond to transplantation or to a switch from conventional to high-flux hemodialysis. The course may be arrested at any time despite continuing or worsening renal failure.

It is hard to predict the likely clinical course in individual patients. Most patients are left with distal motor and sensory deficits, but some become severely disabled with a flaccid quadriparesis or paraparesis. Severe neuropathy has become less prevalent with the introduction of dialysis and transplantation techniques but remains common.

Histopathologic examination of nerve biopsy specimens confirms that the neuropathy is a length-dependent axonal degeneration accompanied by secondary demyelination, although in some cases the demyelination seems the predominant finding; damaged endoneural blood capillaries may also be found and support an ischemic theory as one mechanism in the pathogenesis of uremic neuropathy.

Nerve conduction studies also support an axonal process, with reduced conduction velocities and response amplitudes; abnormalities are common even in clinically unaffected nerves. The amplitude of the sensory nerve action potential is affected particularly, especially that of the sural nerve. Large fibers are affected more often than small fibers, but in occasional patients a predominantly small-fiber neuropathy occurs. The findings on nerve conduction studies may improve after effective treatment of the underlying renal failure, sometimes very rapidly, but this is not always the case; sensory nerve conduction velocities in the median, ulnar, and sural nerves may be the most sensitive electrophysiologic indices of the beneficial effect of hemodialysis. Needle electromyography may reveal evidence of denervation, particularly in the distal muscles of the legs. Abnormalities of late responses (F waves and H reflexes) are frequent and may be helpful early in the course of renal failure, when standard nerve conduction study results are sometimes normal.

Laaksonen and colleagues examined the clinical severity of uremic neuropathy in 21 patients, using a modified version of the neuropathy symptom score combined with results of electrophysiologic studies.[4] They found that 81 percent of uremic patients were diagnosed with neuropathy: the neuropathy was asymptomatic in 19 percent, associated with nondisabling symptoms in 48 percent, and accompanied by disabling symptoms in 14 percent.

TREATMENT

Uremic polyneuropathy may stabilize or even show some improvement with dialysis, but mild progression is not uncommon and recovery from severe neuropathy is unlikely. Renal transplantation improves uremic neuropathy, sometimes very rapidly and with a negative correlation between electrophysiologic change and serum creatinine and *myo*-inositol concentrations, suggesting that metabolic factors may underlie the rapid improvement. In other instances, improvement is more gradual over a number of months, is characterized electrophysiologically by improvement in motor and sensory conduction velocities, and is often incomplete, perhaps because the main reason for improvement is segmental remyelination, with some fibers remaining degenerate in severe neuropathies.

Autonomic Neuropathy

Uremic patients may develop postural hypotension, impaired sweating, impotence, gastrointestinal disturbances, and other dysautonomic symptoms, which progress in some patients—but not all—despite continuing hemodialysis.[5] The dysautonomia correlates with the presence or severity of peripheral neuropathy in some but not all patients and may be corrected by renal transplantation. The mechanism underlying the development of uremic autonomic neuropathy is unknown. In patients with diabetic renal failure, dysautonomia may relate also to the diabetes. Studies of both cardiovagal and sympathetic function (discussed in Chapter 8) have revealed objective evidence of dysautonomia that may be subclinical.

Intradialytic hypotension is a frequent complication of hemodialysis and has been shown to relate in many cases to impaired autonomic function regardless of whether a peripheral neuropathy is present. Midodrine may have a role in the therapy of patients with intradialytic hypotension.

Dialysis may not benefit autonomic neuropathy. After renal transplantation, autonomic function may improve or normalize but at a variable rate and typically slower and less completely than large-fiber neuropathies. Specific symptomatic treatments, for example, with phosphodiesterase inhibitors such as sildenafil for erectile dysfunction, may be helpful.

RESTLESS LEGS SYNDROME

Development of the restless legs syndrome may indicate incipient peripheral nerve involvement or may occur as an isolated disorder. Patients develop an irresistible urge to move the legs that is worse at night and during periods of inactivity. They complain of curious sensations—often described as creeping, crawling, prickling, or itchy feelings—in the lower limbs, and these tend to be worse in the evening or when the limbs are not in motion. Such sensations are experienced most commonly in the legs but occasionally occur in the thighs or feet; the upper limbs are also sometimes involved. The disorder may occur in nondialyzed patients with chronic renal failure. When it occurs in uremic patients undergoing hemodialysis, it has been related to low hemoglobin levels, high serum phosphorus levels, and high anxiety levels. Treatment of restless legs syndrome is with clonazepam, dopamine agonists, levodopa, certain anticonvulsants, or opioids (propoxyphene or codeine) taken at bedtime, but the response often declines with time. Co-existing anemia and hyperphosphatemia should be corrected. Successful renal transplantation may ameliorate or eliminate symptoms within a few weeks, but symptoms can recur with transplant rejection and the disorder remains more common than in the general population.

OTHER MOVEMENT DISORDERS

A variety of movement disorders in addition to restless legs syndrome are seen in patients with kidney disease. Tremor, spontaneous and stimulus-sensitive multifocal myoclonus, and asterixis are all features of uremic encephalopathy, and imaging studies often reveal edema in the basal ganglia as well as more widely, and sometimes frank infarcts or hemorrhage. The myoclonus, discussed earlier, may respond to clonazepam. Parkinsonism and dystonia may also occur, often as a complication of subcortical strokes, and are discussed in Chapter 58.

UREMIC MYOPATHY

Proximal muscle weakness, atrophy, and muscle fatigue are common in uremic patients, and the progression of the underlying myopathy parallels the decline in renal function. Muscle involvement is more common in patients undergoing chronic hemodialysis. Onset is insidious. The hip girdle is affected more than the shoulder girdle. The primary systemic disease responsible for the renal failure—or its treatment, such as with corticosteroids—may lead to a myopathy. Other causal factors include malnutrition, anemia, accumulation of toxins (including aluminum and iron), endocrine disorders (such as secondary hyperparathyroidism), hypercalcemia, hypophosphatemia, vitamin D deficiency, carnitine deficiency, hyper- and hypokalemia, and physical inactivity. Calciphylaxis in end-stage kidney disease is a rare cause of painful ischemic myopathy; vascular calcification and occlusion of small and medium-sized arteries is responsible. Dialysis-associated systemic fibrosis may cause a myopathy. Myopathy may relate to β_2-microglobulin-associated amyloidosis.

Treatment is of the underlying cause of the muscle weakness. Hemodialysis patients treated with vitamin D have been found to have greater muscle size and power than those not receiving vitamin supplementation. Adequate protein intake should be assured and anemia corrected. Physical therapy helps to improve muscle strength. Renal transplantation is sometimes indicated.

STROKE

Chronic kidney disease is common in stroke patients, but the basis of any association between the two is not completely clear. The association could be causal but it could also reflect that stroke and renal disease share cardiovascular risk factors, such as age, diabetes, hypertension, and dyslipidemia.[6] Regardless, meta-analysis of previously published articles suggests that a reduced glomerular filtration rate is a significant risk factor for both ischemic and hemorrhagic stroke, independent of known cardiovascular risk factors. Factors that might be involved include increased inflammatory mediators, oxidative stress, thrombogenic factors, hyperhomocysteinemia, and reduced klotho protein (which is expressed predominantly in the distal renal tubule and thus declines with advancing kidney disease).[6]

Patients with renal disease commonly have a greater volume of white matter lesions on MRI and more silent brain infarcts than otherwise. As the kidney disease advances, the prevalence of these silent infarcts increases. Thus, there seems to be a significant relationship between impaired kidney function and small-vessel disease, which is itself associated with cerebral microbleeds independent of age, sex, and blood pressure. There is also evidence that chronic kidney disease affects the presence and severity of carotid atherosclerosis.

Patients with chronic kidney disease (i.e., reduced glomerular filtration rate) generally have poorer outcomes from ischemic strokes than those without kidney involvement. They are more likely to deteriorate while in hospital, and have a greater risk of recurrent stroke or death in hospital. Proteinuria independently contributes to the increased risks of neurologic deterioration, mortality, and poor functional outcome after acute stroke. Proteinuria is also associated with the hemorrhagic transformation of cerebral infarcts. Among patients with hemorrhagic stroke, impaired kidney function is associated with larger hematoma volume, greater mortality or disability, and reduced likelihood of discharge home.

Stroke management is affected by impaired kidney function. Although alteplase (tissue-type plasminogen activator) is metabolized by the liver, patients with chronic kidney disease have worse outcomes and a higher risk of bleeding complications after intravenous thrombolysis than those with normal kidney function. The management of atrial fibrillation poses additional problems. Patients with end-stage renal disease have an increased risk of bleeding and this risk is increased with warfarin. Accordingly, the routine use of warfarin for atrial fibrillation in this context is often limited to those at high risk of stroke, when the aim is to achieve a target international normalized ratio of 2 to 3. The risks with newer anticoagulants are less clear, but apixaban can be used in place of warfarin.

The control of chronic hypertension is particularly important in reducing stroke risk in patients with chronic kidney disease. Antihypertensive treatment should be rigorous, initially with an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker to improve renal outcome. In patients with previous atherosclerotic strokes, antiplatelet agents help to reduce secondary stroke risk. Optimizing diabetic control, cessation of smoking, dietary salt restriction, weight reduction, and correction of co-existing anemia may be important in reducing cardiovascular and stroke risk in individual cases, and carotid endarterectomy is worthwhile in selected patients. The risk of stroke is also high in patients receiving chronic hemodialysis, as is discussed in a later section.

OPTIC NEUROPATHY

A progressive unilateral or bilateral optic neuropathy may occur over several days, sometimes as the initial manifestation of end-stage kidney disease; visual loss is accompanied by reduced pupillary response to light and by papillitis. Prompt hemodialysis and corticosteroid therapy may restore vision in some patients. The optic neuropathy may be neurotoxic, ischemic, related to side effects of medication or intracranial hypertension, or inflammatory in nature.

In ischemic optic neuropathy occurring in patients on hemodialysis, co-existing hypotension and anemia are important risk factors, and treatment may require intravenous saline or blood transfusions in addition to the other measures mentioned earlier. Calcific uremic arteriolopathy may also have an etiologic role. Several cases of nonarteritic ischemic optic neuropathy related to hemodialysis have been reported. The optic neuropathy is produced by compromise of oxygen delivery to the optic nerve, resulting in hypoxic swelling, nerve compression in the optic canal, and ischemia of the optic nerve head. Presentation is with sudden, unilateral, painless inferior visual field defect and a fixed unreactive pupil after relative hypotension. This complication must be considered when examining dialysis options, particularly in patients with other risk factors such as hypotension, anemia, and a past history of anterior ischemic optic neuropathy.

NEUROLOGIC COMPLICATIONS OF NEPHROTIC SYNDROME

The nephrotic syndrome, which results from glomerular damage, is characterized by excessive proteinuria in the absence of hematuria, and is accompanied by edema, hypoalbuminemia, and hyperlipidemia. There is an increased risk of arterial or venous thromboembolism, and this may involve the cerebral circulation. The causes of the responsible hypercoagulable state are not entirely clear, but alterations occur in various blood coagulation factors, platelet reactivity, and blood viscosity, and in the fibrinolytic system. Cerebral venous thrombosis—particularly involving the major intracranial venous sinuses—is a well-known complication in patients of any age, signaled by the development of headache, seizures, or clinical features of increased intracranial pressure. Arterial thrombosis is less common but may involve a variety of peripheral arteries, including the carotid artery, sometimes as the initial manifestation of the nephrotic syndrome. Presentation is with transient cerebral ischemic attacks or ischemic stroke. By analogy to patients without nephrotic syndrome, treatment of arterial or venous disease involves anticoagulation, typically with heparin followed by oral anticoagulation.

Posterior reversible encephalopathy syndrome (PRES) has also been associated with the nephrotic syndrome or its treatment with immunosuppressive drugs in children and adults. The disorder is characterized by impaired consciousness, seizures, headache, and transient visual disturbances in the setting of hypertension, and is associated with cortical and subcortical edema manifest by high signal intensity on T2-weighted MRI, especially posteriorly. Fluid-attenuated inversion recovery (FLAIR) imaging improves diagnostic confidence and the conspicuousness of the T2 hyperintensities. The prognosis is usually benign, with symptoms settling after several days of adequate treatment. Treatment involves the control of associated hypertension, the management of seizures, and the withdrawal of any medication that is likely to have been responsible for the disorder.

Certain neuromuscular disorders may relate to the nephrotic syndrome. There have been several case reports of the simultaneous development of nephrotic syndrome and Guillain–Barré syndrome. In one such case, plasmapheresis and corticosteroids led to simultaneous recovery of both disorders, suggesting a common pathogenesis of the two conditions. Myasthenia gravis may co-exist with nephrotic syndrome, and its temporary improvement may result from antibody elimination during proteinuria in nephrotic syndrome.

Pierson syndrome, a rare autosomal recessive disorder due to mutations in the *LAMB2* gene, is characterized by congenital nephrotic syndrome leading to end-stage renal disease, and by microcoria and other ocular abnormalities. Severe hypotonia and psychomotor retardation occur in those surviving infancy.

NEUROLOGIC COMPLICATIONS OF DIALYSIS

Dialysis has been associated with subtle *cognitive alterations*, possibly reflecting an early manifestation of dialysis dementia at a reversible stage. More commonly, psychologic studies have shown significant improvement in short-term memory both after onset of maintenance dialysis and when comparisons are made between the day before and after an individual dialysis treatment session; attentional functions also seem to improve after dialysis. *Subdural hematoma* (Fig. 16-3) may occur in patients on maintenance hemodialysis; it has a 20-times higher incidence than in the general population and is associated with high mortality. The symptoms of the subdural hematoma may be attributed erroneously to dysequilibrium syndrome or dialysis dementia. Its occurrence may relate to anticoagulation used to maintain the patency of the conduit for hemodialysis; platelet function may be impaired in uremia but, in itself, is unlikely to be responsible. A rare case of manganese-induced *parkinsonism* has been described in a patient on maintenance hemodialysis and was attributed to long-term ingestion of a health supplement; the clinical, laboratory, and MRI findings were abnormal, but the patient improved on edetic acid infusion therapy.[7] The occurrence of hemodialysis-related *optic neuropathy* was mentioned in an earlier section. These complications will receive no further discussion here.

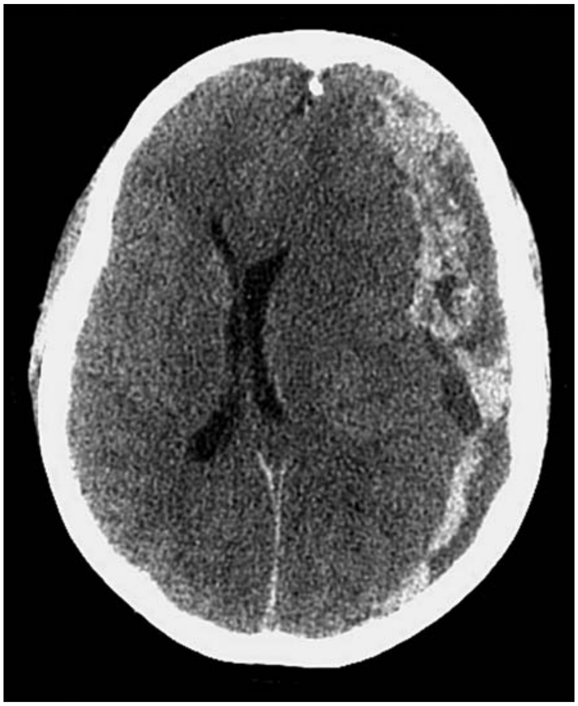

FIGURE 16-3 ■ Axial noncontrast CT scan shows a mixed-density left subdural hematoma producing marked mass effect on the left hemisphere and midline shift. The low density within the subdural hematoma is a feature of active hemorrhage. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

Muscle *cramps* are common, tending to occur toward the end of a dialysis session: their etiology is uncertain, but plasma volume contraction and hyponatremia are among the factors that have been incriminated. Headache, nausea, and vomiting may also occur during dialysis, sometimes as the initial manifestations of the dysequilibrium syndrome (discussed later).

The risk of *cerebrovascular disease* is increased in patients undergoing dialysis and seems related to accelerated cerebrovascular disease and the high incidence of malnutrition, hypertension, diabetes, and hyperlipidemia among these patients. In one study, the high incidence of stroke resulted, at least in part, from inadequately treated hypertension. Presentation may be with hypertensive encephalopathy, posterior reversible encephalopathy syndrome (discussed earlier), transient ischemic attacks, or occlusive or hemorrhagic stroke. Infarcts may show a predilection for the vertebrobasilar arterial territory. Although stroke symptoms are common and are associated with cognitive and functional impairments, clinically significant stroke events are often unrecognized.

Intradialytic hypotension may complicate hemodialysis, and its frequent occurrence is often associated with high intradialytic weight gain and high ultrafiltration rates. Separately or together, these factors contribute to an increased cardiovascular morbidity and mortality observed in the hemodialysis population and increase the stroke risk. The use of lower concentrations of sodium in the dialysate reportedly helps to control or avoid some of these complications.[8]

The *osmotic demyelination syndrome* may occur after hemodialysis, leading clinically to convulsions, an alteration in the level of consciousness, and quadriparesis with hyperactive tendon reflexes and bilateral Babinski responses. MRI shows findings of demyelination in pontine and often extrapontine regions. The effects of dialysis on uremic encephalopathy and neuropathy have already been discussed, but dialysis may cause other neurologic disturbances that merit comment.

Sleep disturbances have a high prevalence in patients with end-stage kidney disease undergoing chronic hemodialysis. They include insomnia, obstructive sleep apnea, excessive daytime sleepiness, restless legs syndrome, and various parasomnias.

Entrapment Mononeuropathies

CARPAL TUNNEL SYNDROME

It was originally believed that carpal tunnel syndrome occurred because of increased venous pressure in the distal limb when an arteriovenous shunt had been placed for hemodialysis, the increased extravascular volume within the carpal tunnel or steal being held responsible for the median nerve compression. Carpal tunnel syndrome is diagnosed significantly more often on the side of an arteriovenous fistula than on the opposite side, and the duration of the fistula correlates with the development of the carpal tunnel syndrome. However, carpal tunnel syndrome is bilateral in about half of the patients.

The occurrence of β_2-microglobulin amyloidosis is probably more important etiologically in this context, particularly in patients on long-term hemodialysis. Amyloid fibrils have been isolated from amyloid-laden tissues inside the carpal tunnel and the protein identified as β_2-microglobulin. Circulating β_2-microglobulin presumably cannot be removed by conventional hemodialysis and accumulates in tissues; the consequent formation of amyloid fibrils appears to occur particularly in the region of the carpal tunnel, leading to carpal tunnel syndrome. A significant increase in carpal tunnel width and thickness in the palmoradiocarpal ligament, correlating with duration of long-term hemodialysis, has been found by ultrasound examination of the wrists of hemodialysis patients. The prevalence of carpal tunnel syndrome and the severity of symptoms have been improved by maneuvers to reduce the levels of β_2-microglobulin. Uremic tumoral calcinosis may also be responsible in some instances.

Treatment is as in other patients, with decompressive surgery if symptoms fail to respond to conservative measures.

ULNAR NERVE LESIONS

A high prevalence (between 41 and 60%) of ulnar neuropathy has been reported in patients receiving hemodialysis for end-stage renal disease. This may relate to arm positioning during hemodialysis, underlying polyneuropathy, upper-extremity vascular access, and uremic tumoral calcinosis.

Ischemic Neuropathy

A shunt for access during chronic hemodialysis and inserted between the radial artery and cephalic vein in the upper arm was reported by Bolton and colleagues to have caused an acute distal, ischemic neuropathy in two patients; electrophysiologic evidence was present of axonal degeneration of sensory fibers with mild ischemia, and of both motor and sensory nerve fibers with more severe ischemia.[9] This has been attributed to shunting of arterial blood away from the limb distally, with the nerves being selectively affected because of their greater vulnerability to ischemia. Other cases of this so-called *ischemic monomelic neuropathy* have since been reported, and the disorder is particularly likely in diabetics with renal failure and pre-existing peripheral vascular disease or neuropathy, although it may also occur in nondiabetic patients. Multiple upper-limb mononeuropathies develop, leading to burning pain and to sensory and motor deficits in the forearm and hand. Motor conduction block may be detected electrophysiologically shortly after the onset of symptoms, preferentially involving the median nerve, with clinical and electrophysiologic improvement following ligation or revision of the shunt. In some instances, onset is more insidious; more widespread signs of upper-extremity ischemia due to arterial steal are found distal to the fistula, such as established or impending tissue loss or nonhealing wounds.

In addition to arterial steal and venous hypertension syndromes, other complications of arteriovenous access for hemodialysis include high-output cardiac failure, pseudoaneurysm formation, hemorrhage, noninfectious fluid collections, acute forearm compartment syndromes, and access-related infections.

Dialysis Dysequilibrium Syndrome

Several neurologic disturbances may arise during or after hemodialysis, including headache, nausea, anorexia, muscle cramps, irritability, restlessness, agitation, confusion, coma, and seizures; increased intracranial pressure may lead to papilledema. Such symptoms tend to occur at the beginning of a dialysis program and were particularly conspicuous in the past when patients with advanced uremia were dialyzed aggressively. Patients now enter dialysis programs at an earlier stage of renal failure and the initial dialysis is started slowly with shortened dialysis times and less efficient dialysis, and this may account for the reduced incidence of the disorder, which seems more common in children and the elderly than in other age groups. Marked metabolic acidosis and the presence of other CNS disease may also be predisposing factors.[10]

Symptoms typically appear toward the end of a dialysis session, sometimes 8 to 24 hours later, and subside over several hours. When an agitated confusional state develops, it may persist for several days. Many patients manifest exophthalmos and increased intraocular pressure at the height of the syndrome, which may be helpful clinically for diagnostic purposes. Headache is the most common symptom reported by patients undergoing dialysis, and migrainous episodes may be precipitated during or after hemodialysis in patients with pre-existing migraine. Headache is otherwise usually diffuse and throbbing in quality. Subdural hematoma sometimes mimics the dysequilibrium syndrome and requires exclusion.

Movement of water into the brain leads to cerebral edema. According to the hypothesis known as the *reverse urea effect*, a rapid reduction in blood urea level lowers the plasma osmolality, thereby producing an osmotic gradient between blood and brain. Although urea is able to permeate cell membranes, this may take several hours to reach completion; accordingly, there is not enough time for urea equilibration when the blood urea level is reduced rapidly by hemodialysis. There is thus an influx of water into the cells. This results in increased intracranial pressure and cerebral edema. Alternatively or additionally, the osmotic gradient between brain and blood may not reflect simply the movement of urea; unidentified osmotically active substances ("idiogenic osmoles") are present in the brain of dialyzed uremic animals (but not dialyzed nonuremic animals) and have been incriminated. A decrease in cerebral intracellular pH, reflecting an increased production of organic acids that are osmotically active, may be important in this regard.[10]

A number of other disorders, such as uremic encephalopathy, intracranial infection or hemorrhage, cerebral infarction, hyponatremia, hypoglycemia, and medication-related encephalopathy must be excluded before the diagnosis is made with confidence. Prophylactic measures involve the gradual reduction in blood urea level by attention to the hemodialysis technique. In patients with established dialysis dysequilibrium syndrome, mild symptoms usually clear spontaneously over several hours, and symptomatic and supportive measures are all that are required; however, it may be necessary to slow or discontinue the dialysis session. Dialysis is stopped in patients with seizures or an altered level of consciousness and, if necessary, the plasma osmolality can be raised with either hypertonic saline or mannitol. Management is otherwise supportive, and improvement can be expected over the following day.

Wernicke Encephalopathy

Thiamine is a water-soluble vitamin that passes through dialysis membranes. However, dialysis does not remove more thiamine than is normally excreted in the urine, and no consistent change occurs after hemodialysis in plasma levels of the B vitamins. Wernicke encephalopathy has occurred in patients on chronic dialysis, but is relatively infrequent. It has been related to anorexia, vomiting, a diet low in thiamine-containing foods, and intravenous alimentation without thiamine supplementation; other potential causes in uremia are infections that may stress thiamine reserves and the use of repeated infusions of glucose, insulin, and bicarbonate to lower the serum potassium level.

Among patients undergoing dialysis in whom Wernicke encephalopathy develops in the absence of alcoholism or other precipitating factors and is diagnosed at autopsy, ophthalmoplegia may be evident in only occasional instances, but in other cases the full triad of ophthalmoplegia, ataxia, and an altered level of consciousness is encountered. Hypothermia is common. Intravenous administration of thiamine reverses the clinical deficit. Given the reversible nature of the disorder, it is important to consider it in all patients on hemodialysis who exhibit at least one of its classic features; dialysis dysequilibrium syndrome, dialysis dementia, and uremic encephalopathy have each been diagnosed erroneously in patients who were subsequently found to have Wernicke encephalopathy. Indeed, in one series of 30 consecutive patients on regular hemodialysis or peritoneal dialysis who were admitted with an alteration in mental status, 10 had an unexplained encephalopathy after initial evaluation and were eventually found to have thiamine deficiency; nine responded to thiamine supplementation and one died.[11]

Dialysis Dementia

Clinical Aspects

There has been a decline in the incidence of this progressive encephalopathy, which may occur in patients undergoing long-term dialysis. The first symptom is often a stammering hesitancy of speech that eventually progresses to speech arrest, dysarthria, and expressive aphasia. The speech disorder is intensified during and immediately after dialysis and initially may occur only at these times. Other manifestations such as tremor, myoclonus, asterixis, seizures, and dementia become apparent as the disorder advances, and hallucinations and delusional thinking round out the clinical picture. Focal neurologic abnormalities are found occasionally. Symptoms initially occur immediately after dialysis and then clear, but eventually they fail to resolve and the patient becomes increasingly demented. The EEG shows abnormal bursts of high-voltage slow activity and spikes anteriorly. The CSF is normal. The differential diagnosis includes other causes of dementia, but metabolic encephalopathy and structural lesions such as subdural hematoma, normal-pressure hydrocephalus, hypertensive encephalopathy, multi-infarct dementia, and stroke require exclusion.

Pathogenesis

A clustering of cases in areas with aluminum-contaminated water was noted originally, and water-purification measures have led to a substantial reduction in the incidence of the disorder. The disorder results from accumulation of aluminum in the brain and is now rarely encountered because of elimination of aluminum in the dialysate. Phosphate retention occurs in renal failure, leading eventually to hyperparathyroidism, and reduction of the serum phosphate concentration with phosphate binders is therefore important. The substitution of phosphate binders such as calcium carbonate and calcium acetate, and of nonmineral-containing phosphate binders, for oral aluminum-containing phosphate binders has also been important in reducing the aluminum content in the brain. The toxicity of aluminum may involve disruption of the inositol phosphate system and calcium regulation, facilitation of oxidative injury, and disruption of basic cell processes.

Treatment

Diazepam is initially helpful in treating the myoclonus and seizures and in improving speech, but it is less effective later. Increased dialysis time and renal transplantation have not altered the natural history. In untreated patients, death usually occurs within a year of the onset of symptoms. The chelator deferoxamine can remove excess aluminum and thereby reverse acute encephalopathy, as well as the osteomalacia and anemia that may also be associated with aluminum overload. However, its introduction may be associated with visual and auditory toxicity and with increased neurologic and other side effects from acute aluminum toxicity (presumably because of the rapid mobilization of stored aluminum) in occasional patients; some patients have developed a rapidly progressive and fatal systemic or rhinocerebral mucormycosis. Experimental studies in animals suggest that deferoxamine enhances the pathogenicity of the responsible organism and reduces the effectiveness of treatment with amphotericin. Nevertheless it is the mainstay of treatment for established dialysis dementia.

Several protocols for the administration of deferoxamine have been proposed. A baseline serum aluminum level is determined: normal levels are 6 ± 3 μg/L, but excess aluminum deposition is unlikely when values are less than 20 μg/L. If baseline levels exceed this, a low-dose deferoxamine test is performed by administering 5 mg/kg 1 hour before the end of dialysis if aluminum overload (serum aluminum levels of 60 to 200 μg/L) is present or toxicity is suspected clinically. If this increases serum aluminum by 50 μg/L or more when measured 2 days after the deferoxamine, the test is considered positive. For treatment purposes, deferoxamine can be given to symptomatic patients once weekly in the last hour of a dialysis session; however, to avoid the risk of deferoxamine neurotoxicity, it is not given to patients with serum aluminum levels exceeding 120 μg/L until the level is first lowered by withdrawal of aluminum exposure. This is because deferoxamine may cause severe, sometimes fatal, complications when administered to patients with very high serum aluminum concentrations. When serum levels exceed 200 μg/L, the deferoxamine test should not be performed; instead, daily hemodialysis using high-flux membranes and a low dialysate aluminum concentration, and withdrawal of all aluminum-containing oral agents, is necessary. A low-dose deferoxamine test (5 mg/kg) is given after 4 to 6 weeks of such treatment (if serum levels are <200 μg/L) to determine the timing of further treatment. National and society guidelines should be consulted for further details.

The length of treatment required is uncertain, but it may need to be for many months. Many cases of dialysis dementia have been stabilized or improved by deferoxamine. The need for treatment is unclear in patients with an asymptomatic increase in aluminum levels.

COMPLICATIONS OF TRANSPLANTATION

Various neurologic complications are caused by the neurotoxicity of immunosuppressive agents, as discussed in Chapter 44. When acute rejection encephalopathy occurs, patients experience headache, confusion, and seizures, sometimes accompanied by papilledema, increased CSF pressure, and computed tomography (CT) evidence of diffuse cerebral edema. The EEG is diffusely slowed and may show focal features. Treatment of the rejection episode leads to improvement.

Femoral and Related Neuropathy

Femoral neuropathy is a common complication of renal transplantation in the iliac fossa, occurring ipsilateral to the transplant surgery with an incidence on the order of 2 percent. Nerve compression typically occurs intraoperatively, for example, with prolonged use of retractors. When compression leads to neurapraxia, recovery is likely to be rapid and complete, as in most patients; severe compression or nerve ischemia leads to axonal loss, delayed recovery, and residual deficits. In patients undergoing renal transplantation involving either the internal or external iliac artery, sensory disturbances may be the sole manifestation and are not necessarily confined to the territory of the femoral nerve: in one series of 20 patients in which the internal iliac artery was used, for example, sensory complaints were in the anterior thigh in 15, lateral thigh in 3, and anterolateral thigh in 2,[12] suggestive of involvement of the lateral femoral cutaneous nerve.

Development of Malignant Disease

The rates of malignancies among 35,765 first-time recipients of deceased or living donor kidney transplantations between 1995 and 2001 was examined by Kasiske and associates using Medicare billing claims.[13] For common tumors, such as of the colon, lung, prostate, stomach, esophagus, pancreas, ovary, and breast, cancer rates were approximately twice as high after kidney transplantation as in the general population. Melanoma, leukemia, hepatobiliary tumors, cervical, and vulvovaginal tumors were each increased about 5-fold; testicular and bladder cancers about 3-fold; kidney cancer (typically of the native kidney) 15-fold; and Kaposi sarcoma, non-Hodgkin lymphomas, and nonmelanoma skin cancers more than 20-fold. Thus, cancer screening and attention to prophylactic measures are important after kidney transplantation. The development of such neoplasms may involve the nervous system

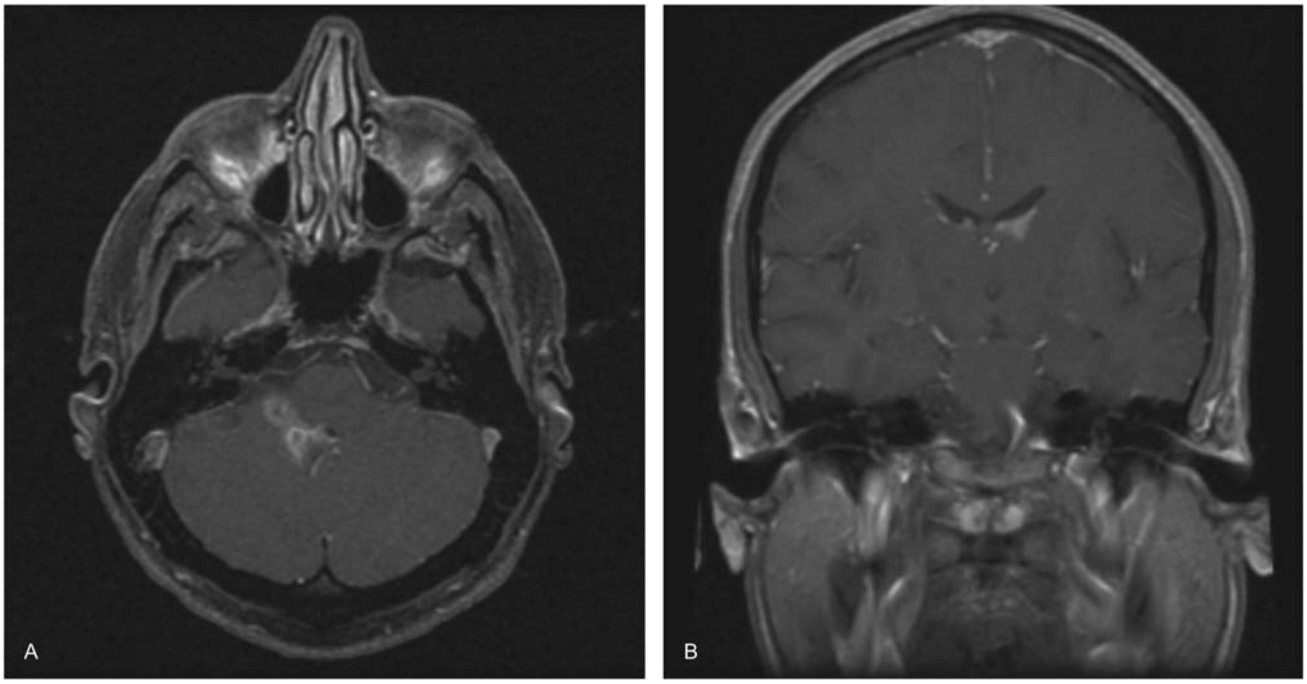

FIGURE 16-4 ■ *A*, Axial postcontrast T1-weighted MRI demonstrates an enhancing mass located in the right lateral recess of the fourth ventricle. *B*, Coronal postcontrast T1-weighted image shows an enhancing subependymal mass involving the left lateral ventricle. The findings are most consistent with CSF spread of lymphoma. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

directly by metastatic spread, may lead to a paraneoplastic syndrome, or may produce secondary neurologic abnormalities as a consequence of treatment (Chapters 26, 27, and 28).

Brain Tumors

Non-Hodgkin lymphoma constitutes more than 90 percent of lymphomas in transplant recipients. Most of these lymphomas are of the B-cell type and follow B-cell proliferation related to infection with Epstein–Barr virus in patients who are chronically immunosuppressed. Extranodal involvement after organ transplantation occurs commonly and—in almost one-quarter of patients—involves the CNS (Fig. 16-4). Involvement of the transplanted kidney may also occur, causing renal failure. The degree of immunosuppression, age (greater in those younger than 25 years), time since transplant (greater in the first year), race (greater in Caucasians than in African Americans), and serologic status regarding Epstein–Barr virus infection influence the risk of disease. The development of mental status changes or new neurologic abnormalities should raise concern about the possibility of CNS involvement. Imaging studies (CT or MRI) of the head, CSF analysis for Epstein–Barr virus and cytologic examination for malignant cells, and brain biopsy generally lead to the diagnosis. MRI may underestimate the extent of the tumor. The use of corticosteroids, which alter the imaging and histopathologic findings, may confound interpretation of imaging studies.

The incidence of *primary CNS lymphoma* is increasing, especially among the elderly. The tumor is located supratentorially in more than two-thirds of instances and typically is periventricular and involves deep subcortical structures such as the basal ganglia and corpus callosum (Fig. 16-5); subependymal spread is common. Abnormal lymphocytes may disseminate along CSF pathways and subsequently spread throughout the CNS. The eye may also be involved. As with systemic lymphoma, the high incidence of primary CNS lymphoma in transplant recipients receiving immunosuppressants indicates involvement of the immune system in its pathogenesis and, again, the Epstein–Barr virus may have a role. Presenting symptoms depend on the location of the lesion. Supratentorial lesions may cause headaches (sometimes from increased intracranial pressure or meningeal involvement), personality

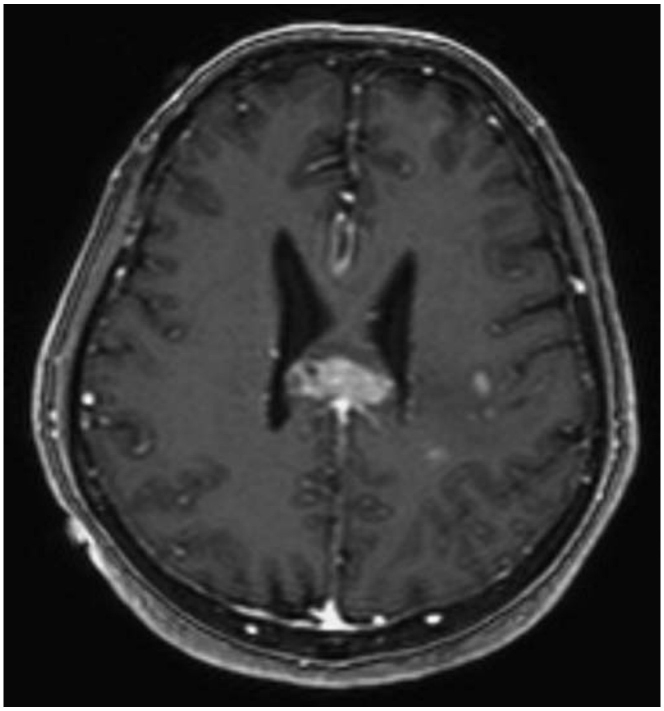

FIGURE 16-5 ■ MRI of a patient with biopsy-proven primary lymphoma of the brain. Axial postcontrast T1-weighted MRI shows an enhancing mass involving the splenium of the corpus callosum as well as two satellite nodules within the white matter of the left posterior frontal lobe. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

changes, cognitive abnormalities, blurred vision, or focal motor or other deficits. Convulsions are relatively uncommon. Cranial neuropathies, ataxic syndromes, and other signs of brainstem involvement occur with infratentorial intracranial involvement. Meningeal involvement is relatively common as the disease advances and leads to multifocal disease with cranial and spinal neuropathies, headaches, signs of meningeal irritation, and, occasionally, hydrocephalus. In rare instances of primary spinal involvement, there is weakness, sensory loss, and sphincter dysfunction, depending on the site and extent of the lesion. Spinal lesions are more often intramedullary, whereas in patients with systemic lymphoma diffuse leptomeningeal involvement or extradural nodules are more likely. Recurrence is usually within the brain, but systemic dissemination occurs occasionally and tends to involve extranodal organs, such as kidneys or skin.

The CSF usually shows nonspecific findings, but cytology may reveal malignant cells, especially if repeated examinations are performed. The absence of such cells does not exclude the diagnosis. CT usually shows a mass much larger than that suggested by the clinical findings; there are usually isodense, hyperdense, and hypodense areas, with contrast enhancement. On T2-weighted MRI, the mass may appear isointense to hypointense, enhances homogeneously with contrast administration, may be associated with extensive edema, is often in contact with the subarachnoid space, and typically is without necrosis. One-third of these tumors are multifocal. Tumors may be missed by one imaging modality and detected by the other; both may miss meningeal disease. MRI or myelography detects spinal disease. A definitive diagnosis is made by histopathologic examination after stereotactic biopsy. Extensive resection of the tumor is usually not attempted given its deep location and often multifocal nature and because of the high surgical morbidity.

Surgery has no role in treatment. Treatment is with high-dose methotrexate in combination with other chemotherapeutic agents and rituximab. Subsequent consolidation therapies have included whole-brain radiotherapy and autologous stem-cell transplantation. The efficacy of immunotherapy for salvage therapy is under study.

Central Nervous System Infections

In renal transplant recipients, the risk of infections (and neoplasia), with their attendant mortality and morbidity, increases with increasing immunosuppression rather than with the use of a specific immunosuppressive agent. It is important to bear this in mind when the addition of a potent immunosuppressive agent is under consideration for the treatment of acute rejection episodes. The risk of infection is also influenced by environmental exposure, by the presence of indwelling catheters that may serve as a conduit for infection, and by whether peritoneal dialysis rather than hemodialysis was utilized prior to transplantation (as the former is associated with a higher risk of infection). Other factors that bear on the issue are co-existing diseases such as diabetes that render patients more prone to infection, poor nutritional status, metabolic abnormalities such as uremia, and infection with immunomodulating viruses such as Epstein–Barr and human immunodeficiency virus.

CNS infections are an important consideration in transplant recipients. When acute meningitis occurs, it is usually caused by *Listeria monocytogenes*, whereas subacute or chronic meningitis is commonly caused by *Cryptococcus neoformans*, although systemic infection with *Mycobacterium tuberculosis*, *L. monocytogenes*, *Histoplasma capsulatum*, *Nocardia asteroides*, and certain other organisms may have a similar presentation. Signs of meningeal irritation may be subtle or absent because of the anti-inflammatory effects of immunosuppressants. Fever, headache, and impairment of consciousness may also be due to CNS lymphoma, which must therefore be distinguished, as described earlier. The presence of unexplained fever and headache in transplant recipients mandates brain imaging by CT scan or MRI and examination of the CSF. Brain abscesses (Fig. 16-6) are well described in transplant recipients and, in most instances, the primary source of infection is the lung. CT of the chest is therefore important, especially when chest radiographs are normal or unhelpful, for diagnostic purposes in differentiating fungal brain abscess from brain tumor in transplant recipients. *Aspergillus* has a predilection for dissemination to the brain and accounts for most fungal brain abscesses; such fungal infections usually lead to multiple brain abscesses and have a poor prognosis. Abscess may also result from *L. monocytogenes*, *Toxoplasma gondii*, or *N. asteroides*. With *Listeria* infection, abscesses are also commonly multiple, with a high mortality. The clinical presentation is often with neurologic deficits or seizures of abrupt onset or with a worsening confusional state. The CT scan may show poorly circumscribed, low-absorption areas with minimal or no contrast enhancement and little mass effect. MRI shows ring-enhancing lesions with surrounding edema; distinction from tumor is sometimes difficult, but diffusion-weighted imaging is helpful in this regard. The CSF may be unrevealing. Brain biopsy is sometimes the only reliable way to establish a diagnosis. Treatment is discussed in later chapters.

Progressive multifocal leukoencephalopathy (Fig. 16-7) due to JC virus infection has been described in transplant recipients and leads to cognitive changes, seizures, and focal neurologic deficits. In one reported case, immunosuppression was discontinued and the patient returned to hemodialysis; his neurologic symptoms and imaging abnormalities gradually resolved completely. Similar clinical deficits may relate to other viral infections, such as herpes simplex or Epstein–Barr virus, or may reflect toxicity of immunosuppressants such as cyclosporine or tacrolimus.

West Nile virus infection manifests similarly in transplant recipients as in other patients, but neurologic damage tends to be especially severe.

HEREDITARY DISORDERS OF THE NERVOUS SYSTEM AND KIDNEYS

Various uncommon inherited disorders affect both the kidneys and the nervous system, meriting brief discussion here.

Fabry Disease

Fabry disease is an X-linked lysosomal storage disease resulting from deficiency of ceramide trihexosidase (α-galactosidase), which catalyzes the hydrolytic cleavage of the terminal galactose from globotriaosylceramide. It relates to mutations of the α-galactosidase A (*GLA*) gene at Xq22. Presentation may be at any age.[14]

A small-fiber neuropathy leads to severe neuropathic or limb pain and dysautonomic symptoms, such as hypohidrosis and fever. Vascular skin lesions (angiokeratomas) and corneal opacities occur, and renal, cardiac, endocrine, and other organ involvement results from glycosphingolipid accumulation. Renal involvement leads to proteinuria, polyuria, and polydipsia; progressive renal failure typically develops in adulthood. Kidney function is worse in patients with undetectable α-galactosidase activity compared to those with some residual activity.

Cerebrovascular involvement is associated with transient ischemic attacks and strokes, with the vertebrobasilar circulation being symptomatic most often. Elongated, ectatic, tortuous vertebral and basilar arteries are common angiographic and pathologic findings. The MRI may show focal or multifocal white matter lesions in affected males and in female carriers, and these may reflect an underlying vasculopathy. A fatal outcome is common in middle life from uremia or cerebrovascular disease.

Management involves the administration of enzyme replacement therapy with agalsidase alfa or agalsidase beta. This helps to reduce—but often does not eliminate—neuropathic pain. Treatment of the pain with gabapentin, carbamazepine, or amitriptyline may be helpful. Nonsteroidal anti-inflammatory agents are usually ineffective, and narcotics are best avoided. Enzyme replacement therapy also helps to improve sensory thresholds over the long term, but the effect of such treatment on CNS manifestations—and especially on stroke risk—is unclear. Antiplatelet agents are therefore required to lessen the risk of stroke.

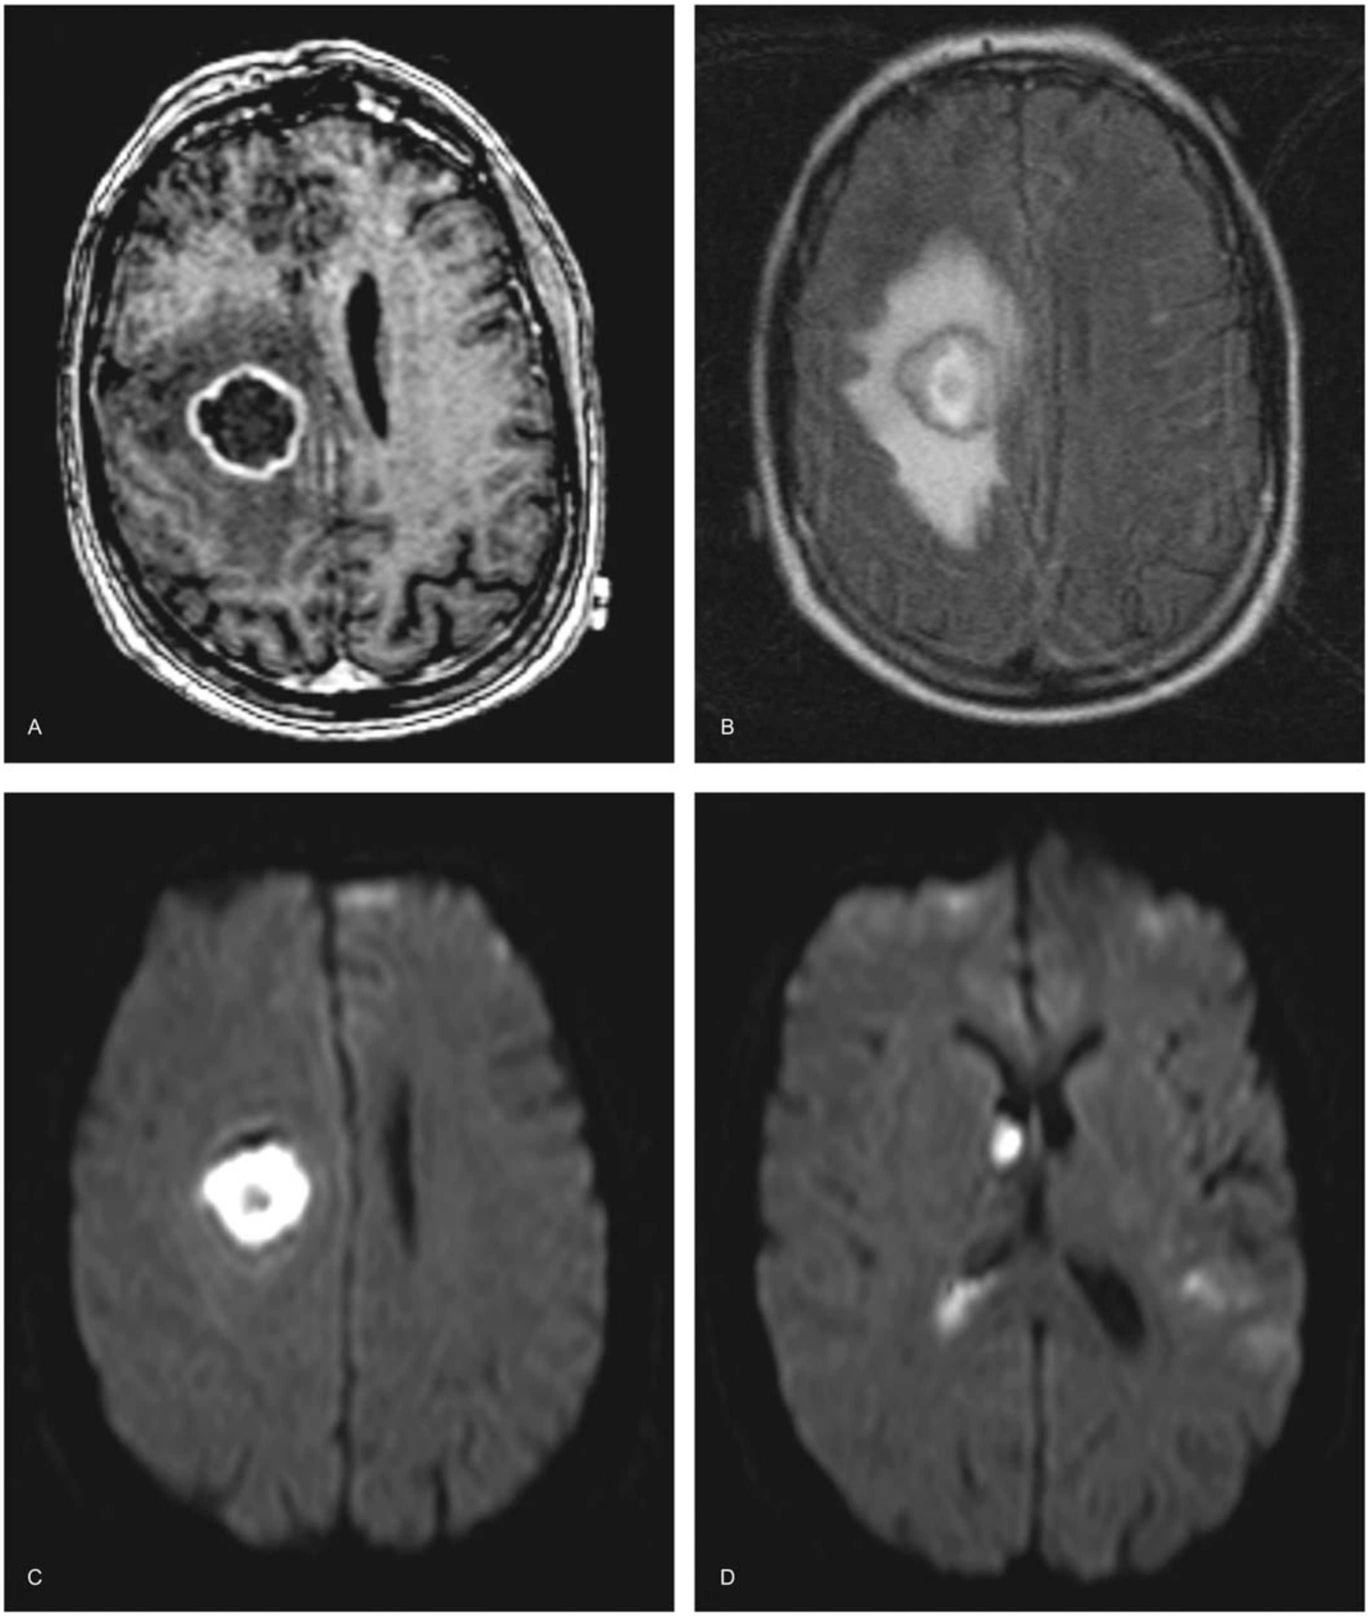

FIGURE 16-6 ■ *A*, Axial postcontrast T1-weighted image demonstrates a ring-enhancing mass lesion in the right frontal lobe with surrounding vasogenic edema. *B*, Axial T2-weighted FLAIR image demonstrates a mass surrounded by a zone of increased signal intensity consistent with vasogenic edema. The mass itself consists of several layers of abnormal signal. Within the center of the mass, a zone of lower signal is seen, surrounded by alternating zones of higher and lower signal. The capsule of the mass shows low signal and is the area that enhances with contrast material (see *A*). *C*, Axial diffusion-weighted image. The central portion of the mass shows high signal, consistent with restricted diffusion. The appearance of a ring-enhancing mass containing material with restricted diffusion is most consistent with a cerebral abscess. *D*, Axial diffusion-weighted image at the level of the lateral ventricles shows abnormal high-signal layering within the right lateral ventricle and in the sulci of the left hemisphere, consistent with both meningeal and intraventricular extension of abscess material. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

The decline in renal function may be slowed by enzyme replacement therapy and also responds to angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Kidney transplant is sometimes necessary.

von Hippel–Lindau Disease

In autosomal-dominantly inherited von Hippel–Lindau disease, the responsible gene maps to chromosome 3p25 and is a tumor suppressor gene. Genetic screening can be performed when the diagnosis is suspected. Renal cysts and cancers occur in patients with CNS and retinal hemangioblastomas (often bilateral), and sometimes with pancreatic cysts and pheochromocytoma. The CNS hemangioblastomas commonly involve the cerebellar hemispheres and may be asymptomatic; spine and brainstem lesions are also well described (Fig. 16-8). A variety of visual complications may occur, mandating the need for regular ophthalmologic screening. Monitoring for the development of renal lesions by CT scan and ultrasound, and for CNS lesions by gadolinium-enhanced MRI of the entire neuraxis, also is important. Treatment is surgical or by radiation therapy.

Polycystic Kidney Disease

At least two different genetic loci for autosomal-dominant polycystic kidney disease have been identified (16p13 and 4q21). The renal manifestations of this disorder include hypertension, urinary tract infection, polyuria, hematuria, nephrolithiasis, pain in the flank, and progressive renal failure. Hypertension also may occur in relation to the kidney disease.

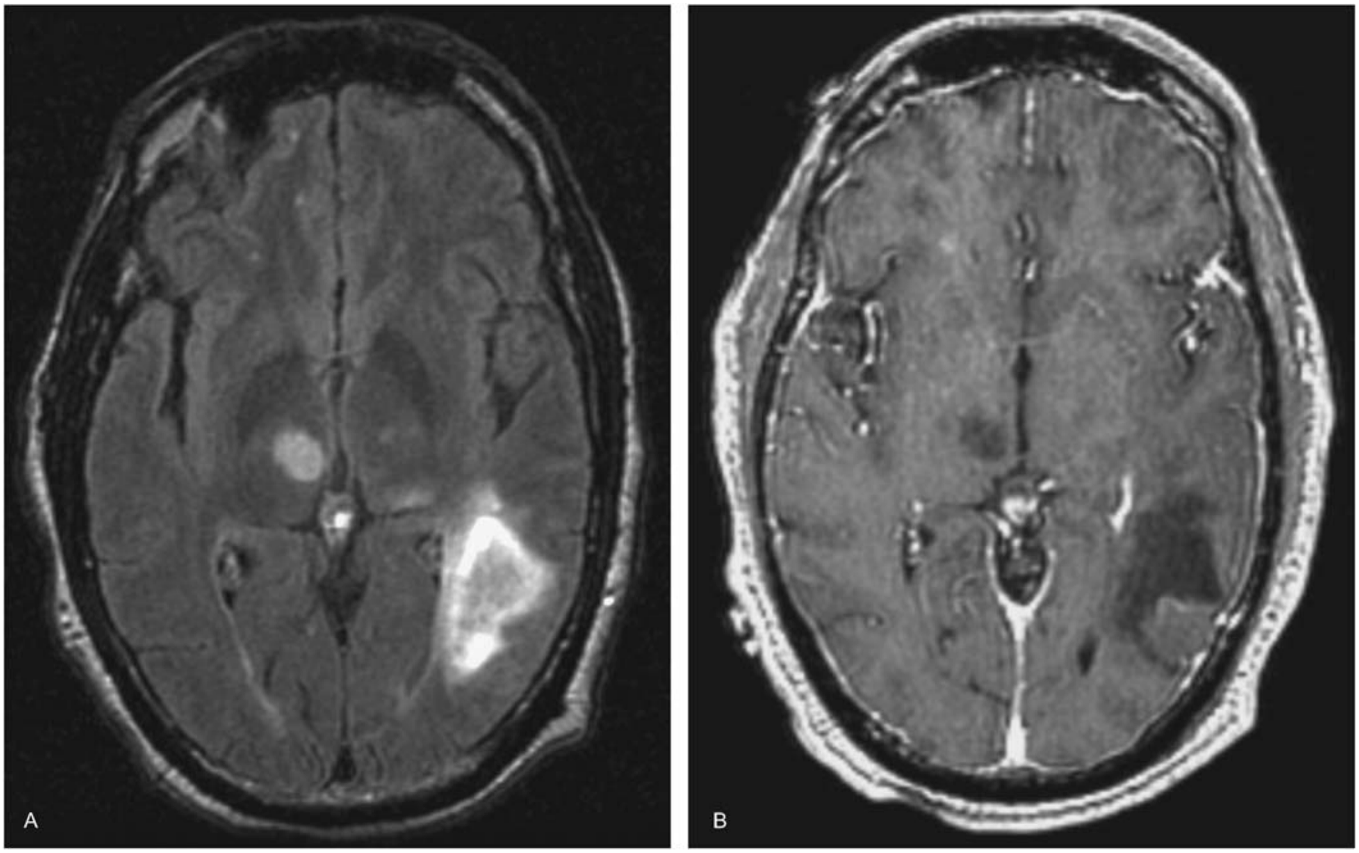

FIGURE 16-7 ■ *A*, An immunosuppressed patient with alteration of mental status. Axial T2-weighted fluid-attenuated inversion recovery MRI demonstrates several discrete areas of T2 prolongation involving the right and left thalamus and the left posterior frontotemporal area. Despite the large size of the lesion, no mass effect is present. *B*, Axial postcontrast T1-weighted image demonstrates well-circumscribed low-intensity lesions without contrast enhancement. Subsequent brain biopsy confirmed the diagnosis of progressive multifocal leukoencephalopathy. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

(Courtesy of William P. Dillon, MD, University of California, San Francisco.)

Intracranial arterial aneurysms, sometimes multiple and unrelated to the occurrence of hypertension, are associated, occurring in between 5 and 20 percent of patients depending on age. Aneurysmal rupture, which occurs especially in older subjects and those with large aneurysms, may lead to subarachnoid or intracerebral hemorrhage. In a retrospective study of 77 patients from 64 families with ruptured (71 instances) or unruptured (6) aneurysms, mean age at the time of rupture was 39.5 years (range, 15 to 69 years), renal function was normal in half of the patients, and 11 percent were on renal replacement therapy. The ruptured aneurysm was usually located on the middle cerebral artery; in 31 percent of the patients, additional intact aneurysms were found. On long-term follow-up, 27 (38%) were left with severe disability. Five patients bled from another aneurysm 2 days to 14 years after initial rupture.[15] Treatment of ruptured aneurysms is as for aneurysmal subarachnoid hemorrhage occurring for other reasons, involving emergency CT scanning, four-vessel angiography, and surgery or endovascular treatment. The indications for surgical or other treatment for unruptured aneurysms are the same as in patients without polycystic kidney disease.

Screening of patients with autosomal-dominant polycystic kidney disease by MR angiography or high-resolution CT angiography at periodic intervals for the presence of cerebral aneurysms is probably worthwhile, at least in high-risk patients, such as those with previous aneurysmal rupture or a positive family history of an intracerebral bleed, but no clear guidelines exist for the frequency with which this should be undertaken. The value of widespread screening for intracranial aneurysms in patients with polycystic kidneys has otherwise been questioned because most intracranial aneurysms detected by presymptomatic screening in this population are small, and follow-up studies do not suggest an increased risk of growth and rupture, compared to intracranial aneurysms in the general population.

Other Hereditary Disorders

Alport syndrome (hereditary nephritis) is a genetically heterogeneous disorder with autosomal dominant or recessive or an X-linked pattern of inheritance. Patients develop progressive glomerular disease leading eventually to end-stage renal disease, and—especially in the X-linked and recessive forms—ocular abnormalities (affecting the retina, cornea, or lens) and bilateral sensorineural hearing loss. Aortic aneurysms may occur. Diagnosis is usually based on the history and family background, supported by biopsy or genetic testing. There is no specific treatment.

Psychomotor retardation and developmental delay occur in the X-linked recessive *Lowe syndrome* (in which there is progressive renal impairment) and autosomal recessive *Bartter syndrome* (in which ionic resorption is impaired in the loop of Henle). Cerebellar ataxia is a feature of *Hartnup disease*, in which there is impaired renal resorption of amino acids leading to aminoaciduria. In *Joubert syndrome* of cerebellar (vermian) and brainstem maldevelopment, multicystic renal dysplasia and chronic kidney disease may be conjoined.

- Hypermagnesemia

Electrolyte disturbances are frequent and associated with a variety of central and peripheral neurologic manifestations. Electrolyte disturbances are usually secondary processes related to a primary metabolic or endocrine disorder. Effective management requires prompt identification and treatment of the underlying primary disorder, and correction of the electrolyte abnormality. Neurologic consequences of electrolyte disorders are usually functional rather than structural. Consequently, the neurologic manifestations of electrolyte disturbances are often reversible, particularly if corrected and effectively managed at an early stage. The neurologic manifestations of abnormalities of serum sodium, potassium, calcium, and magnesium are reviewed.

SODIUM

Extracellular fluid volume is directly dependent on total body sodium, the principal osmotic component of that fluid compartment. Consequently, most patients with hyponatremia are also hypo-osmolar, and those with hypernatremia are hyperosmolar. The symptomatic neurologic manifestations of serum sodium abnormalities typically involve the central, rather than the peripheral, nervous system. Neurologic manifestations are generally the consequence of hypo-osmolarity in hyponatremia and hyperosmolarity in hypernatremia. Slow changes to sodium, even to extreme values, infrequently produce symptoms due to the brain's adaptation to serum osmolality. Rapid sodium change, up or down, produces characteristic neurologic symptoms.

Hyponatremia

Hyponatremia is defined as a serum sodium level of less than 135 mEq/L. It is most often associated with hypo-osmolarity and is classified into three categories based on whether extracellular fluid volume is decreased, normal, or increased. *Hypo-osmolar hyponatremia with hypovolemia* results from renal sodium loss (e.g., from diuretic usage, mineralocorticoid deficiency, salt-losing nephropathy, or osmotic diuresis) or extrarenal sodium loss (e.g., from vomiting, diarrhea, or third-space losses). *Hypo-osmolar hyponatremia with normovolemia* (no edema) results from conditions such as the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), glucocorticoid deficiency, hypothyroidism, and stress. It can also occur in response to various drugs, including carbamazepine and psychotropic

Aminoff's Neurology and General Medicine, Sixth Edition.

agents. *Hypo-osmolar hyponatremia with excess extracellular fluid* (edema) occurs in conditions such as cirrhosis, cardiac failure, nephrotic syndrome, and acute or chronic renal failure. Other less common variants include *hyponatremia with normal osmolarity* (pseudohyponatremia), which occurs in the setting of hyperlipidemia or hyperproteinemia, and *hyponatremia with hyperosmolarity*, which occurs in the setting of hyperglycemia.

The separation of hypo-osmolar hyponatremia into these three categories based on the extracellular fluid volume status has therapeutic implications. In normovolemic and hypervolemic hypo-osmolar hyponatremia, the fundamental principle of therapy is water restriction. In hypovolemic hypo-osmolar hyponatremia the basis of therapy is replacement of water and sodium (generally with isotonic saline or lactated Ringer solution). Overall, the rate of sodium correction should be no more than 6 to 12 mEq/L in the first 24 hours.

Among hospitalized patients, hyponatremia is the most common electrolyte abnormality that occurs. Hyponatremia is associated with increased risk of death, more likely discharge to short- or long-term care facility, and longer length of stay.[1] However, these associations may reflect the seriousness of underlying disorders rather than the hyponatremia itself.[2]

Neurologic symptoms related to hyponatremia are seen much more frequently in patients with acute, rather than chronic, hyponatremia. For example, a serum sodium concentration of 130 mEq/L might produce neurologic symptoms if it developed rapidly, whereas a serum sodium concentration of 115 mEq/L might be asymptomatic if it developed very slowly. An alteration in mental status is the most common neurologic manifestation of hyponatremia and ranges from mild confusion to coma. Patients with underlying neurodegenerative disorders and those of advanced age are particularly susceptible to delirium from even small changes in serum sodium. This hyponatremic encephalopathy may be associated with nonspecific generalized slowing on the electroencephalogram. As the level of serum sodium decreases, the risk of seizures increases. The occurrence of convulsions in the setting of acute hyponatremia (typically with a serum sodium concentration less than 120 mEq/L) can portend a high mortality rate. The occurrence of seizures in patients with acute hyponatremia represents a medical emergency and necessitates rapid, but only partial, correction of the serum sodium concentration. Control of hyponatremic seizures can be obtained by the judicious use of 3 percent saline (4 to 6 mL/kg) in an attempt to raise the serum sodium concentration by small 3 to 5 mEq/L increments.[3] When hypertonic saline is used, it is prudent to check the serum sodium levels every 2 to 4 hours.

Occasionally, focal neurologic signs and symptoms are seen in the setting of hyponatremia and include hemiparesis, monoparesis, ataxia, nystagmus, tremor, rigidity, and aphasia. These focal abnormalities can represent aggravation of an underlying structural lesion and often remit with resolution of the hyponatremia. Such focal deficits require neuroimaging even if they fully resolve with sodium correction. The central nervous system (CNS) manifestations of acute hyponatremia are related to cerebral edema and displacement of brain amino acids, although mechanisms are being studied. Although occasional muscle twitches, fasciculations, and cramps may be seen in acute hyponatremia, muscle symptoms are not common.

Hyponatremia associated with limbic encephalitis is characteristic of anti-LGI1 encephalitis.[4] Patients with this disorder also present with faciobrachial dystonic seizures. This form of voltage-gated potassium channel encephalitis is important to recognize in order to promptly initiate anti-inflammatory therapies.

SUBARACHNOID HEMORRHAGE AND OTHER INTRACRANIAL DISEASES

Hyponatremia frequently develops in patients with subarachnoid hemorrhage. There is controversy on whether hyponatremia is associated with symptomatic cerebral vasospasm and cerebral infarction. One classic study of 134 patients showed that 27 out of 44 patients who developed hyponatremia also developed cerebral infarctions. The authors emphasized that fluid restriction, the typical strategy to treat SIADH, was dangerous in these patients.[5] Guidelines have cited this evidence in describing a link between hyponatremia and morbidity in subarachnoid hemorrhage. However, recent studies have shown contradictory results. In one study of 198 patients, hyponatremia was not associated with worse neurologic outcomes.[6] Rather, patients with sodium variability of or exceeding 6 mEq/L had increased cerebral infarction and worse functional outcomes. These fluctuations may occur in patients with either hyponatremia or hypernatremia. Further study in larger cohorts of patients is needed to understand the involved mechanisms.

Therapeutically, hyponatremia is typically treated with oral or intravenous sodium repletion in an attempt to restore or maintain normovolemia. Fluid restriction in patients with subarachnoid hemorrhage is discouraged because these patients usually do not have SIADH. Rather, their hyponatremia is more likely to be due to cerebral salt wasting. In a prospective study of 21 patients with aneurysmal subarachnoid hemorrhage, plasma volume decreased by more than 10 percent in 11 of the patients.[7] Serum sodium decreased in 9 of the 21 patients. Plasma volume decreased by more than 10 percent in 6 of 9 patients with hyponatremia, and a similar decrease occurred in 5 of 12 patients with normal serum sodium. Eight of the 9 patients with hyponatremia had a negative sodium balance, whereas only 4 of the 12 patients with normal serum sodium had a negative sodium balance. Finally, 10 of the 12 patients with a negative sodium balance had a decrease in plasma volume exceeding 10 percent. Therefore, fluid restriction instituted to correct hyponatremia attributed to presumed SIADH may exacerbate an already volume-depleted state and subject patients to a greater risk of ischemic cerebral damage from vasospasm.

CENTRAL PONTINE MYELINOLYSIS (OSMOTIC MYELINOLYSIS)

Central pontine myelinolysis was recognized as a distinct clinical entity in 1959 in four cases, occurring on a background of alcoholism and malnutrition. Its pathologic features involve a symmetric noninflammatory demyelination in the base of the pons with relative sparing of neurons and axons. The classic clinical presentation includes pseudobulbar palsy and spastic quadriparesis. Following the original description, many additional cases were reported in rapid succession, suggesting that central pontine myelinolysis is not a rare disorder. Many cases were not associated with alcoholism or malnutrition. It may, for example, occur in subjects with extensive burns or liver transplants. By 1964, the relatively high frequency of subclinical lesions (Fig. 17-1) was noted, and this was validated by many subsequent reports. The history of the recognition and pathogenesis of central pontine myelinolysis has been summarized elsewhere.[7]

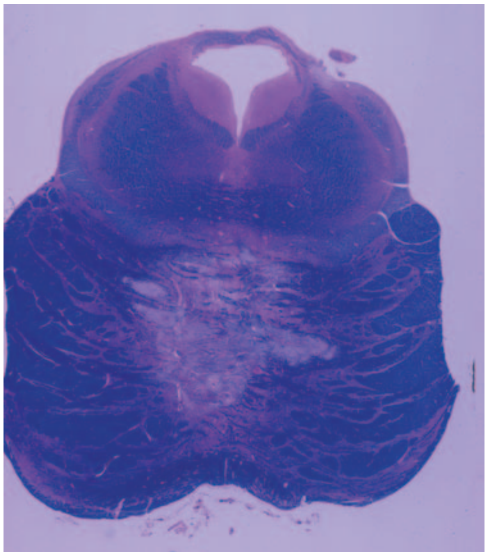

FIGURE 17-1 ■ Macrosection of the pons demonstrating central demyelination, an incidental finding of subclinical central pontine myelinolysis in a patient with a history of electrolyte abnormalities and diuretic use (Luxol fast blue).

Rapid sodium correction of more than 12 mEq/L per day causing central pontine myelinolysis was popularized by a paper published in 1986.[8] Sterns and colleagues noted neurologic complications in eight patients whose serum sodium had been corrected by more than 12 mEq/L per day. Conversely, patients with hyponatremia that was corrected more slowly made uncomplicated recoveries. In a review of the literature, those authors found 80 patients with severe hyponatremia (less than 106 mEq/L). Of these 80 patients, enough detail was reported in 51 to determine a maximal rate of correction of serum sodium. In 39 of 51 patients who were corrected rapidly (greater than 12 mEq/L per day), 22 (58%) had some type of neurologic complication. Of these 22 patients, 14 (64%) were suspected of having central pontine myelinolysis. Of the 13 patients who were corrected slowly (less than 12 mEq/L per day), none experienced a neurologic complication. The authors concluded that the risk of central pontine myelinolysis was greatest in patients with chronic hyponatremia, where a judicious correction strategy should be employed. Experimental animal models have confirmed the occurrence of demyelination after rapid sodium correction. In dogs and rats, demyelination follows rapid correction of sustained, vasopressin-induced hyponatremia with hypertonic saline.

The label *osmotic myelinolysis* has been suggested in preference to *central pontine myelinolysis* because of the well-recognized occurrence of extrapontine myelinolysis. This myelinolysis occurs in areas of the brain characterized by an extensive admixture and apposition of gray and white matter. Although the pathogenesis of osmotic myelinolysis remains undefined, the topography of oligodendrocytes may play a role. Oligodendrocytes in these vulnerable areas are predominantly located within adjacent gray matter rather than within the white matter bundles (Fig. 17-2). Because gray matter is much more vascular than white matter, oligodendrocytes in this location may be more vulnerable to serum osmotic shifts.

A judicious approach to the correction of chronic hyponatremia is urged, especially in cases where the sodium has been chronically depressed. There is no justification for using hypertonic saline to treat asymptomatic hyponatremia, or to rapidly correct hyponatremia to levels above 120 to 125 mEq/L in significantly symptomatic hyponatremia. The rapid reinduction of hyponatremia has shown unclear benefit in animals and humans; therefore, it should not be employed routinely to prevent or treat osmotic demyelination syndrome. Corticosteroids, *myo*-inositol, immunoglobulin, and thyrotrophin-releasing hormone have all been suggested as possible treatments of or preventive measures for the syndrome, with little evidence to recommend such therapies. The lack of proven treatment for this disorder further emphasizes the need to avoid its occurrence by slow correction of hyponatremia.

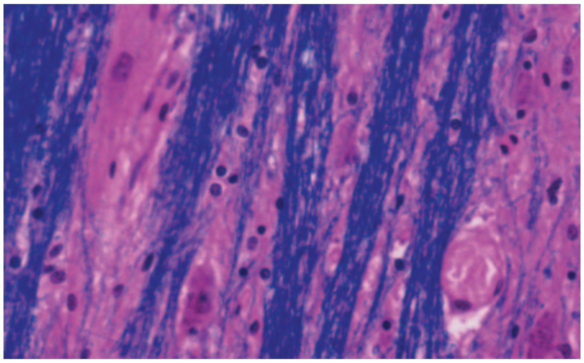

FIGURE 17-2 ■ Gray and white matter bundles in normal human pons. Note that most oligodendrocytes (*small cells with dark nuclei*) are within gray matter rather than within the white matter bundles (hematoxylin and eosin, 640 ×).

Hypernatremia

Hypernatremia is serum sodium concentrations above 160 mEq/L. It is most frequently encountered in the very young or very old. In infants, fluid loss due to gastroenteritis is a common cause. In the elderly, dehydration resulting from an inability to obtain water because of debilitation is the most frequent cause. Diabetes insipidus rarely presents with severe hypernatremia unless the patient is also denied access to water. Structural lesions (e.g., gliomas and metastatic tumors) in the hypothalamic thirst center are an uncommon cause of hypernatremia in patients with neurologic disease.

Altered mental status is a frequent manifestation of hypernatremia and ranges from lethargy to coma. Pathologic studies suggest that osmotic forces present during the development of hypernatremia, particularly when acute, may produce shrinkage of brain parenchyma. This may result in parenchymal hemorrhages or tearing of bridging veins, producing subdural hematomas or subarachnoid hemorrhage. For example, Fig. 17-3 shows a patient with acute hypernatremia before (*A*, *B*) and after treatment (*C*, *D*).[9] The patient was a 73-year-old man who presented with altered mental status, vomiting and tremor 12 hours after ingesting soy sauce in a suicide attempt. Serum sodium was 188 mEq/L and serum osmolarity was 314 mOsm/kg H_2O. MRI images (T1 left and T2 right) showed brain shrinkage and subdural fluid collections bilaterally. After sodium was corrected, imaging showed that the brain volume had been restored.

An initial mortality rate of 20 percent and an incidence of permanent brain damage of more than 33 percent have been noted in children with severe hypernatremia. Seizures may occur in the setting of hypernatremia and paradoxically may be more frequent during rehydration. These hypernatremic seizures may be related to either focal hemorrhages that occur during the development of hypernatremia or cerebral edema that may develop during rehydration. Rigidity, tremor, myoclonus, asterixis, and chorea have also been associated with hypernatremia. Transient thalamic signal changes on MRI have been seen with severe hypernatremia. Neuromuscular manifestations of hypernatremia are much less frequent. Rhabdomyolysis and episodic muscle weakness have been reported. Treatment of symptomatic hypernatremia typically involves administration of hypotonic fluids

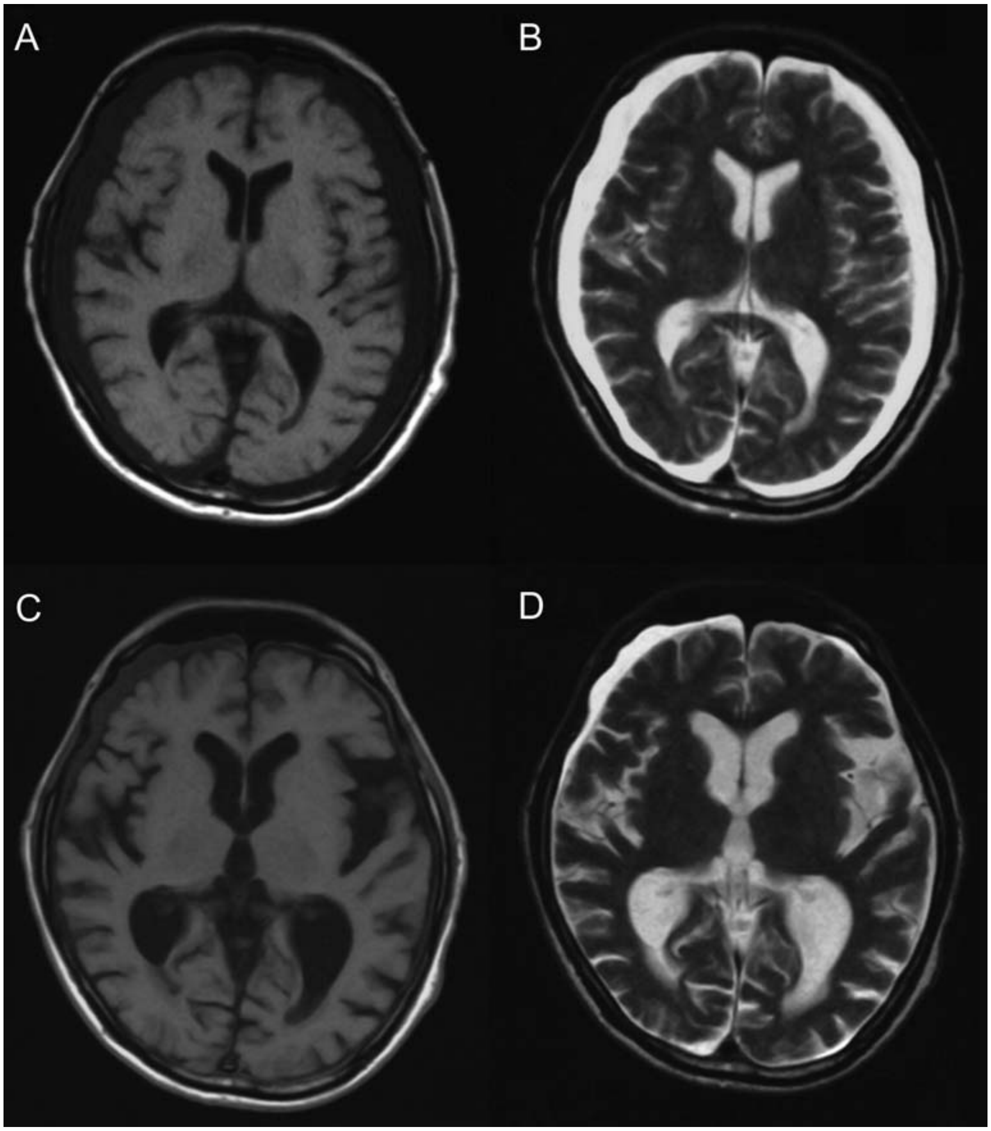

FIGURE 17-3 ■ MRI of patient with acute hypernatremia before (*A*, *B*) and after treatment (*C*, *D*). Note T1-weighted image on left shows brain shrinkage and T2-weighted image shows bilateral subdural collection. Brain volume is restored on MRI after 3 weeks. (From Machino T, Yoshizawa T: Brain shrinkage due to acute hypernatremia. Neurology 67:880, 2006, with permission.)

to correct the free water deficit, using caution to avoid rapid correction.

POTASSIUM

In contrast to sodium, the neurologic manifestations of potassium disturbance rarely involve the CNS. About 98 percent of total body potassium is located intracellularly, and 60 percent of intracellular potassium is within muscle. This distribution may, in part, account for the predominance of muscle symptoms associated with either hypokalemia or hyperkalemia.

Hypokalemia

Hypokalemia is defined as a serum potassium level of less than 3.6 mEq/L. It is the most frequent electrolyte disorder encountered in clinical practice and is produced by a variety of mechanisms, including inadequate potassium intake or excessive renal or gastrointestinal potassium loss. Neurologic symptoms of hypokalemia are typically muscular. Serum potassium concentrations of 3.0 to 3.5 mEq/L may be associated with mild muscle weakness, myalgia, and ease of fatigue. Serum potassium concentrations of 2.5 to 3.0 mEq/L are associated with the development of clinically significant muscle weakness, particularly of the proximal limb muscles, and muscle cramps. The cranial musculature is characteristically spared in hypokalemia-induced muscle weakness. When the serum potassium level falls below 2.5 mEq/L, and usually below 2.0 mEq/L, structural muscle damage, including rhabdomyolysis and myoglobinuria, may occur.

Tetany occurs in some patients with hypokalemia, particularly when associated with alkalosis. Hypokalemia may mask the tetany of hypocalcemia. Paradoxically, tetany may occur during the treatment of hypokalemia in patients who are also hypocalcemic.

Cerebral symptoms in hypokalemia are distinctly unusual. Reference to symptoms such as lethargy, apathy, drowsiness, confusion, irritability, delirium, and coma in hypokalemia are rare and suggest that an associated acid–base disturbance or other electrolyte abnormality may have been responsible for these encephalopathic symptoms. Brain concussion has been shown to lead to a mild transient hypokalemia.

Hyperkalemia

Hyperkalemia is defined as a serum potassium level exceeding 5.2 mEq/L. The cardiac toxicity of hyperkalemia essentially precludes the appearance of significant neurologic manifestations. Most patients develop serious cardiac abnormalities, such as ventricular fibrillation or asystole, before the appearance of neurologic symptoms.

The most frequent neurologic manifestation of hyperkalemia is the development of mild muscle weakness, which occurs most often in the setting of chronic adrenal insufficiency. Profound muscle weakness with hyperkalemia is reported only rarely. Chronic potassium homeostasis is dependent on renal mechanisms. Acute potassium regulation is dependent on extrarenal hormonal mechanisms primarily involving insulin, aldosterone, and epinephrine. Clinically important etiologies of hyperkalemia include renal failure, adrenal insufficiency (Addison disease), and acidosis with or without insulin deficiency. Cerebral symptoms due to hyperkalemia must be uncommon, since they do not occur in hyperkalemic periodic paralysis. The cerebral symptoms (nervousness and lethargy) that frequently occur in Addison disease are more likely related to the associated hyponatremia or acidosis than the elevated potassium.

CALCIUM

Plasma calcium stabilizes excitable membranes in muscle and nervous tissue. Disorders of calcium would therefore be expected to produce neurologic manifestations. The coordinated interactions of parathyroid hormone, cholecalciferol, and probably calcitonin regulate plasma calcium concentration. The main sources of calcium are intestinal calcium absorption, renal calcium reabsorption, and bone resorption.

Hypocalcemia

Hypocalcemia is defined as total serum calcium of less than 8.8 mg/dL or serum ionized calcium less than 4.7 mg/dL. It is relatively rare except in neonates and individuals with renal failure. Severe acute hypocalcemia is most frequently iatrogenic, following thyroid or parathyroid surgery. Hypocalcemia is also a common complication of acute pancreatitis and is frequent in patients in the intensive care unit with a variety of conditions. The neurologic manifestations of hypoparathyroidism resulting from primary, secondary, or pseudohypoparathyroidism (parathyroid hormone-resistant syndromes) largely reflect hypocalcemia.

The most common CNS manifestations of hypocalcemia are altered mental status and seizures (which may be focal or generalized). Altered mental status symptoms include irritability, anxiety, agitation, confusion, delirium, delusions, hallucinations, psychosis, depression, mental dullness, mental retardation, and dementia. Chorea and parkinsonism are seen with increased frequency in patients with chronic hypocalcemia. Although a causal relationship has not been established, the regularity with which calcification of the basal ganglia is seen in patients with chronic hypoparathyroidism seems more than coincidental, and some patients have quite prominent associated movement disorders (discussed in Chapter 58).[10] Less frequent CNS manifestations of hypoparathyroidism are pseudotumor cerebri and myelopathy due to vertebral lamina overgrowth.

Tetany is the most frequently recognized symptom of hypocalcemia referable to the peripheral nervous system. Tetany originates in the peripheral nerve axon and is due to spontaneous, irregular, repetitive nerve action potentials. When the ionized calcium concentration reaches a low enough level, the peripheral nerve membrane may spontaneously discharge at the normal resting membrane potential. Latent tetany may be unmasked clinically by hyperventilation or temporary local ischemia by an inflated blood pressure cuff (Trousseau test). The first symptom of tetany is tingling that initially occurs periorally and distally in the limbs and then spreads proximally. This is followed by a feeling of muscle spasm that has an initial distribution similar to that of the early sensory complaints and becomes increasingly severe as it spreads proximally. Finally, muscles may go into tonic spasms, commencing distally (carpopedal spasm). Laryngeal stridor may ultimately develop. Opisthotonos may occur if spasms involve the trunk.

Elevated serum creatine kinase levels have been reported in patients with hypoparathyroidism, although clinical and morphologic evidence of myopathy has been scant. Hypoparathyroidism has been associated with the mitochondrial disorder Kearns–Sayre syndrome as well as with muscle phosphorylase deficiency (perhaps related to failure of calcium to activate phosphorylase kinase).

Hypercalcemia

Hypercalcemia is defined as serum calcium levels exceeding 10.5 mg/dL. Malignant neoplasms and hyperparathyroidism account for 70 to 80 percent of cases of hypercalcemia. The neoplasms most frequently associated with hypercalcemia are breast cancer, lung cancer, and multiple myeloma. Although most instances of hypercalcemia in the setting of malignancy are due to osteolytic skeletal metastases, some carcinomas, particularly of the lung, are associated with hypercalcemia due to elevated levels of parathyroid hormone. Single adenomas of the parathyroid gland account for 75 percent of cases of primary hyperparathyroidism. Because patients with malignant neoplasms often have several mechanisms for neurologic injury, the incidence of neurologic manifestations in hyperparathyroidism (which is at least 40%) represents a reasonable incidence of the neurologic disorders associated with hypercalcemia.

Alterations in mental status are common in hypercalcemia, particularly with serum calcium concentrations of more than 14 mg/dL. Symptoms consist of progressive lethargy, confusion, and ultimately coma. These reversible symptoms are directly related to the degree of hypercalcemia and require immediate therapy. Headache, elevated cerebrospinal fluid protein, and, rarely, convulsions also occur in patients with hypercalcemia. Hyperparathyroidism has also been associated rarely with other CNS disturbances including ataxia, internuclear ophthalmoplegia, corticospinal tract dysfunction, dysarthria, and dysphagia. Hypercalcemia has been associated with apnea in children as well as with the posterior reversible encephalopathy syndrome, a radiographic diagnosis due to many etiologies that can present with seizures, altered mental status, or focal neurologic deficits.[11]

Hypercalcemia produces reduced neuromuscular excitability and may cause muscle weakness. Easy fatigability and muscle weakness are more common in hyperparathyroidism than in other hypercalcemic conditions. The clinical features of hyperparathyroid myopathy include proximal, though seldom disabling, muscle weakness and wasting with preserved or even brisk reflexes and mild nonspecific myopathic features on electromyography and muscle biopsy, as discussed in Chapter 60. The pathogenesis of hyperparathyroid myopathy remains undefined, although hypercalcemia, vitamin D deficiency, chronic phosphate deficiency, or neuropathic influences may play a role. Hyperparathyroid myopathy is similar to the vitamin D deficiency myopathy that can occur with uremia, phenytoin therapy, and osteomalacia. Neuropathy is not a common feature of hypercalcemia, but carpal tunnel syndrome has occasionally been associated with hyperparathyroidism.

MAGNESIUM

Less than 2 percent of total body magnesium is located within the extracellular fluid compartment. Although magnesium has an intracellular–extracellular distribution similar to that of potassium, most of the intracellular magnesium is bound and not exchangeable with the extracellular fluid. Intracellular free magnesium is rigidly regulated despite wide variations in extracellular magnesium concentrations. The teleologic basis for this rigid regulation is the critical role of magnesium in intracellular metabolism. Magnesium is required for activation of a wide range of intracellular enzymes. Additionally, extracellular magnesium exerts significant effects on synaptic transmission in the central and peripheral nervous system.

Hypomagnesemia

Hypomagnesemia is defined as serum magnesium concentration less than 1.6 mg/dL, although signs and symptoms do not typically arise until levels are less than 1.2 mg/dL. Because magnesium is predominantly an intracellular electrolyte, the finding of hypomagnesemia does not always accurately reflect magnesium depletion. Important mechanisms of hypomagnesemia and magnesium depletion include decreased intake (as in starvation), decreased intestinal absorption (as in malabsorption syndromes such as nontropical sprue), and increased renal loss (as with diuretic usage, chronic alcoholism, diabetic acidosis, and renal tubular acidosis).

The neurologic manifestations of hypomagnesemia are essentially hyperirritability with agitation, confusion, seizures, tremor, myoclonus, hyperreflexia, Chvostek sign, and tetany. Occasionally, even focal neurologic signs may be seen in patients with hypomagnesemia. When convulsions occur in patients with hypomagnesemia, parenteral administration of magnesium salts is required. However, renal function should be assessed before parenteral magnesium is administered as those with renal failure may not be able to excrete magnesium adequately. When magnesium is given, it should be given by slow intravenous bolus, and calcium gluconate should be available to counteract transient hypermagnesemia, which may rarely cause apnea as a result of respiratory muscle paralysis.

Hypomagnesemia and hypocalcemia need to be considered together in diagnosis and management. The neurologic manifestations of hypomagnesemia are similar to those of hypocalcemia, which is not surprising, since hypocalcemia often accompanies hypomagnesemia. The hypocalcemia or hypomagnesemia is produced or exaggerated in some instances by a hypomagnesemia-induced decrease in parathyroid hormone or end-organ resistance to the action of parathyroid hormone. This leads to an important therapeutic point—it is necessary to evaluate magnesium in a hypocalcemic patient who fails to respond to calcium supplementation. Conversely, in magnesium-deficient patients who are normocalcemic but have symptoms suggestive of hypocalcemia, calcium may still be responsible for the symptoms. Normocalcemic hypomagnesemic patients may have decreased serum ionized calcium concentrations.

Hypomagnesemia develops frequently with cisplatin use. In that setting, only patients who are also hypocalcemic develop tetany with carpopedal spasm. Muscle weakness develops in some patients with hypomagnesemia, although co-existent hypokalemia or hypophosphatemia may contribute. Chronic hypomagnesemia has been associated with a cardioskeletal mitochondrial myopathy.[12]

Hypermagnesemia

Hypermagnesemia is defined by a serum level exceeding 2.3 mg/dL (1.9 mEq/L). Symptomatic hypermagnesemia occurs rarely in the setting of excessive magnesium intake in conjunction with impaired renal function. Unsuspected symptomatic hypermagnesemia may occur more frequently in the elderly.

The predominant neurologic manifestation of severe hypermagnesemia is muscular weakness or paralysis. Untreated, this weakness, which can involve respiratory muscles, may result in respiratory insufficiency with subsequent hypoxia, hypercapnia, coma, and ultimately death. The flaccid muscle weakness of hypermagnesemia is due to a blockade of neuromuscular transmission, which may not resolve until magnesium levels return to normal through renal excretion or with the aid of hemodialysis. In general, the neurologic manifestations of hypermagnesemia are characterized by nervous system depression. Loss of deep tendon reflexes is an early sign of hypermagnesemia and occurs at serum magnesium concentrations of 5 to 6 mEq/L. This loss of reflexes may be utilized in obstetrics to titrate magnesium sulfate infusions used in the treatment of pre-eclampsia. At serum magnesium concentrations of 8 to 10 mEq/L, CNS depression is said to occur, with lethargy and confusion being the most common reported neurologic manifestations. However, in human subjects in whom the serum magnesium concentration was increased to 15 mEq/L, no CNS depression occurred, although there was slowing of the electroencephalogram. This leads to the conclusion that clinical CNS effects of hypermagnesemia are likely rare.

MISCELLANEOUS ASSOCIATIONS BETWEEN NEUROLOGIC DISORDERS AND THYROID DYSFUNCTION

- Endocrine Dysfunction in Long-Term Survivors of Primary Brain Tumors
- Multiple Sclerosis and Thyroid Disease
- Recurrent Laryngeal Nerve Palsy

Disorders of the thyroid gland are common and are frequently accompanied by neurologic complications. Prevalence estimations have suggested that 1 to 2 percent of general medical, geriatric, and psychiatric inpatients have some form of thyroid disease. Neurologists should be aware of the common and the more unusual neurologic complications of thyroid disease, since they may be the presenting feature of the thyroid disorder and because they are usually readily corrected with appropriate treatment.

NEUROLOGIC COMPLICATIONS OF HYPOTHYROIDISM

Hypothyroidism is a common disorder, with data from the National Health and Nutrition Examination Survey indicating that 1 in 300 persons in the United States has hypothyroidism. The commonest causes of hypothyroidism are autoimmune destruction, thyroidectomy, and radioiodine ablation of the gland. Fewer than 10 percent of cases of hypothyroidism are secondary to pituitary or hypothalamic disease.

Neurologic complications are common in patients with hypothyroidism, and all levels of the nervous system may be involved. The neurologic complications of hypothyroidism may be grouped into the following categories: (1) congenital hypothyroidism; (2) encephalopathy that may result in coma or a seizure disorder; (3) psychologic changes; (4) sleep disorders; (5) cerebellar ataxia; (6) cranial nerve lesions; (7) myopathy; (8) peripheral nerve disorders; and (9) miscellaneous conditions.

Neurologic Features of Congenital Hypothyroidism

Congenital hypothyroidism (CH), previously called cretinism, is the commonest treatable cause of neonatal encephalopathy, with data from neonatal screening programs revealing an incidence of 1:3,000 to 1:4,000. It occurs secondary to dysgenesis of the thyroid gland or to severe maternal deficiency of dietary iodine. Neurologic complications include developmental delay, pyramidal signs in a proximal distribution, and extrapyramidal signs. Many patients have a characteristic gait, reflecting dysfunction of both the pyramidal and the extrapyramidal motor systems, in combination with laxity and deformity of the joints. Other common clinical features include strabismus, deafness, ataxia, and primitive reflexes. Imaging of the brain shows basal ganglia calcification in one-third of patients. In addition, evidence suggests that CH leads to reduced hippocampal volume, even when treated, and psychometric testing reveals that patients score below age-matched controls in verbal memory. Similarly, reduced IQ scores have also been reported in children with CH. Learning impairment and changes in hippocampal CA1 pyramidal cell excitability have been reported in hypothyroid mice.

Adult patients with CH typically manifest physical signs of spasticity affecting the trunk and proximal limb-girdle musculature, with relative sparing of the distal extremities. Magnetic resonance imaging (MRI) of the brain has shown abnormalities in the globus pallidus and substantia nigra, with increased signal on T1-weighted images and hypointensity on T2-weighted images, and only a modest degree of cerebral atrophy. Overall however, neuroradiologic findings seem to be similar in children with CH when compared to healthy controls. It has been suggested that the main insult to the central nervous system (CNS) may involve processes such as dendritic arborization and synaptogenesis, which are not evident on MRI.

In the developing brain, thyroid hormone has important effects on the regulation of neurofilament gene expression and on several genes encoding mitochondrial proteins. Thyroid hormone also regulates the timing of appearance and regional distribution of laminin, an extracellular matrix protein that provides key guidance signals to migrating neurons within the CNS. Disruption in the expression of laminin may play a role in the derangement of neuronal migration observed in the brain of patients with CH.

A detailed consideration of the inborn errors of thyroid gland development and thyroid hormone synthesis responsible for permanent CH is beyond the scope of this chapter, but recent reviews on the topic provide additional details.[1] Primary CH is due to abnormal development of the thyroid gland in 85 percent of instances. A group of patients with CH poorly responsive to treatment and featuring additional signs of choreoathetosis, muscular hypotonia, and pulmonary problems were found to have mutations to thyroid transcription factor 1. Mutations to genes coding proteins required for thyroid hormone synthesis cause 10 to 15 percent of permanent primary CH; thyroid peroxidase is the protein most commonly affected. Furthermore, mutations in a transmembrane thyroid hormone transporter, MCT-8, result in abnormal levels of circulating iodothyronines as well as global developmental delay, central hypotonia, spastic quadriplegia, dystonic movements, rotatory nystagmus, and impaired gaze and hearing in affected males. Heterozygous females have a milder thyroid phenotype and no neurologic abnormalities.

Encephalopathy, Coma, and Seizures

Slowness, impairment of attention and concentration, somnolence, and lethargy are common symptoms in hypothyroidism. Occasionally, a life-threatening encephalopathy termed "myxedema coma" develops in patients with chronic, untreated hypothyroidism. A high index of suspicion is required to diagnose myxedema coma, particularly in the elderly, in whom features of hypothyroidism may be difficult to distinguish from depression or dementia.

In the compensated hypothyroid state, physiologic adaptations include a shift of the vascular pool away from the periphery to the central core to sustain normal body temperature. In chronic hypothyroidism, these adaptations tend to produce a degree of diastolic hypertension as well as a decrease in blood volume of up to 20 percent. Many organ systems and metabolic pathways are profoundly altered by chronic deficiency of thyroid hormone. Alterations in myocardial biochemistry produce impairment of cardiac contractility; the ventilatory response to hypercapnia is abnormal; hyponatremia may result from a reduction in free water clearance; and suppression of bone marrow function may result in normochromic normocytic anemia and an impaired white blood cell response to infection. Reduction in insulin clearance and decreased gluconeogenesis may produce a tendency to hypoglycemia, and patients are predisposed to toxic drug effects owing to reduced plasma clearance of all drugs. The corticosteroid response to stress is also likely to be impaired, even when basal serum cortisol levels are normal.

The majority of patients who develop myxedema coma are elderly and have a history suggestive of gradual deterioration. Three key clinical features are universally present in myxedema coma: depression of consciousness, a precipitating illness or event, and defective temperature control. Common precipitating factors include infection, trauma, stroke, hypothermia, hypoglycemia, carbon dioxide narcosis, and administration of certain drugs that have a CNS depressant effect. The body temperature is subnormal in many cases, but relative hypothermia may also occur, with the patient having an inappropriately normal temperature in the presence of sepsis. Most patients have clinical signs in keeping with long-standing hypothyroidism. Seizures occur in approximately 20 percent of cases; focal neurologic signs are not usually observed unless there has been a concomitant cerebrovascular event.

The pathophysiology is not fully understood but centers on the effects of low intracellular triiodothyronine (T3), particularly on the heart, which leads to decreased inotropism and chronotropism. Laboratory investigations are often abnormal but seldom show diagnostic abnormalities. In critically ill patients, it may be difficult to distinguish between severe hypothyroidism and the sick euthyroid syndrome, and it may be necessary to measure levels of free circulating thyroid hormone. The electrocardiogram typically shows sinus bradycardia, with low voltage and prolongation of the QT interval. Chest radiography may reveal a pleural or pericardial effusion. Hyponatremia may be present, and the serum cholesterol level is sometimes elevated. Serum creatine kinase (CK) and lactate dehydrogenase levels are often raised. Lumbar puncture may reveal an elevated opening pressure, and the cerebrospinal fluid (CSF) protein concentration is often raised. The electroencephalogram (EEG) is commonly abnormal; in keeping with a metabolically induced encephalopathy, the frequency of the posterior dominant rhythm decreases, often into the theta range, and triphasic waves may be present.

The key to the successful treatment of myxedema coma is early recognition and the rapid institution of appropriate therapeutic measures, usually in the intensive care unit (ICU). Hypothyroid coma has a high mortality rate, and treatment should not be delayed for confirmatory laboratory data. Besides the use of intravenous thyroxine, it should include broad-spectrum antibiotics to cover any underlying infection and stress doses of glucocorticoids until specific laboratory results become available. Patients may not mount an appropriate leukocyte response or fever even in the presence of severe infection. The main principles of management also include correction of electrolyte and blood sugar abnormalities, passive rewarming, control of seizures, and respiratory and circulatory support. Different specific treatment regimens are advocated, with some authors preferring thyroxine (T4) monotherapy at a loading dose of 200 to 300 μg intravenously followed by 100 μg intravenously for maintenance. When stable, oral replacement at a dose of 1.6 μg/kg can be used with dose adjustment guided by thyroid-stimulating hormone (TSH) and free T4 levels.[2]

Early recognition and improved ICU care have improved outcomes, but mortality remains at around 20 percent[2]; factors associated with poor outcome include hypotension and bradycardia at presentation, sepsis, reduced Glasgow Coma Scale score, the need for mechanical ventilation, and hypothermia unresponsive to treatment.

Neuropathologic studies of patients with myxedema coma have been few and usually have shown only the presence of cerebral edema with or without diffuse neuronal changes.

There is a relatively high incidence of seizures in hypothyroidism, occurring in up to 20 percent of untreated patients. Drop attacks (sudden repeated falls without warning symptoms and without loss of consciousness) also occur and resolve with therapy. Patients with severe hypothyroidism may present with convulsive or nonconvulsive status epilepticus. Clinicians should be alert to the possibility of underlying hypothyroidism when the recovery time of the patient following a seizure is unusually prolonged.

Mental Changes

Hypothyroidism may be associated with mood disorders, in particular, depression.[3] Treatment of the hypothyroidism usually resolves the affective problem, although the response of individuals to treatment may be modulated by common polymorphisms of thyroid hormone transporters and deiodinases.[3] The colorful term *myxedema madness* has been used to describe the florid mental-state changes that may occur in hypothyroid patients, including irritability, paranoia, hallucinations, delirium, and psychosis. These symptoms are typically reversible but often take longer than physical symptoms to resolve; in some cases a degree of cognitive impairment may persist, particularly if treatment is delayed, perhaps due to irreversible damage secondary to chronic metabolic changes.

An increased incidence of hypothyroidism has been noted in patients with various major psychiatric illnesses. For example, there is an association between hypothyroidism and bipolar affective disorder, particularly in patients with a "rapid cycling" form of the illness, and up to 50 percent of these patients have positive antithyroid antibody titers. Clinical and subclinical hypothyroidism in depression and bipolar disorder may adversely affect or delay the response to treatment. Many patients with depression, even when viewed as chemically euthyroid, have alterations in their thyroid function, including slight elevation of the serum thyroxine, blunting of the TSH response to thyrotropin-releasing hormone stimulation, and detectable titers of antithyroid antibodies. These changes are generally reversed following alleviation of the depression. It has also been recognized that depressed patients with hypothyroidism may manifest different symptoms than patients with low mood and no concurrent hypothyroidism. Generally speaking, hypothyroidism is a reversible cause of cognitive impairment, most commonly manifesting as psychomotor slowing, memory impairment, visuospatial problems, and reduced constructional dexterity.

More subtle neuropsychologic abnormalities have also been documented in hypothyroid patients and may include impairment of learning, word fluency, and some aspects of attention, visual scanning, and motor speed. Treatment of the hypothyroidism may result in some cognitive improvement. Mood and neuropsychologic function may improve more satisfactorily in hypothyroid patients treated with a combination of thyroxine plus triiodothyronine, rather than thyroxine alone.

Disorders of Sleep

Both obstructive and central sleep apnea may occur in patients with hypothyroidism. Obstructive sleep apnea (OSA) appears to be far more common, with estimates that the prevalence is over 50 percent in patients with hypothyroidism, while the prevalence of hypothyroidism in all OSA patients is less than 3 percent. The combination of hypothyroidism and OSA appears to increase the risk of cognitive impairment. Factors contributing to the development of OSA include narrowing of the upper airway due to deposition of mucopolysaccharides and extravasation of protein into the tissues of the tongue and nasopharynx, as well as hypertrophy of the genioglossus. Centrally, there appears to be reduced chemosensitivity to hypercapnia.

Thyroid hormone replacement therapy usually results in improvement in ventilatory drive following normalization of TSH. Improvement in airway dimensions may require a longer period of euthyroidism (up to 12 months), and only at this stage will nocturnal snoring decrease. In some patients, additional measures such as nasal continuous positive airway pressure may be required.

Cerebellar Ataxia

Reference to unsteadiness of gait may be found in the earliest clinical descriptions of hypothyroidism. In a recent review of the literature, it was found that all patients develop significant broad-based gait, and other typical clinical features include, in decreasing frequency, incoordination of the limbs, cerebellar dysarthria, nystagmus, and vertigo.[4] Rapid and complete or almost complete resolution of the cerebellar features usually occurs following achievement of euthyroidism.

The pathophysiologic basis of cerebellar dysfunction in hypothyroidism remains unknown. The rapid resolution of the ataxia with thyroid replacement therapy in most patients suggests a reversible metabolic factor. However there may be an immune-mediated mechanism of cerebellar degeneration in those patients that have been noted to be ataxic despite being euthyroid. For this latter group, immunosuppression may be a therapeutic option. Pathologic reports are few, but depletion of Purkinje cells may occur. Changes on imaging are rare, but MRI may demonstrate atrophy of the vermis and cerebellar hemispheres.[4]

Cranial Nerve Disorders

Primary thyroid failure may be associated with pituitary enlargement resulting from hyperplasia due to lack of negative feedback from circulating thyroid hormones. Pituitary enlargement, as determined on MRI, has been found in 70 percent of patients with primary hypothyroidism, and a reduction in pituitary size following treatment occurs in the majority. Visual evoked potentials may be abnormal in hypothyroid patients, but severe visual field loss and blindness are rare. The association between pituitary gland enlargement and primary hypothyroidism should be kept in mind when pituitary hyperplasia is detected on neuroimaging, so that unnecessary invasive interventions are avoided.

Some patients with hypothyroidism develop pseudotumor cerebri (idiopathic intracranial hypertension) resulting in headache and papilledema following the initiation of thyroxine replacement therapy. An atypical facial pain syndrome may also occur.

Hearing impairment and tinnitus commonly occur in patients with hypothyroidism. Estimations of reduced auditory acuity based on pure-tone audiometry vary, but it is likely that over half of patients suffer hearing impairment that may originate from the cochlea, central auditory pathways, or the retrocochlear region. The hearing loss associated with hypothyroidism is thought to be sensorineural in nature and may improve when the hypothyroidism is treated.

Dysphonia in patients with hypothyroidism appears to arise from local myxedematous changes in the larynx rather than from cranial nerve dysfunction.

Hypothyroid Myopathy

CLINICAL FEATURES

Muscle involvement is common in clinical and subclinical hypothyroidism, with more than 60 percent of patients reported to have an elevated serum CK level.[5] The level of increase correlates with the severity of hypothyroidism and corrects when thyroid function normalizes with treatment. Symptomatic muscle disease is less common. Clinical evidence of hypothyroid myopathy occurs in 30 to 80 percent of patients. A study of clinical and electrophysiologic features prior to commencement of thyroxine therapy revealed that 45 percent of patients with hypothyroidism had decreased or absent deep tendon reflexes, 30 percent had clinical muscle weakness, 15 percent had neuropathy, and 8 percent had evidence of myopathy on electromyography (EMG).[5]

The major clinical features of hypothyroid myopathy include weakness, cramps, aching or painful muscles, sluggish movements and reflexes, and myoedema (mounding of the muscle on direct percussion). There may be a discernible increase in muscle bulk that is most obvious in the tongue, arms, and legs. The degree of weakness is usually relatively mild and tends to involve the pelvic- and shoulder-girdle muscles. The gait tends to be slow and clumsy. Occasionally, patients have been described with more severe myopathic symptoms, including the development of rhabdomyolysis and renal failure or, very rarely, respiratory insufficiency, which may respond to hormone replacement. Muscle pain, particularly during and after exertion, is a prominent feature, and hypothyroidism should be considered in patients presenting with musculoskeletal pains of uncertain cause.

Muscle pain, stiffness, cramps, and delayed relaxation of the tendon reflexes in adult hypothyroidism are sometimes referred to as Hoffmann syndrome.

Kocher–Debré–Sémélaigne syndrome is the unusual association of muscle hypertrophy with childhood hypothyroidism. The patient may have the typical clinical features of CH, with the added feature of generalized muscular hypertrophy so that the child has an athletic, almost Herculean appearance.

A delay in the relaxation of muscle (pseudomyotonia) is commonly observed during assessment of the tendon reflexes in hypothyroid patients. All phases of the tendon reflex are delayed, although slowing of the relaxation phase is most apparent clinically. Pseudomyotonia differs from true myotonia in that there is reduction in the speed of both the contraction and relaxation phases, and this slowness is not increased after rest or relieved by repeated muscle contractions. EMG does not show the characteristic "dive-bomber" effect seen in true myotonia; in the pseudomyotonia of hypothyroidism, there is a continuous burst of action potentials that begins and terminates abruptly, with firing at a constant rate. Percussion of the muscle commonly causes a slow prolonged mounding effect (myoedema). This event, unlike myotonia, is electrically silent and has been attributed to derangement of intracellular calcium homeostasis.

The differential diagnosis of hypothyroid myopathy includes other causes of painful stiff muscles, such as polymyalgia rheumatica and polymyositis. Attention has been directed to the frequency of neuromuscular symptoms in patients with subclinical hypothyroidism, and the suggestion has been made that such patients should be treated early, not only to prevent progression to frank hypothyroidism, but also to improve neuromuscular dysfunction.

INVESTIGATIONS

The majority of patients with hypothyroidism have an elevated serum CK level, even when the myopathic features are not clinically obvious. In symptomatic patients, the serum CK level may rise to more than 10 times the upper limit of normal.[5] Due to the patchy nature of the myopathy, neurophysiologic assessment may show no significant abnormalities. However, up to one-third of patients with hypothyroidism may have "myopathic" short-duration, low-amplitude, polyphasic motor unit potentials on EMG.

PATHOLOGY

In many cases of hypothyroidism, pathologic changes in muscle are subtle and nonspecific. Light microscopy may reveal increased central nuclear counts, type I fiber predominance, or type II fiber atrophy; common abnormalities on electron microscopy include the accumulation of glycogen and lipids, abnormal and increased numbers of mitochondria in perinuclear and subsarcolemmal regions, dilated sarcoplasmic reticulum, and focal myofibrillar degeneration.[5] There may be vacuolation in many large fibers, and crescents of material containing acid mucopolysaccharides may be found beneath the sarcolemmal sheath. Often these changes resolve with thyroxine replacement therapy.

PATHOPHYSIOLOGY

Thyroid hormone is intimately linked to carbohydrate metabolism, mitochondrial function, and possibly to the function of the sarcoplasmic reticulum and intrinsic contractile properties of muscle. However, these structure–function relationships are still incompletely understood, although it is assumed that underlying biochemical changes in hypothyroidism lead to prolongation of the contraction and relaxation phases of muscle activity. Magnetic resonance spectroscopy of hypothyroid muscle shows a low intracellular pH in resting muscle and delayed glycogen breakdown in exercising muscle. In addition, mitochondrial oxidative capacity is reduced in hypothyroidism.[5] Low levels of the mitochondrial transcription factor A (h-mtTFA), a proposed thyroid hormone target, occur in hypothyroid myopathy, and abnormal h-mtTFA turnover may be implicated in mitochondrial alterations in the condition. The decreased responsiveness to adrenergic stimulation and alterations in muscle carbohydrate metabolism may contribute to the impaired ischemic lactate production, weakness, exertional pain, and fatigue occurring in hypothyroidism. Hypothyroidism is associated with changes in myosin, lactate dehydrogenase, and myofibrillar ATPase activity. These changes may underlie the observed slowing of muscle contraction and relaxation. Both protein synthesis and breakdown are reduced in hypothyroidism, resulting in net protein catabolism.

TREATMENT AND PROGNOSIS

The only effective therapy for hypothyroid myopathy is to restore the patient to the euthyroid state. Most patients respond to thyroxine therapy with complete clinical and biochemical recovery; however, some patients require prolonged therapy with thyroxine before they recover from their muscle disorder and some may never regain full function. Serum CK levels correct rapidly with thyroxine replacement therapy. Some patients may develop increased muscle pain and weakness after starting thyroxine replacement, and the short-term addition of corticosteroid therapy may be helpful if this problem arises.

Peripheral Neuropathy

Hypothyroidism may be complicated by the development of entrapment mononeuropathies or a more diffuse peripheral neuropathy.

Entrapment Neuropathy

Evidence of entrapment neuropathy is found in around 35 percent of patients with hypothyroidism. The most common mononeuropathy is carpal tunnel syndrome involving compression of the median nerve at the wrist from deposition of acid mucopolysaccharides in the nerve and surrounding tissues. Surgical decompression for the median nerve entrapment is not usually required in patients with underlying hypothyroidism, as symptoms gradually resolve once euthyroidism is achieved.

Diffuse Peripheral Neuropathy

The peripheral neuropathy of hypothyroidism is usually a relatively mild, predominantly sensory axonal peripheral neuropathy. The symptoms of peripheral neuropathy in patients with hypothyroidism may be masked by more intrusive symptoms. Perhaps for this reason, the reported incidence of peripheral neuropathy has varied widely, ranging from 15 to 60 percent. Damage to small-diameter nerve fibers also occurs, and a minority of patients may have only small-fiber involvement. In patients with a generalized large-fiber neuropathy, the severity appears to correlate with the duration of the disease rather than the degree of the biochemical disorder. Multifocal motor neuropathy, associated with elevated titers of IgM antibodies against GM1 and responsive to intravenous immunoglobulin therapy, has also been associated with Hashimoto thyroiditis.

The pathologic changes described in hypothyroid neuropathy include axonal degeneration, segmental demyelination, and deposition of mucopolysaccharides in the endoneurial interstitium and perineurial sheath. Opinions have varied as to whether axonal degeneration or demyelination is the primary pathologic process, but most reports favor a primary axonal pathology.

Miscellaneous Associated Conditions

Myasthenia Gravis

An association between hypothyroidism and myasthenia gravis has been reported, although this is less common than the association of myasthenia gravis with hyperthyroidism.[6] Myasthenic symptoms can appear before, with, or after the development of hypothyroidism, and the severity of the myasthenia may or may not improve following treatment of the hypothyroidism.

Giant Cell Arteritis and Polymyalgia Rheumatica

An association of giant cell arteritis and polymyalgia rheumatica with hypothyroidism has long been appreciated. Clinicians managing such patients should be careful not to misinterpret the musculoskeletal symptoms of hypothyroidism as an exacerbation of previously diagnosed polymyalgia rheumatica.

Hypothyroidism and Anticonvulsant Therapy

Subclinical hypothyroidism may occur in children with epilepsy treated with valproic acid or carbamazepine therapy. Rare cases of central hypothyroidism believed to be secondary to treatment with oxcarbazepine have been reported. Phenytoin may also impact thyroid function, either by inducing hypothyroidism or by worsening pre-existing hypothyroidism. Hypothyroidism also increases the risk of phenytoin toxicity.

NEUROLOGIC COMPLICATIONS OF HYPERTHYROIDISM AND GRAVES DISEASE

There are several potential underlying causes of hyperthyroidism including: (1) Graves disease; (2) excess release of stored hormone during subacute thyroiditis or following thyroid irradiation; (3) uncontrolled hormone formation in single or multinodular goiters (Plummer disease); (4) ingestion of excess thyroid hormone; (5) rare TSH-secreting pituitary tumors; and (6) drug-induced disease. Graves disease is the commonest cause of thyrotoxicosis and occurs with a female-to-male preponderance of 7:1. The neurologic complications of hyperthyroidism are diverse.

Hyperthyroid Myopathy

CLINICAL FEATURES

Muscle weakness and wasting in patients with thyrotoxicosis were observed in early classic descriptions of the condition. A degree of predominantly proximal muscle weakness probably occurs in almost every patient with hyperthyroidism. The muscle weakness may not always be sufficiently severe for the affected individual to be aware of it. Men appear to develop symptomatic myopathy more commonly than women. The thyroid overactivity can be relatively mild and of long duration, or may be present for only a few weeks before the onset of weakness. Approximately two-thirds of hyperthyroid patients may have neuromuscular complaints at the time of diagnosis of thyroid dysfunction, and marginally fewer have objective muscle weakness. In addition, myalgias and elevated serum CK levels have been reported in hyperthyroid patients after commencement of therapy, suggesting that relative hypothyroidism may also contribute to musculoskeletal complaints in previously hyperthyroid patients.

Individuals with thyrotoxic myopathy characteristically complain of difficulty with activities involving use of the shoulder- and pelvic-girdle muscles, such as climbing stairs, rising from a low chair, or performing tasks that involve raising the arms above the head. Muscle pain and stiffness are commonly associated symptoms, and occasionally patients report severe muscle cramps. Symptomatic weakness of the bulbar musculature resulting in dysphagia and dysarthria is very uncommon in hyperthyroidism and usually follows the development of limb weakness, although there are reports of isolated bulbar dysfunction (sometimes of acute onset) attributed to hyperthyroid myopathy. Bulbar symptoms in hyperthyroid patients may not be due to bulbar myopathy but may have another cause. A large goiter or thymic hyperplasia may physically compress the esophagus, leading to mechanical dysphagia, or compress the recurrent laryngeal nerve, leading to dysphonia. Involvement of the respiratory muscles occurs rarely but may necessitate ventilatory support. Muscle wasting is commonly found on examination of patients and most notably affects proximal girdle muscles such as the deltoid, supraspinatus, and quadriceps muscles. Some patients, especially males, show gluteal muscle wasting, and in some patients winging of the scapula is noticeable. The presence of tremor may create the appearance of muscle fasciculations; these disappear if the limb is relaxed. The tendon reflexes are normal or hyperactive, with shortening of the relaxation phase. Other features of thyrotoxicosis may not be obvious or may be masked, for example, if the patient is on β-blocker therapy.

These neuromuscular features may resemble the progressive muscular atrophy variant of motor neuron disease. The severity of the muscle weakness may be marked, but most patients retain the ability to walk. Acute thyrotoxic myopathy is rare and some have doubted its existence, suggesting that most of the described cases had myasthenia gravis superimposed on the hyperthyroid state. Patients present with muscle weakness progressing rapidly over a few days; weakness may be profound, bulbar muscles are often affected, and the patient may develop respiratory failure. The tendon reflexes may be reduced or absent. Some patients develop an associated encephalopathic state.

In contrast to hypothyroid myopathy, the serum CK level in hyperthyroid myopathy is usually normal or reduced, although rhabdomyolysis and elevation of the serum CK level may occur. EMG abnormalities are found in most patients with thyrotoxicosis and include the typical features of myopathy.

PHYSIOLOGIC AND BIOCHEMICAL CHANGES IN SKELETAL MUSCLE

Skeletal muscle is a major target organ of the thyroid hormones so it is not surprising that the biochemistry, electrophysiology, and even structure of skeletal muscle can be profoundly affected by an excess of thyroid hormone. A detailed examination of this literature is beyond the scope of this review, and more detailed consideration of the subject can be found elsewhere.[7]

Hyperthyroidism affects both the physiologic and the biochemical properties of skeletal muscle with a preferential effect on type I (slow) muscle fibers, shifting their characteristics toward those resembling fast muscle fibers. The speed of muscle contraction is enhanced and its duration is reduced. This effect underlies the clinical observation that the duration of muscle contraction after a deep tendon is struck with a tendon hammer is briefer than normal in the hyperthyroid state and prolonged in the hypothyroid state. The expression of isotypes of the myosin heavy chain is altered in hyperthyroidism to favor expression of MHC type IIx associated with fast-fiber characteristics, with this isoform replacing MHC type I associated with slow-fiber characteristics. These changes reverse on treatment.

The pattern of glycogen utilization and lactate production in muscle is also altered in hyperthyroidism, resulting in increased energy requirements for normal function. Thyrotoxic patients have higher concentrations of phosphocreatine at rest, and a larger magnitude of glycolysis activation during exercise, resulting in a marked decrease in pH. Additionally, in hyperthyroidism the mitochondrial transport chain is uncoupled, which promotes thermogenesis rather than energy production.

PATHOLOGY

There is no pathognomonic pathologic finding in hyperthyroid myopathy. Biopsy may be needed on occasion to exclude other pathologic processes. Microscopic examination may show no abnormality or varying degrees of fiber atrophy, fatty infiltration, and nerve terminal damage, with clubbing of the motor end-plate and swelling of terminal axons. Most patients show an increase in mitochondrial size and number in muscle fibers.

TREATMENT AND PROGNOSIS

Computed tomography (CT) and isometric strength tests suggest that muscle mass of thyrotoxic patients is reduced by approximately 20 percent and muscle strength by about 40 percent. Normal muscle mass and power can be expected to be restored 3 to 9 months following treatment. Dysphagia and dysarthria due to hyperthyroid myopathy also typically resolve after treatment.

Periodic Paralysis

Hypokalemic periodic paralysis as a complication of hyperthyroidism is relatively common in Asian populations, with a reported incidence of about 1.9 percent in those with thyrotoxicosis.[8] The disorder is rare in other ethnic groups, but the effects of globalization on population mobility mean that it is now seen more often in other parts of the world. Periodic paralysis may occur in association with hyperthyroidism of any cause, but is most commonly seen in patients with Graves disease.

CLINICAL FEATURES

Except for concomitant features of thyrotoxicosis, the clinical picture of thyrotoxic periodic paralysis (TPP) is identical to that seen in familial hypokalemic periodic paralysis (FHPP). Males are affected much more commonly than females. Affected individuals develop recurrent attacks of flaccid weakness, which may be asymmetric and affect the lower more than the upper limbs, and the proximal more than the distal muscles. The attacks may be heralded by prodromal symptoms of muscle aching, stiffness, or cramps. The weakness usually develops rapidly and varies in severity from mild weakness to total paralysis. The muscles most vigorously used before an attack tend to be most severely affected. Bulbar, ocular, and respiratory muscles tend to be spared, although there have been occasional reports of respiratory compromise. Cardiac dysrhythmias occasionally accompany the paralytic attacks. Usually, the tendon reflexes are depressed or absent during an attack, but in some patients they remain normal. Weakness usually resolves within 24 hours, but in the wake of severe attacks weakness and muscle pain may persist for several days. Patients may be able to abort impending attacks by mild exercise.

Attacks may occur with or without a triggering factor. Recognized precipitants include high carbohydrate intake, strenuous physical activity followed by a period of rest, trauma, cold exposure, infection, menses, and drugs, including amiodarone and corticosteroids.[8] A seasonal pattern of attacks has been recognized, with episodes being more common in the summer months. There is also a characteristic diurnal pattern, with attacks frequently developing during the night while patients are in bed.

The cardinal biochemical abnormality during an attack of TPP is hypokalemia resulting from an intracellular shift in potassium. Although serum potassium decreases during the attack, it may not always decline below the normal range. Urinary excretion of potassium is reduced with a low potassium–creatinine ratio. The neuromuscular symptoms resolve over a period of hours as potassium moves back to the extracellular space.

Between attacks, a long exercise test may prove a useful diagnostic aid. In this test, a pre-exercise compound muscle action potential (CMAP) is recorded from a selected muscle. The patient then performs maximal voluntary muscle contractions for 5 minutes, with relaxation for 3 to 4 seconds every 15 seconds or so to avoid muscle ischemia. The CMAP is then recorded every 2 minutes until the amplitude of the elicited potential stabilizes. The test is interpreted as positive if the decrement exceeds 40 percent.

The most consistent ultrastructural finding in muscles from patients with thyrotoxic periodic paralysis is a proliferation and focal dilatation of the sarcoplasmic reticulum and transverse tubular system, resulting in the appearance of vacuoles. These vacuoles are characteristically seen in paralyzed muscles and are less apparent between attacks.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Attacks of weakness in TPP are clinically similar to those of FHPP, a channelopathy caused by inherited defects to genes encoding sodium and calcium channels in skeletal muscle. This phenotypic similarity led investigators to postulate that TPP might also be a channelopathy, albeit one that manifests only in the presence of excess thyroid hormone. It is thought that TPP patients have a genetic predisposition to the disease unmasked by independently occurring hyperthyroidism.

Gene sequencing in cohorts of largely Asian TPP patients has revealed no mutations in FHPP-causing genes or in the components of the sodium–potassium ATPase (Na^+,K^+-ATPase) pump. However, six different mutations to an inwardly rectifying potassium channel, Kir2.6, expressed strongly in skeletal muscle, were found in 33 percent of an unrelated cohort of TPP patients from the United States, Brazil, and France, as well as 25 percent of a Singaporean cohort, but none of 31 patients from Thailand.[9] The mutations discovered all have effects upon the stability of the muscle cell membrane, altering its excitability. The gene for Kir2.6 is transcriptionally regulated by thyroid hormone, and levels of the channel are increased in hyperthyroidism, explaining why it is only in this circumstance that the mutation becomes manifest. A susceptibility locus has been identified near the gene for Kir2.1, which is also highly expressed in skeletal muscle and can associate with other K^+ channels, including Kir2.6. Incorporation of Kir2.6 into the channel heterotetramer reduces the abundance of Kir2-type channels on the plasma membrane with consequences for membrane excitability.

Mutations in potassium channels appear to combine with other factors to produce the clinical phenotype. Thyroid hormones increase the activity of the Na^+,K^+-ATPase, which drives K^+ into cells; catecholamines have a similar effect. The Na^+,K^+-ATPase pump is also stimulated by insulin, hence attacks may be precipitated by carbohydrate-rich meals and exercise. In addition, testosterone appears to drive the Na^+,K^+-ATPase pump, while estrogen and progesterone reduce activity, perhaps explaining the male preponderance. Interestingly, men with TPP have higher levels of testosterone than men with a sole diagnosis of thyrotoxicosis. These effects on the Na^+,K^+-ATPase pump sum together to increase the intracellular K^+ concentration and as the efflux usually permitted by outwardly rectifying K^+ channels is reduced, a paradoxical depolarization occurs inactivating Na^+ channels. As a result, the hypokalemia seen in attacks of weakness in TPP is not due to loss of potassium, but rather to the shift of extracellular potassium into cells driven by the Na^+,K^+-ATPase pump, which has direct implications for treatment.

TREATMENT

First, emergency treatments of the attack of weakness, hypokalemia, and any complications are required. TPP patients presenting with severe weakness are treated with potassium chloride to speed recovery. Urgent assessment of cardiac and respiratory involvement must be carried out and appropriate supportive management and monitoring instituted, pending recovery. Potassium chloride may be administered orally or intravenously until weakness resolves. Mid-attack, TPP patients do not have a potassium deficit but rather an intracellular shift of their potassium. There is therefore a risk of rebound hyperkalemia on recovery as the potassium shift reverses. While patients recover twice as quickly with potassium treatment, up to 70 percent may experience rebound hyperkalemia. In practice this is rarely of clinical importance, but most authorities recommend giving lower doses of potassium (<50 mEq total). Potassium chloride does not always abort an attack of weakness in TPP. In cases of refractory weakness, propranolol administered intravenously or orally may be effective.

Patients should also be educated about TPP and its precipitants in order to prevent further attacks. They should avoid food and drink with high salt or carbohydrate content as well as alcohol. Formal exercise is best halted until the patient is euthyroid. Propranolol (40 mg daily) reduces the likelihood of further attacks until the euthyroid state is regained. Finally, definitive treatment of the hyperthyroidism and return of the patient to the euthyroid state stop further attacks of weakness altogether although, depending upon the underlying cause, it may take months for the euthyroid state to be achieved.

Myasthenia Gravis

A long-recognized association exists between thyroid disease and myasthenia gravis. There is no evidence that thyroid dysfunction causes myasthenia gravis, and the co-existence of the two conditions probably reflects an underlying predisposition to autoimmune disease.

A meta-analysis of nearly 25,000 patients with myasthenia gravis demonstrated that approximately 10 percent had thyroid autoantibodies, compared to 1 to 5 percent of the general population.[6]

Hyperthyroidism is diagnosed before or concurrent with the onset of myasthenia in roughly three-quarters of patients. In general, there are few unusual characteristics of either condition in terms of clinical features or management when the two occur in the same patient. The clinical expression may be mild, the likelihood of detectable acetylcholine receptor antibodies is reduced, and interestingly, patients who are hyperthyroid are more likely to have pure ocular myasthenia.

While control of the myasthenia may deteriorate with departure from the euthyroid state, treatment of the thyroid disorder does not have a predictable effect on the myasthenia. Dramatic increases in the severity of myasthenia have been reported following treatment of the thyroid disease, but this is uncommon. In some patients, an improvement in myasthenic weakness occurs after treatment of hyperthyroidism.

Peripheral Neuropathy

Peripheral neuropathy is rarely associated with hyperthyroidism, in contrast to its relatively common association with hypothyroidism. As a result, the pathophysiologic basis of any peripheral nerve dysfunction in hyperthyroidism is unclear, although a severe subacute motor axonal neuropathy induced by T3 hyperthyroidism and reversible on control of the hyperthyroid state has been described.

Mononeuropathies associated with hyperthyroidism are also relatively rare. Up to 5 percent of patients may have clinical and neurophysiologic features of carpal tunnel syndrome, the symptoms of which often resolve once control of the thyroid disease is achieved.

A rare acute thyrotoxic peripheral neuropathy resembling Guillain–Barré syndrome and causing paraplegia was first described by Charcot and termed Basedow paraplegia by Joffroy. The syndrome is acute in onset and presents as a flaccid, areflexic paraplegia with upper limbs much less affected than the lower limbs. There is sensory involvement in some cases and sphincter function is typically preserved. Electrophysiologic examination reveals a mixed sensorimotor peripheral neuropathy with demyelinating and axonal features; ultrastructural analysis in one case with sural nerve biopsy demonstrated axonal loss and myelin damage. Treatment usually results in a full recovery.

Corticospinal Tract Dysfunction

Signs of corticospinal tract dysfunction may be associated with thyrotoxicosis. Clinical features include spasticity and weakness, particularly affecting the lower limbs, as well as hyperreflexia, clonus at the ankles and knees, and extensor plantar responses. Occasionally, patients with upper motor neuron signs in the limbs also have had sensory abnormalities, including impaired vibration sensation and proprioception, upper motor neuron bladder disturbance, and urinary incontinence. A clinical picture similar to that of motor neuron disease has also been noted in patients with untreated hyperthyroidism. Treatment of the hyperthyroid state usually results in complete or near-complete recovery of the upper motor neuron signs.

A neurophysiologic correlate of these observations can be seen using transcranial magnetic stimulation of the motor cortex. Further histopathologic and neurochemical studies are required to define the pathophysiologic basis of corticospinal tract dysfunction in thyrotoxicosis.

Movement Disorders

CHOREA

Chorea is an unusual complication of hyperthyroidism and its association with the condition is not universally accepted. Some authors suggest that it is simply an exaggeration of the fidgetiness seen in thyrotoxicosis, whereas others believe that hyperthyroidism unmasks pre-existing and subclinical basal ganglia dysfunction. The problem appears to be more common in women, and the underlying cause of the hyperthyroidism is most commonly Graves disease. Choreiform movements typically involve the limbs, with the face, neck, or tongue affected in some cases. Less commonly, hemichorea and bilateral ballismus have been associated with thyrotoxicosis. The chorea usually resolves once hyperthyroidism has been controlled, but it can persist long after euthyroidism has been achieved.

The pathophysiologic basis of hyperthyroid chorea is unknown. Given that most cases occur in autoimmune hyperthyroidism, many have assumed that the associated chorea also has an autoimmune basis. It has been suggested that chorea may be mediated by the sympathetic nervous system because β-blockers may help to control symptoms. A disruption of striatal dopamine receptors may have some role and dopamine receptor antagonists, such as haloperidol, have been effective in the treatment of hyperthyroid chorea. Cases in which chorea develops when a patient is hyperthyroid, resolves on treatment, and then recurs when the patient once more becomes hyperthyroid due to, for instance, poor compliance, lend support to the idea that the chorea is a direct effect of high levels of thyroid hormone on the function of the basal ganglia.

TREMOR

Tremor is almost invariably seen in hyperthyroidism, so it is best considered a feature of the hyperthyroid state rather than a neurologic complication. The tremor seen in thyrotoxicosis can be considered an exaggerated physiologic tremor. It is postural, persists on movement (but is not present at rest), and has a frequency of 8 to 12 Hz. The tremor most commonly affects the outstretched hands and the tongue, but the lips and facial muscles may also be affected. Therapy with β-blockers provides relief, suggesting that increased β-adrenergic activity is likely to be responsible.

OTHER MOVEMENT DISORDERS

Other movement disorders that have been described in patients with hyperthyroidism include platysmal myoclonus and paroxysmal kinesogenic dyskinesia.

Thyroid-Associated Ophthalmopathy

Graves disease is an autoimmune condition in which antibodies to thyrotropin receptors are generated and bind to their antigen on follicular cells in the thyroid gland, inducing them to produce and release excess thyroid hormone, which causes hyperthyroidism. It is associated with two main extrathyroid complications: thyroid dermopathy (also known as pretibial myxedema) and thyroid-associated ophthalmopathy. Thyroid-associated ophthalmopathy, sometimes called Graves ophthalmopathy, is a potentially disfiguring and sight-threatening complication most commonly occurring in patients with hyperthyroidism due to Graves disease, or who have a past history of hyperthyroid Graves disease. While present in around 50 percent of patients, only 3 to 5 percent of those with Graves disease have severe, sight-threatening ophthalmopathy requiring aggressive therapeutic intervention. Graves ophthalmopathy is generally managed by ophthalmologists. Patients do, however, present to neurologists with complaints of visual loss or diplopia, and a summary focusing on these neurologic presentations and diagnosis therefore follows. More detailed descriptions can be found elsewhere.[10]

CLINICAL FEATURES

Symptoms and signs of Graves ophthalmopathy are usually bilateral and begin within 18 months of the onset of Graves hyperthyroidism. Ophthalmopathy in Graves disease may uncommonly appear to be unilateral (5 to 14%), although in these cases orbital imaging usually identifies subclinical involvement of the clinically unaffected eye. The onset of ophthalmopathy may precede the development of hyperthyroidism and may also develop some years after Graves disease has been diagnosed and treated. Whether Graves ophthalmopathy may be induced or existing eye disease worsened by radioiodine treatment for hyperthyroidism remains contentious. Smoking is clearly an independent and modifiable risk factor, and the more cigarettes smoked, the greater is the risk. The group at most risk appears to be patients treated with radioiodine who also smoke.

The majority of ocular symptoms and signs in Graves ophthalmopathy are the result of an increase in the amount of cushioning fat within the orbit and an enlargement of the extraocular muscles. Patients complain of a sensation of grittiness in the eyes, photophobia, and pressure or pain behind the eyes. The commonest features of Graves ophthalmopathy are periorbital and conjunctival edema and erythema (secondary to compression of orbital veins and resultant venous stasis), retraction of the upper eyelid (due to overactive sympathetic activity), and proptosis due to the increased volume of orbital contents (Fig. 18-1). If proptosis is severe, ptosis may occur. Proptosis is defined as measured exophthalmos greater than 2 mm above the upper normal limit. It is found in approximately 20 to 30 percent of patients with Graves disease. Proptosis serves to decompress the orbit—visual loss due to compressive optic neuropathy occurs more often in those with little or no compensatory proptosis. Apart from any cosmetic problems associated with proptosis, failure of the eyelids to close completely may result in sight-threatening exposure keratopathy.

Extraocular muscle involvement leading to ophthalmoparesis is clinically apparent in 10 to 15 percent of patients with Graves hyperthyroidism. Orbital imaging demonstrates enlargement of the extraocular muscles in 60 to 98 percent of these patients (Fig. 18-2). Patients may complain of blurred vision with binocular gaze, diplopia that may be continuous or intermittent, or a pulling sensation on attempted upgaze. For reasons that are not understood, there is preferential involvement of the inferior and medial rectus muscles.

Optic nerve compression occurs in fewer than 5 percent of patients with Graves disease. It results from apical crowding of the orbit due to enlargement of the extraocular muscles and excess orbital connective tissue. Early recognition is important to prevent loss of vision, and since there may not always be accompanying proptosis and orbital inflammation, careful examination for optic disc swelling and impaired color vision is paramount, together with radiologic assessment for optic nerve compression.

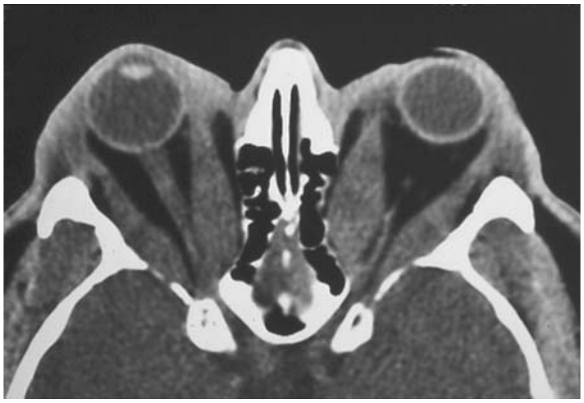

FIGURE 18-2 ■ Axial computed tomographic scan of the patient in Fig. 18-1, showing massive enlargement of the horizontal rectus muscles and soft-tissue edema in each orbit, causing compression of the optic nerves. (Courtesy of Jonathan Horton, MD, PhD.)

DIAGNOSTIC TOOLS

Diagnosis is largely based on clinical features, with orbital imaging used to confirm the diagnosis and exclude other entities, especially in apparently unilateral cases. As levels of antithyrotropin antibody correlate with disease severity, these should be measured and thyroid function tests performed. In patients with Graves orbitopathy, MRI is the imaging modality of choice and can reveal disease activity with interstitial edema within the extraocular muscles. The presence of such observations, rather than the fibrotic changes associated with end-stage disease, may direct treatments toward immunomodulatory therapies. MRI may also be used to assess response to such interventions. By contrast, CT is suited to the assessment of bony periorbital structures and is thus the technique of choice for planning of CT-guided orbital decompression surgery. Amplitude reduction on pattern electroretinogram may be a sensitive measure for demonstrating early impairment of optic nerve function, as may measurements of visual evoked potentials.

PATHOGENESIS

Although significant progress has been made in understanding the pathogenesis of Graves ophthalmopathy, there remain a number of contentious issues and unanswered questions.[10] Environmental, immune, and genetic factors are all likely to play a role. It is widely accepted that antithyrotropin antibodies are pathogenic in Graves ophthalmopathy and that their target within the eye is orbital fibroblasts, which express the thyrotropin receptor to a greater extent than do orbital fibroblasts in unaffected subjects. Interaction of these pathogenic antibodies with thyrotropin receptors triggers an inflammatory cascade within the orbit, resulting in the expansion of orbital adipose tissue. Antithyrotropin antibodies are not the only pathogenic antibodies in Graves ophthalmopathy. The best supported of several additional candidates are antibodies to insulin-like growth factor-1. It seems likely that many of the other antibodies detected in Graves ophthalmopathy will turn out to be secondary markers of the orbital immune-mediated reaction rather than pathogenic effectors.

TREATMENT

A consensus statement on the management of thyroid-associated ophthalmopathy was released in 2008 and has been addressed in review articles.[10] In summary, there is currently no recommended preventive therapy and the condition is usually only treated when symptoms are severe or vision is threatened. In ophthalmopathy where there is evidence of active inflammation, corticosteroids and orbital radiotherapy may be used. Sight-threatening keratopathy due to proptosis and optic neuropathy due to apical crowding are treated surgically with orbital decompression. Some authorities use a 3-month course of corticosteroids starting immediately after radioiodine treatment in order to prevent development or exacerbation of Graves ophthalmopathy. Treatment of dysthyroid strabismus is surgical once Graves disease has burnt out and the ophthalmoparesis is stable. Prism glasses are an alternative in those preferring not to undergo surgery. During the active phase of the disease, botulinum toxin may also be used to improve strabismus. A number of immunomodulatory therapies have been suggested for use in Graves ophthalmopathy.[10]

Encephalopathy

Florid thyrotoxic encephalopathy, sometimes referred to as "thyroid storm," is seen less often now that active monitoring and treatment of hyperthyroidism is undertaken. Its clinical features and treatment are well described.[11] Thyroid storm is thought to make up 1 to 2 percent of thyroid-related admissions to hospital. Precipitating factors include radioactive iodine therapy, surgery (either thyroid or nonthyroid), trauma, pregnancy, and intercurrent illness. While there is no consensus definition of what constitutes thyroid storm, four groups of symptoms dominate the clinical picture—fever, tachycardia, CNS dysfunction, and gastrointestinal symptoms. Fever is high and associated with profound sweating. Patients may develop supraventricular tachyarrythmias including atrial fibrillation with consequent cardiac failure or embolic stroke. Diarrhea and vomiting are common, and patients may have jaundice. Biochemically, thyroid storm may be indistinguishable from uncomplicated thyrotoxicosis, making its diagnosis a clinical one. CNS symptoms may be prominent. Affected individuals are commonly confused or agitated and may present with frank psychosis. The patient's level of consciousness may deteriorate, with the development of coma sometimes associated with seizures and status epilepticus, bulbar weakness, and corticospinal tract signs.

The mortality of thyroid storm remains over 10 percent, so patients should be managed in an ICU.[11] Successful treatment depends on early recognition and aggressive intervention. Treatment is aimed at: (1) reducing production and secretion of thyroid hormones by the thyroid gland, for which antithyroid medication and sometimes iodine are used; (2) reducing the effects of the excess thyroid hormone on target organs in the periphery using β-blockade; (3) reversing systemic problems such as fever and cardiovascular compromise; and (4) treating any precipitating factor such as systemic infection. Administration of corticosteroids is suggested in recognition of adrenal axis dysfunction. Plasmapheresis has been employed occasionally to reduce levels of thyroid hormone.

Seizures

Seizures are a relatively frequent complication of metabolic encephalopathy in general, but are not commonly seen as a complication of thyrotoxicosis. A retrospective analysis of over 3,000 patients diagnosed with hyperthyroidism revealed that only 0.2 percent experienced seizures not attributable to other causes.[12] In these instances, generalized tonic-clonic events were most common. The cause of the hyperthyroidism appears not to be important, with seizures happening even in the context of hypothyroidism overtreated with thyroxine. The etiology of thyrotoxic seizures is unknown.

A range of nonspecific EEG abnormalities may be seen in patients with hyperthyroidism, including generalized slow activity and an excess of fast activity.[12] EEG changes usually improve when the thyrotoxic state is controlled.

Mental and Psychiatric Disorders

Minor mental disturbances are almost uniformly found in patients presenting with untreated hyperthyroidism. Complaints of insomnia and impairment of concentration and attention are common. Patients' acquaintances frequently describe irritability, emotional lability, and capricious behavior. Agitated delirium, presenting with confusion, restlessness, hyperkinesia, and an apathetic state with lethargy and depression may occur in thyrotoxic patients; this often resolves with successful treatment of the hyperthyroidism. Both psychosis and affective disorders have been described, and there is a significant overlap between symptoms of hyperthyroidism and that of depression-anxiety. It is important to be alert to the possible psychiatric manifestations of thyroid dysfunction and to reassess patients once they become euthyroid.

Stroke

The association between thyroid disease and stroke has been thoroughly reviewed elsewhere.[13] Atrial fibrillation may develop in 10 to 15 percent of patients with hyperthyroidism and it has been suggested that 10 to 40 percent of patients with thyrotoxic atrial fibrillation have embolic events, the majority of which are cerebral. Whether thyrotoxic patients in atrial fibrillation have a higher embolic risk than euthyroid patients with chronic atrial fibrillation is uncertain. Prognostically, a meta-analysis of observational studies concluded that following an ischemic stroke subclinical hypothyroidism was associated with a better outcome, and low T3 and free T3 (fT3) levels were correlated with a worse outcome. Conversely, elevated T3 and fT3 values were associated with a better outcome, while elevated T4 was associated with a poor prognosis. Thyroid hormone is thought to have both a neurotoxic and neuroprotective effect which may explain the complex relationship described.[13]

Evidence for associations between hyperthyroidism and rarer causes of stroke is sparse. There is a possible link between moyamoya syndrome and hyperthyroidism, secondary to an increased level of thyroid antibodies.

Hashimoto Encephalopathy

Hashimoto encephalopathy (HE) is a relatively rare condition arising as a complication of Hashimoto thyroiditis. In Hashimoto thyroiditis, an antibody-mediated attack on the thyroid gland eventually brings about hypothyroidism although there may be an initial, transient hyperthyroidism and a period of intervening euthyroidism. HE typically occurs in patients with Hashimoto thyroiditis who are hypothyroid or euthyroid but it can, less often, occur in hyperthyroid patients. For this reason, HE is not believed to be a consequence of the patient's thyroid status. Numerous case studies of HE exist, as well as a few small case series.[14] The rarity of the disorder and the absence of consensus diagnostic criteria mean that qualifying clinical features and even the existence of HE as an entity are ongoing subjects of debate.

CLINICAL FEATURES

Clinical features of HE include relapsing episodes of encephalopathy, seizures, and sometimes superimposed stroke-like neurologic deficits. The encephalopathy ranges from confusion to coma with an acute or subacute onset, but it may also present insidiously as gradual cognitive decline. In adults it may be confused with dementia, and in children it can manifest as a falling-off of school performance. Seizures in HE may be focal or generalized, and status epilepticus can occur. Patients have high levels of antithyroid antibodies and the episodes are responsive to treatment with corticosteroids.

Patients with HE are usually euthyroid but may be hypothyroid. Patients may have encephalopathy with antithyroid antibodies, an abnormal EEG, and hyperthyroidism and, if so, are termed thyrotoxic Hashimoto thyroiditis. Women are affected by HE more than men, and while the typical age of onset is around 40 years, it can occur in children. The encephalopathy is generally accepted as essential for a diagnosis of HE to be contemplated but there is less agreement about associated features. Cases of HE featuring aphasia, ataxia, myoclonus, tremor, headache, psychosis, and visual hallucinations have all been reported.

PATHOPHYSIOLOGY

The presence of antithyroid antibodies is a prerequisite for the diagnosis of HE, but it remains unclear whether these antibodies are pathogenic effectors or simply proxy markers of the disease. The fact that antithyroid antibodies are associated with diverse and unrelated conditions and are found in a proportion of the healthy population argues against a direct role. Few reports have found HE-specific CNS epitopes to which antithyroid antibodies bind. Antithyroid peroxidase antibodies have been found to bind to cerebellar astrocytes in HE but not Hashimoto thyroiditis, although the significance of this finding is unclear. The presence of lymphocytic infiltration of CNS vessels implies that the disorder invokes a vasculitic process, but the largely favorable outcome of this rare condition means that few cases come to autopsy when the condition is active.

DIAGNOSIS

Differential Diagnosis

The lack of clear diagnostic criteria and the variety of neurologic symptoms and signs reported in addition to encephalopathy mean that HE should be considered in the differential diagnosis of all cases of encephalopathy in which an alternative explanation is not quickly evident. Although HE is rare, it is treatable. Thyroid antibodies therefore should be checked as part of the standard laboratory evaluation of encephalopathy. In a series of 20 patients with a final diagnosis of HE, all were initially given another diagnosis including dementia, encephalitis, stroke, Creutzfeldt–Jakob disease, and migraine.[14]

Antithyroid Antibodies

Antibodies directed against thyroid antigens are a defining feature of HE. Despite this, there is little consensus about which antithyroid antibodies are associated with HE and whether they have a role in pathogenesis. Antithyroid peroxidase (anti-TPO) antibodies are elevated in almost all cases of HE. They are also raised in other nonthyroid autoimmune disorders and in some healthy controls. Antibodies against thyroglobulin (anti-TG) are often found in cases of HE but less commonly than are anti-TPO antibodies. Anti-TG antibodies are also found in a proportion of healthy subjects without thyroid disease. Anti-α-enolase antibodies have also been found in the serum of some patients with HE.

Cerebrospinal Fluid

The most common finding in HE is a raised protein concentration, although a mild pleocytosis and oligoclonal bands (not present in serum) or an elevated IgG index are also common.

Imaging

Although CT of the brain is typically normal, MRI in HE has shown diffuse white matter abnormalities in up to half of patients, and these may resolve with treatment. A variety of other abnormalities have been reported in individual cases, but no HE-defining abnormality has been identified and some patients may have normal imaging.[14] The few reports of single photon emission CT in HE document focal hypoperfusion, generalized hypoperfusion, or no abnormalities at all. Cerebral angiography is generally normal, showing no evidence of large-vessel vasculopathy.

Electroencephalography

Most patients have an abnormal EEG. Generalized slowing is the commonest abnormality, but triphasic waves and periodic complexes have also been reported. No HE-specific EEG features have been identified.

TREATMENT

There is reasonable evidence that the vast majority of episodes of HE respond to treatment with corticosteroids, while only two-thirds of patients respond if treated solely with levothyroxine. Plasmapheresis can also be effective, including in cases resistant to corticosteroids. Treated, the prognosis of HE is generally good. It is therefore sensible to consider a trial of corticosteroids in an encephalopathic patient with antithyroid antibodies and no other obvious underlying cause, once CNS infection has been excluded.

MISCELLANEOUS ASSOCIATIONS BETWEEN NEUROLOGIC DISORDERS AND THYROID DYSFUNCTION

Endocrine Dysfunction in Long-Term Survivors of Primary Brain Tumors

Endocrine dysfunction, including hypothyroidism, is a frequent and often overlooked long-term complication of radiotherapy for primary brain tumors, with a significant impact on the well-being of patients. One-quarter of patients may develop hypothalamic hypothyroidism. Hypothalamic hypogonadism in males and hyperprolactinemia and oligomenorrhea in female patients are also recognized. Endocrine function should therefore be evaluated periodically in long-term survivors of primary brain tumors treated with radiotherapy.

Multiple Sclerosis and Thyroid Disease

Thyroid disease has been found to be at least three times more common in women with multiple sclerosis, and this is largely a hypothyroid burden. Recent reports have also documented thyroid-related complications in patients treated with alemtuzumab, which alters the immune response from the Th1 phenotype, suppressing disease activity in multiple sclerosis but permitting the generation of antibody-mediated thyroid disease.[15]

Recurrent Laryngeal Nerve Palsy

Both malignant disease of the thyroid gland and thyroidectomy may be associated with hoarseness and other bulbar symptoms due to damage to the recurrent laryngeal nerve. Invasion of the recurrent laryngeal nerve by thyroid carcinoma can be accurately predicted by the finding of effaced fatty tissue on MR imaging.

Both type 1 and type 2 diabetes mellitus commonly target the nervous system. In the peripheral nervous system, complications include polyneuropathies and focal neuropathies. In the central nervous system (CNS), diabetes may be associated with cognitive decline, leukoencephalopathy, and heightened risk of both stroke and dementia. Acute changes in blood glucose levels are also associated with neurologic signs and symptoms. This chapter summarizes the acute and chronic neurologic complications of diabetes mellitus. For a detailed discussion of diabetes and the nervous system, with relevant reference citations, readers are also referred to a recent monograph on the topic.[1]

NEUROLOGIC FEATURES OF HYPERGLYCEMIA AND HYPOGLYCEMIA

Diabetic Ketoacidosis

Diabetic ketoacidosis in patients with type 1 diabetes is a medical emergency that may present with neurologic signs and symptoms.[2] Anorexia, lethargy, thirst, polyuria, vague abdominal pain, and Kussmaul respiration are followed by confusion and a decreased level of consciousness. Rarely, diabetic ketoacidosis accompanies a primary CNS infection, such as bacterial meningitis. Cerebral edema complicates diabetic ketoacidosis and may present with headache, papilledema, and bilateral abducens neuropathies. It may develop on presentation or during correction of the metabolic disorder. Secondary complications include cerebral infarction, cerebral venous sinus thrombosis, and compression neuropathies.

Nonketotic Hyperosmolar Syndrome

Neurologic symptoms and signs may also reflect a nonketotic hyperosmolar syndrome, defined as a blood glucose level exceeding 33 mmol/L (600 mg/dL) and a plasma osmolarity greater than 320 mOsm/L, without accompanying acidosis or ketonemia. Polyuria, polydipsia, thirst, fatigue, and overall weakness are

Aminoff's Neurology and General Medicine, Sixth Edition.

general symptoms; neurologic signs include decreased level of consciousness, hemiplegia, aphasia, brainstem abnormalities, dystonia, chorea, and seizures. The seizures are often focal and can include tonic, movement-induced, or continuous forms (e.g., epilepsia partialis continua). Unusual neurologic features are visual symptoms, hallucinations, hemichorea, tonic eye deviation, nystagmus, abnormal pupils, and meningeal signs. The correction of hyperglycemia may be more effective than using antiepileptic agents to treat the seizures.

Hypoglycemia

Hypoglycemia most often presents with altered neurologic function.[2] In diabetic subjects, hypoglycemia is common in the setting of insulin use. A high index of suspicion is required as patients may present with focal neurologic signs or seizures. Hypoglycemia is defined as a plasma glucose concentration less than 2.7 mmol/L (50 mg/dL), a level associated with a decline in cognitive function. Premoni-tory systemic symptoms include anxiety, tachycardia, perspiration, nausea, and tremor, but these signs may be absent in patients taking β-adrenergic-blocking medications or in patients with autonomic neuropathy. Early neurologic symptoms are decreased attention and concentration, drowsiness, poor memory, disorientation, behavioral changes, clumsiness, and tremor. Patients may progress to experience seizures and loss of consciousness. Seizures may be focal or generalized and may lead to status epilepticus. Rapid detection through expectant testing and early treatment are essential. Severe untreated hypoglycemia is associated with diffuse cortical, basal ganglia and dentate gyrus damage, leading to permanent disability.

PERIPHERAL NEUROPATHIES

Diabetes mellitus targets the peripheral nervous system in several ways. Polyneuropathy is a chronic, symmetric disorder that targets the distal terminals of axons first. Focal or localized neuropathies of a single plexus or nerve, also known as mononeuropathies, are also common and develop from mechanical compression, ischemia, or other, less well-defined causes. Autonomic neuropathy is the other major category of peripheral nervous system dysfunction in these patients.

Diabetic Polyneuropathy

Diabetic polyneuropathy is the most common form of peripheral neuropathy.[3,4] With detailed evaluation, approximately 50 percent of both type 1 and type 2 diabetic subjects have evidence of polyneuropathy. Symptomatic polyneuropathy may occur in a smaller proportion, estimated as approximately 15 percent of these patients.[5] Lower prevalence numbers have been derived from studies of hospitalized patients or utilizing exclusively clinical signs of polyneuropathy. Polyneuropathy is most often sensory, or sensorimotor but with lesser motor involvement. Positive sensory symptoms are common and include prickling, tingling, "pins and needles," burning, crawling, itching, electric, sharp, jabbing, and tight sensations in the legs, feet, hands, and fingers. Warm stimuli may be inappropriately perceived as cold, and cold stimuli as warm or hot. Nocturnal burning of the feet accompanies allodynia (the generation of pain or discomfort from normally innocuous stimuli). Many of these symptoms are associated with pain, sometimes severe or intractable, as discussed later.

Symptoms are generally symmetric and initially confined to the toes, with later spread to more proximal parts of the feet and legs and to the fingers (Fig. 19-1). Negative symptoms include loss of sensation to light touch, pinprick, and hot and cold. In more severe diabetic polyneuropathy, loss of protective sensation predisposes patients to the development of foot ulcers. Additional factors that promote foot ulceration include loss of sweating, abnormal foot architecture from muscle wasting, delayed healing, and both macrovascular (atherosclerosis) and microvascular disease.

There is a stocking-and-glove pattern of sensory symptoms and loss. Motor involvement is less common in early diabetic polyneuropathy but may eventually lead to distal weakness of foot and toe dorsiflexion, predisposing patients to falls. Weakness accompanies wasting of intrinsic foot muscles. Symptoms from concurrent abnormalities of the autonomic nervous system are common. They include erectile dysfunction (ED) in men, distal loss of sweating, orthostatic dizziness, and bowel and bladder dysfunction.

A detailed neurologic examination provides a low-cost, patient-interactive means of direct evaluation. While some variation in findings, especially in patients with early disease, is expected, the examination remains the gold standard for

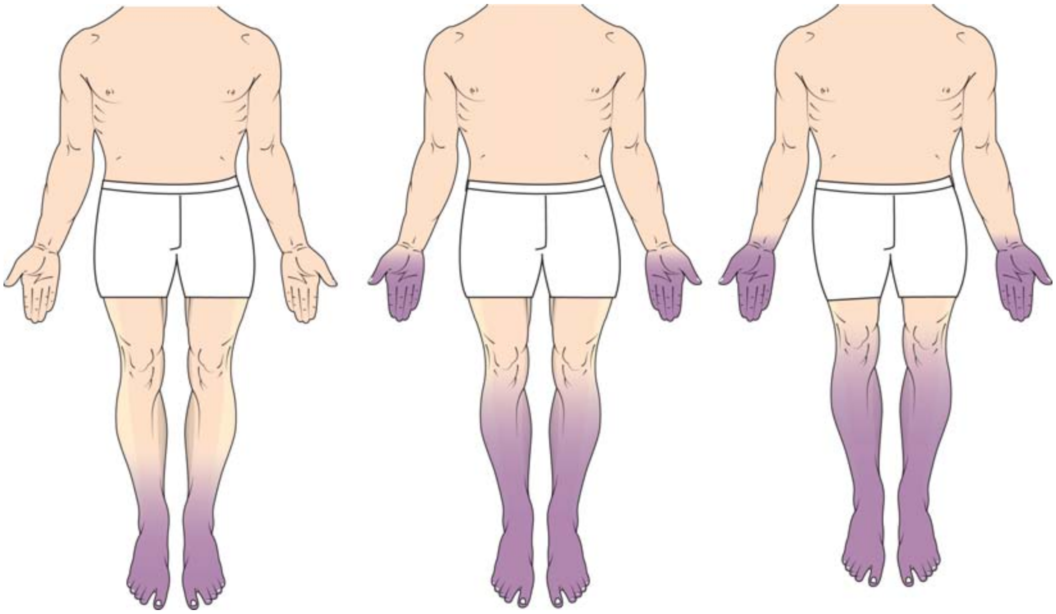

FIGURE 19-1 ■ Illustration of progressive stocking-and-glove sensory changes in a patient with progressive diabetic polyneuropathy. Sensory symptoms and signs begin in the distal territories of sensory nerves in the toes and fingers, with a gradual spread proximally. (From Zochodne DW, Kline G, Smith EE, et al: Diabetic Neurology. Informa Healthcare, New York, 2010, with permission.)

diagnosis and is not replaced by quantitative methods or electrophysiologic evaluation, which are considered ancillary tests.

On sensory examination, there is distal loss of sensation to light touch, pinprick, cold, and vibration with a 128-Hz tuning fork. Some patients with more dense sensory loss are unable to distinguish sharp (pinprick) from dull (analgesia) or to feel light touch at all (anesthesia). The Semmes–Weinstein (10 g) monofilament test is a useful adjunct to the neurologic examination. The filament is pressed against the skin over the dorsum of the great toe or other selected areas of the foot until it bows into a C shape for 1 second, and the patient is asked whether the stimulus is felt. The Rydel–Seiffer tuning fork provides semiquantitative information about vibratory sensory perception and can contribute to grading the severity of the polyneuropathy. Vibratory loss may involve the distal toes, the foot below the ankle, or more extensive territories, depending on its severity. Testing for proprioceptive abnormalities in the toes is often normal except when the polyneuropathy is severe.

Distal motor wasting, such as in the extensor digitorum brevis muscle, and associated weakness especially involving foot and toe dorsiflexion, usually accompany more severe sensory loss. Patients may have foot ulcers or, less commonly, a destructive arthropathy from repetitive injury, known as a Charcot joint. Loss of the muscle stretch reflex at the ankle is common in early diabetic polyneuropathy; all the muscle stretch reflexes may be lost with more severe neuropathies. The feet may be dry from loss of sweating. Patients with concurrent atherosclerosis have loss of distal pulses and sometimes femoral bruits. Orthostatic vital signs should be assessed; in patients with involvement of the autonomic nervous system, a decline of 20 mmHg or more in the systolic blood pressure or 10 mmHg in diastolic pressure indicates postural hypotension.[3]

Diabetic polyneuropathy has been divided into subcategories depending on whether large- or small-fiber involvement occurs. In large-fiber polyneuropathy, there is more prominent loss of sensation to light touch, vibration, and proprioception. Patients may have accompanying ataxia of gait. In small-fiber polyneuropathy, pinprick and thermal appreciation are impaired and autonomic dysfunction is common, as is neuropathic pain, especially at night. Neuropathic pain can accompany other forms of diabetic polyneuropathy as well.

Several scales have been developed to grade the severity of diabetic polyneuropathy for clinical trials, including the Modified Toronto Neuropathy Scale, the Utah Neuropathy Scale, the Michigan Neuropathy Scale, and the Mayo Clinic diabetic polyneuropathy classification.

TABLE 19-1 ■ Differential Diagnosis of Diabetic Polyneuropathy

Vitamin Deficiency

B vitamin deficiency (e.g., vitamin B_1 or B_{12})
Vitamin E deficiency

Infectious and Inflammatory

Human immunodeficiency virus (HIV) infection
Leprosy
Lyme disease
Hepatitis C infection
Guillain—Barré syndrome
Chronic inflammatory demyelinating polyneuropathy
Anti-MAG neuropathy
Lewis—Sumner syndrome
Distal demyelinating sensory neuropathy
Neuropathies associated with monoclonal gammopathies
Primary biliary cirrhosis
Sarcoidosis

Endocrine

Hypothyroidism
Acromegaly (with diabetes)

Drugs and Toxins

Antibiotics (e.g., metronidazole, isoniazid, nitrofurantoin)
Antineoplastic agents (e.g., vincristine, vinblastine, cisplatinum)
Ethanol (often in association with thiamine deficiency)
Organophosphate poisoning
Pyridoxine
Antiretroviral therapies
Interferon-α
Anti-TNF-α treatment for inflammatory disorders
Sinemet (via vitamin B_{12} deficiency)
Metformin (via vitamin B_{12} deficiency)
Others

Metabolic

Hepatic cirrhosis
Renal failure
Critical illness (sepsis and multiorgan failure)
Acquired amyloidosis
Bariatric surgery

Congenital/Inherited

Charcot—Marie—Tooth disease (multiple subtypes)
Hereditary susceptibility to pressure palsies
Hereditary amyloidosis
Hereditary sensory and autonomic neuropathies

Vascular

Necrotizing vasculitis (confined to peripheral nerves or in association with systemic vasculitis)
Severe peripheral vascular disease
Cryoglobulinemia (with or without hepatitis C infection)

Neoplastic

Paraneoplastic neuropathies (anti-Hu, anti-Ma, others)
Leptomeningeal carcinomatosis, lymphomatosis, gliomatosis
Angioendotheliosis
Primary intraneural lymphoma

TESTING

In patients with established diabetes mellitus and typical symptoms of polyneuropathy, extensive additional testing may not be required. Exclusion of other causes of sensory polyneuropathy can be accomplished through judicious screening for hypothyroidism, vitamin B_{12} deficiency, monoclonal gammopathy, and ethanol abuse. Table 19-1 is an extensive list of alternative diagnoses that may resemble diabetic polyneuropathy.

Electrophysiologic testing is recommended for patients with unexpectedly severe or atypical forms of polyneuropathy including motor-predominant disease, rapidly progressive symptoms, asymmetric signs, or when another neuromuscular condition is suspected. It is important to choose a laboratory with appropriate certification, training, and experience in performing these techniques. Two major components are usually performed: nerve conduction studies and needle electromyography (EMG). In patients with only sensory symptoms and findings, nerve conduction studies alone may be sufficient. Initial changes in patients with diabetic polyneuropathy include reductions in the amplitude and conduction velocity of the sural sensory nerve action potential (SNAP) recorded from behind the ankle. Slowing of conduction velocity in fibular (peroneal) motor axons detected by recording over the extensor digitorum brevis muscle of the foot is an additional early abnormality. In severe neuropathy, there may be widespread loss of SNAPs and diffuse mild-to-moderate conduction velocity slowing in a number of motor and sensory nerve territories (Fig. 19-2). In some patients with severe involvement, these findings may resemble the changes expected in a demyelinating polyneuropathy such as chronic inflammatory demyelinating polyneuropathy (CIDP), but it is usually possible to distinguish this condition. In CIDP, there are many more striking electrophysiologic features of primary demyelination such as motor conduction block or dispersion of compound muscle action potentials (CMAPs).

Loss of motor axons in more advanced diabetic polyneuropathy is detected by a decline or loss of

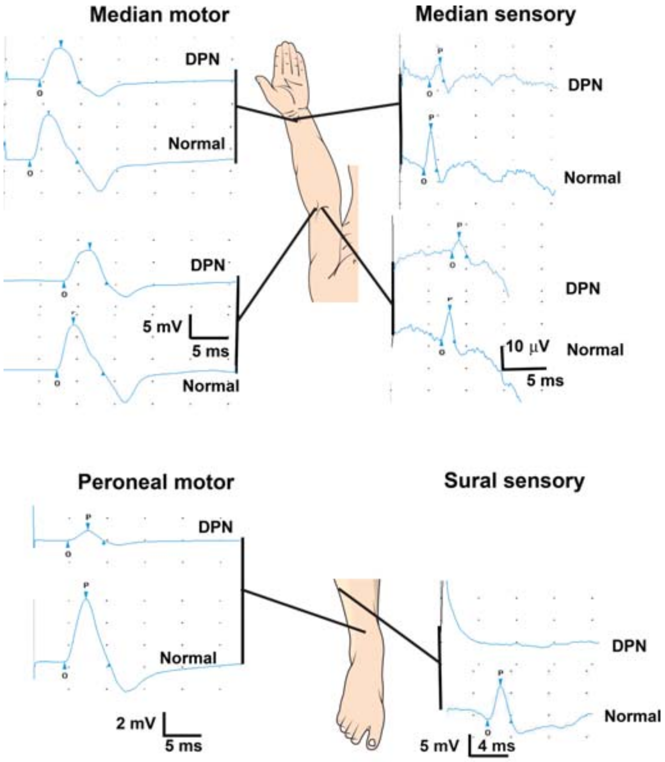

FIGURE 19-2 ■ Examples of nerve conduction abnormalities in a patient with moderately severe diabetic polyneuropathy (DPN) compared with waveforms in a normal subject. Note the decreased amplitude and prolonged latency of compound muscle action potentials and sensory nerve action potentials. The sural sensory nerve action potential is absent. Lines indicate nerve stimulation sites (recording site for the median motor nerve is the abductor pollicis brevis; for the median sensory nerve, the index finger; for the fibular [peroneal] motor nerve, the extensor digitorum brevis; and for the sural nerve, behind the lateral ankle). (From Zochodne DW, Kline G, Smith EE, et al: Diabetic Neurology. Informa Healthcare, New York, 2010, with permission.)

CMAPs, initially in the lower and then the upper limbs. In these patients, needle EMG may detect abnormal spontaneous activity, including fibrillation potentials and positive sharp waves, in muscles that have undergone denervation. In the setting of partial loss of motor axons, remaining fibers sprout and innervate adjacent denervated muscle fibers. When activated, the motor unit action potentials recorded from these partially denervated muscles are enlarged but reduced in number, indicative of chronic denervation and reinnervation. Electrophysiologic testing is also valuable in identifying superimposed entrapment or compression neuropathies, which are discussed later.

To reproducibly detect or track sensory changes, quantitative sensory testing (QST) using a computer interface may be used. While its chief utility is currently for clinical trials, it may offer early detection should better therapy for diabetic polyneuropathy emerge. QST equipment is available from several manufacturers and most use calibrated electronic interfaces to measure thermal thresholds (warm, cold), pain, touch-pressure, and vibration. As expected, these thresholds in the feet are raised in diabetic polyneuropathy.

Specific testing of the autonomic nervous system is available for evaluating co-existing autonomic involvement (see Chapter 8). In some patients with diabetes mellitus, however, prominent and apparently selective autonomic damage occurs without polyneuropathy, as discussed later. Since postganglionic autonomic axons are unmyelinated, autonomic function testing may detect small-fiber forms of diabetic polyneuropathy.

Two additional forms of testing, not in routine clinical use for diabetic polyneuropathy, also evaluate small-fiber involvement. These include skin biopsy, using a 3-mm punch to count the number of epidermal axons, and corneal confocal microscopy, which provides a noninvasive measure of unmyelinated axons in the cornea and complements skin biopsy.[6]

Biopsy of the sural nerve is not indicated for the routine evaluation of diabetic polyneuropathy and should be reserved for the diagnosis of unusual or progressive neuropathies that are atypical and suspected to be from another cause. In diabetes, sural nerve biopsies show loss of myelinated and unmyelinated axons that can accompany microvascular basement membrane thickening, endothelial cell reduplication, or vessel occlusion. Sural nerve biopsies leave the patient with a sensory deficit and therefore should be performed judiciously.

Cerebrospinal fluid (CSF) examination is not indicated routinely for typical diabetic polyneuropathy, although when performed it may show an elevated CSF protein concentration without pleocytosis.

Imaging studies are used to exclude spinal cord disease, spinal stenosis, or other central disorders with symptoms that may resemble diabetic polyneuropathy. There are no specific imaging characteristics of diabetic polyneuropathy although newer approaches—including ultrasound—are under evaluation.

Differential Diagnosis

A number of neurologic disorders may resemble diabetic polyneuropathy. Other polyneuropathies with prominent sensory involvement are listed in Table 19-1. A detailed neurologic examination is essential to exclude other syndromes in diabetic patients; for example, spinal cord disease may present with limb tingling and numbness, but other signs of upper motor neuron dysfunction are usually present on examination. Lesions at the cervicomedullary junction may cause sensory symptoms that begin in one limb and then progressively involve all four limbs. "Pseudoneuropathy" is a term used to describe the combination of lower limb sensory symptoms from spinal stenosis with upper limb tingling caused by carpal tunnel syndrome. It is important to identify patients with CIDP because they may respond to immunomodulatory therapies.

Pathogenesis

A number of mechanisms have been considered in the pathogenesis of diabetic peripheral neuropathy, all with limited definitive evidence, and they are discussed elsewhere in recent reviews.[7,8] Most have been evaluated in rat and mouse models of diabetes. Excessive flux of polyols (sugar alcohols), especially sorbitol, through the aldose reductase pathway is one such proposed mechanism. Aldose reductase inhibitors or protein kinase C inhibitors that interrupt this pathway have had limited clinical benefits, problematic side effects, or lack of penetration into the peripheral nervous system. Free radical oxidative/nitrergic stress and mitochondrial dysfunction along with impaired antioxidant defenses likely contribute to neuronal damage. Diabetic microangiopathy may lead to ischemic damage of neurons and axons. We have suggested that microangiopathy contributes to diabetic polyneuropathy later in the illness rather than serving as a primary trigger.

Trophic mechanisms that support neurons are impaired in diabetes. To date, separate clinical trials with nerve growth factor, neurotrophin-3, and brain-derived neurotrophic factor have been disappointing. In each case, the ability to protect all types of peripheral neurons targeted by diabetes has been limited. An intriguing alternative is insulin itself, an important growth factor which is neurotrophic; its receptors are widely expressed on most neurons of the peripheral nervous system. Novel forms of near-nerve or intranasal insulin have improved experimental diabetic neuropathy.

Treatment

Despite extensive experimental work, no therapy is available to arrest or reverse diabetic polyneuropathy. Tight control of hyperglycemia reduces the incidence of polyneuropathy and its progression. Daily foot inspection for injuries and early ulceration is recommended. There is no role for multiple nerve decompressive procedures to treat diffuse diabetic polyneuropathy. Treatment for neuropathic pain is discussed later.

Focal Mononeuropathies

Focal neuropathies involving single peripheral nerves are common in diabetes. Many of these mononeuropathies develop at sites of entrapment or compression. Others are of uncertain origin or may develop from nerve trunk ischemia.

Carpal Tunnel Syndrome

Carpal tunnel syndrome arises from compression of the median nerve at the wrist beneath the transverse carpal ligament, often following repetitive use of the wrist. It is characterized by tingling, pain, and numbness in the thumb, index, and middle fingers, especially at night or on awakening. Asymptomatic carpal tunnel syndrome (electrophysiologic diagnosis) can be detected in 20 to 30 percent of diabetics but symptoms are present only in approximately 6 percent.[5] It is the most common entrapment neuropathy overall and the most common type in diabetic subjects. Women are affected more often than men and the dominant hand is involved more often than the nondominant hand.

Tinel sign (tapping over the median nerve at the wrist evokes positive sensory symptoms that resemble the patient's symptoms distal to the wrist) and Phalen sign (reproduction of tingling by having both wrists flexed and held against each other for 1 minute) may be present, but are nonspecific and insensitive. In mild carpal tunnel syndrome, clinical signs may be absent. Later, sensory loss may occur in the median nerve territory. In more severe carpal tunnel syndrome, weakness and wasting of the abductor pollicis brevis develops. Electrophysiologic testing helps to distinguish the disorder from radiculopathy or other upper limb neuropathies by identifying selective slowing of conduction in median nerve fibers across the carpal tunnel. Nerve ultrasound may be helpful in identifying nerve trunk enlargement.

Carpal tunnel syndrome may improve with a change in activity and the nocturnal use of wrist splints. Decompression by section of the transverse carpal ligament is the only curative procedure. Since diabetes delays nerve regeneration, recovery in diabetics, particularly those poorly controlled, may be less robust than in nondiabetics.

ULNAR NEUROPATHY AT THE ELBOW

Ulnar neuropathy at the elbow presents with pain and sensory symptoms in the medial half of the ring finger and in the fifth digit, sometimes radiating into the palm as far proximally as the wrist. Sensory loss involves these fingers as well as the medial volar and dorsal hand to the wrist. There may be wasting and weakness of intrinsic ulnar-innervated hand muscles, especially the first dorsal interosseous muscle, making it difficult for the patient to abduct or adduct the fingers. Manipulation of the ulnar nerve at the elbow may generate tingling that radiates into the hand and reproduces symptoms. Ethanol use and previous elbow trauma or fractures are predisposing factors. The disorder is commonly caused by the patient leaning on the medial elbow, compressing the nerve. The prevalence of ulnar nerve entrapment in patients with diabetes mellitus is estimated to be approximately 2 percent.[9]

Electrophysiologic studies identify slowing of ulnar motor and sensory conduction across the elbow, loss of ulnar SNAPs and CMAPs, and sometimes conduction block across the elbow. EMG demonstrates evidence of denervation in weak muscles. Changes in elbow position or protecting the nerve with padding can reverse the neuropathy. There are no controlled clinical trials specifically in diabetic patients to show that surgical decompression improves long-term outcome. However, current clinical practice suggests decompression is a reasonable approach when the lesion is symptomatic, involves motor axons, and is progressive despite conservative measures.

MERALGIA PARESTHETICA

Meralgia paresthetica is an entrapment neuropathy involving the lateral femoral cutaneous nerve of the thigh as it passes under the inguinal ligament. Symptoms are numbness, tingling, prickling, and sometimes pain over the lateral thigh that may be relieved by sitting. Bilateral involvement may occur. Examination findings include loss of sensation to light touch and pinprick over the lateral thigh. The extent of findings may vary from a small patch to most of the lateral thigh from just below the inguinal area to the knee. Hip flexion and knee extension muscle power is preserved, as is the quadriceps stretch reflex. In some patients, a compressive lesion such as an enlarged lymph node, inguinal hernia, or scar from a previous hernia repair is present. Additional risk factors are abdominal obesity, pregnancy, and the wearing of low-riding belts. The differential diagnosis includes diabetic lumbosacral plexopathy (distinguished by weakness and wasting along with loss of the quadriceps reflex), plexopathy secondary to a retroperitoneal lesion, or an L3 or L4 radiculopathy associated with back pain, weakness, positive straight leg raising sign, and loss of the quadriceps reflex. There is no evidence to support benefit from surgical decompression at the inguinal ligament; however, some patients may choose to undergo decompression if weight loss, local anesthetic, or corticosteroid injections are unhelpful and pain is intractable. Conservative management of pain and limiting activities that provoke symptoms may allow spontaneous recovery over time.

INTERCOSTAL OR TRUNCAL RADICULAR NEUROPATHIES

Intercostal neuropathies involve the thorax and abdominal wall and may be ischemic in origin. Patients may present with severe thoracic or abdominal wall pain mistaken for an intra-abdominal or thoracic emergency. Differential diagnoses include herpes zoster without rash or radiculopathy from a segmental structural lesion. Several contiguous territories may be involved unilaterally or bilaterally.[10] Symptoms other than pain include tingling, pricking, lancinating, aching (especially at night), radiation around the chest or abdomen causing a feeling of constriction, and allodynia. Patients may occasionally have asymptomatic sensory loss over the chest or abdomen from longstanding truncal or radicular neuropathy or asymmetric weakness of the abdominal muscles when sitting up (asymmetric bulging). Men are affected more often than women. Imaging of the spinal cord and roots by magnetic resonance imaging (MRI) with gadolinium should be performed to exclude nerve root compression when a structural lesion is suspected. In some patients, EMG may detect signs of denervation in weak thoracic intercostal or abdominal muscles; such changes commonly are more extensive and may involve the paraspinal muscles at multiple levels. Pain may be severe enough to require treatment, but usually reaches a maximum after several weeks, continues for some months, and then gradually resolves completely. Sensory loss may also slowly resolve with time.

OCULOMOTOR NEUROPATHY

Oculomotor neuropathy develops in older diabetic patients, particularly if they are also hypertensive. Symptoms consist of sudden-onset diplopia and ptosis, with an aching pain around or behind the eye. The eye is deviated laterally. Diabetic oculomotor palsy typically spares the pupil because axons within the center of the nerve are targeted rather than peripheral pupillomotor fibers. This centrofascicular involvement in diabetes suggests that the pathology is ischemic nerve damage. A single pathologic study of a patient with oculomotor palsy noted demyelination in the center of the oculomotor nerve within the cavernous sinus.[11] Imaging should include MRI of the brainstem and the course of the oculomotor nerve; MR angiography is indicated to search for an aneurysm compressing the third cranial nerve. CT angiography may also be used to exclude aneurysm but there is a risk of contrast nephropathy from the contrast load. Although no specific treatment is available for the neuropathy, spontaneous resolution usually occurs over approximately 3 months. An eye patch prevents diplopia but interrupts binocular depth vision and patients should therefore refrain from driving.

DIABETIC LUMBOSACRAL PLEXOPATHY

Diabetic lumbosacral plexopathy (also known as radiculoplexus neuropathy, diabetic amyotrophy, Bruns–Garland syndrome, and proximal diabetic neuropathy) usually develops in patients with type 2 diabetes mellitus, especially in men. It may emerge early in the course of diabetes or following onset of insulin therapy. Nondiabetics rarely can develop a similar syndrome. Symptoms are severe and disabling with impairment in standing and walking. The subacute onset of unilateral intense deep boring or aching muscle pain is typical, sometimes worse at night, located within the muscles of the thigh but also often radiating to the back and perineum. These symptoms are followed by weakness and wasting of the proximal thigh muscles including the quadriceps, iliopsoas, hip adductor muscles, and occasionally the anterior tibial muscles (with associated foot drop). Sensory loss and tingling are less prominent. The condition can be distinguished from a femoral neuropathy by the pattern of muscle involvement, which typically includes the medial adductor muscles innervated by the obturator nerve, and the iliopsoas muscle innervated directly by the lumbar plexus. Over the months, slow recovery of muscle power occurs. In some patients, contralateral symptoms may emerge a few weeks after onset.

Variations of diabetic lumbosacral plexopathy include symmetric involvement, more prominent foot drop, or apparent worsening of polyneuropathy. The pathophysiologic mechanism for this form of focal neuropathy is uncertain but may include occlusive changes in microvessels supplying the lumbosacral roots or plexus or inflammatory changes suggestive of a localized form of vasculitis. Perivascular inflammation, epineurial inflammation, microvessel occlusion, and iron deposition (indicative of intraneural bleeding) accompany loss of axons in biopsies of the sural nerve or cutaneous nerves of the thigh.[12]

Imaging studies of the lumbar intraspinal space (MR with gadolinium) and the lumbosacral plexus (MR with gadolinium or CT with contrast) help to exclude a retroperitoneal compressive plexus lesion. Electrophysiologic studies in diabetic lumbosacral plexopathy show loss of amplitude of the CMAP recorded over the quadriceps muscle and EMG evidence of denervation in weak muscles.

No therapy has been shown to arrest or reverse the motor deficit. Despite the inflammatory changes seen on pathologic examination, the response to immunosuppressive therapy is unproven. Patients require intensive pain management. Physiotherapy and occupational therapy are essential to recovery and a knee brace helps to prevent buckling when weight bearing.

OTHER FOCAL NEUROPATHIES

Other focal neuropathies described in diabetic patients are less common. Bell palsy, presenting with unilateral facial weakness, may be more common in diabetics. Abducens palsy presents with lateral gaze weakness of the abducting eye and is seen in older diabetic patients; other causes include compression, trauma, and hypertension. Trochlear palsy presents with diplopia and difficulty looking down and inward because of weakness of the superior oblique muscle.

The patient tilts the head to the side opposite the palsy to reduce diplopia.

Autonomic Neuropathy

Autonomic neuropathy in diabetes may target one or more components of the autonomic nervous system.

Cardiovascular abnormalities include loss of reflexes such as heart-rate variability in various circumstances including at rest, with the Valsalva maneuver, and following standing. In severe disease, patients may have a fixed, mildly elevated heart rate that resembles a transplanted heart without innervation. More commonly, partial denervation of the heart may contribute to abnormal contractility and arrhythmias. For example, prolonged QTc intervals in patients with type 1 diabetes may predict an increased risk of mortality. Postural hypotension, from loss of sympathetic control of resistance arterioles, is defined as a decline of systolic pressure by 20 mmHg or more—or of diastolic pressure by at least 10 mmHg—after 1 minute of standing, with associated orthostatic dizziness or fainting; it occurs in 3 to 6 percent of diabetics and may be a late feature of diabetic autonomic neuropathy. Some patients may also have abnormal tachycardia with standing (postural orthostatic tachycardia syndrome), as discussed in Chapter 8.

Treatment includes stopping or reducing medications that may cause postural hypotension (e.g., tricyclic antidepressants, antihypertensive medications, and other vasodilators); arising from a bed or chair slowly; sleeping with the head of the bed raised 20 degrees; avoiding prolonged standing; avoiding early morning or postprandial exercise; avoiding prolonged heat exposure, hot baths or showers; increasing salt and fluid intake; and limiting alcohol intake. Medications used to treat postural hypotension include fludrocortisone, midodrine, L-dihydroxyphenylserine (Droxidopa), and desmopressin (see Chapter 8).

The Ewing battery is a set of cardiovascular autonomic tests that includes heart-rate response to the Valsalva maneuver, standing, and to deep breathing, as well as blood-pressure response to standing up and sustained handgrip. Radioiodinated metaiodobenzylguanidine (MIBG) is an injectable marker of sympathetic terminals found in cardiac muscle; loss of MIBG uptake in the inferior, posterior, and apical portions of the heart occurs in diabetes, indicating sympathetic denervation or dysfunction.

Sexual dysfunction is common in diabetic men. ED, defined as the inability to achieve or maintain an erection sufficient for sexual intercourse, may occur in over 40 percent. Direct vascular factors, such as atherosclerosis, also cause ED but other causes should be excluded including psychologic factors, Peyronie disease, problems with the sexual partner, and medications (e.g., sedatives, antidepressants, and antihypertensives). The additional loss of ejaculation suggests more severe autonomic involvement. Testing includes duplex ultrasonography and nocturnal measurements of penile tumescence. Treatment for male ED involves phosphodiesterase-5 inhibitors (sildenafil, tadalafil, others), apomorphine, intracavernosal and intraurethral therapy, vacuum devices, and penile prostheses, as discussed in Chapter 30. Female sexual dysfunction may also occur from vaginitis, loss of vaginal lubrication, cystitis, and other causes.

Gastrointestinal neuropathy is associated with abdominal pain, weight loss, early satiety, postprandial fullness, heartburn, nausea (rarely vomiting), dysphagia, fecal incontinence, diarrhea (which may be nocturnal), and constipation. Esophageal transit and gastric emptying are slowed, a change directly linked to elevated glucose levels. Similarly, small intestine dysmotility develops and may accompany an increased risk of cholelithiasis and cholecystitis. Colonic dysfunction causes constipation and diarrhea that may be alternating and may be associated with abdominal pain. Anorectal dysfunction with incontinence develops from abnormal internal or external sphincter function, loss of sensitivity, and disrupted anorectal reflexes. A superimposed history of obstetric trauma may predispose diabetic women to this complication. Exclusion of other gastrointestinal problems that can occur in patients with diabetes is important, including esophageal candidiasis, gastric bezoar, *Helicobacter pylori* infection, bacterial overgrowth, anorectal disorders, celiac disease, hemorrhoids, impaired sphincter tone, rectal prolapse, local tumors, ulcers, rectal intussusception, and fecal impaction.

Gastric and intestinal motility studies are performed using radiography or scintigraphy, manometry, pH recordings, and endoscopy or colonoscopy. Anorectal dysfunction is studied by manometry, ultrasonography, proctoscopy, and sigmoidoscopy. High-fiber, low-fat diets may facilitate gastric emptying. Pharmacologic treatments of slowed gastric emptying include prokinetic agents (e.g., domperidone, metoclopramide, erythromycin). Cisapride has been withdrawn from the market in many countries because of an increased risk of cardiac arrhythmia and death. For intractable impaired gastric emptying, a temporary or permanent jejunostomy may rarely be required. For diarrhea, opioids (e.g., loperamide, codeine), cholestyramine, fiber, and bulking agents may be useful. Biofeedback may help with fecal incontinence.

Bladder neuropathy leads to loss of bladder sensitivity and later detrusor muscle weakness, both of which contribute to incomplete bladder emptying, recurrent infection, and eventual overflow incontinence (see Chapter 29). In late disease, an end-stage insensitive noncontractile atonic bladder can result. Symptoms of bladder neuropathy include urgency, nocturia, and incontinence. Other urologic problems such as bladder tumor, infection, urethral stricture, or prostatic hypertrophy should be excluded. Urodynamic studies may be helpful, including urinary tract imaging (e.g., intravenous pyelography), cystography, uroflowmetry, and post-void ultrasonography to test for residual urine. Pharmacotherapy may include parasympathomimetics and α-adrenergic blockade to relieve sphincter hypertonicity. End-stage dysfunction may require intermittent self-catheterization.

Sudomotor neuropathy, or abnormalities of sweating, can cause stocking-and-glove distribution anhidrosis, a risk factor for skin ulceration in the feet. Generalized loss of sweating increases heat intolerance. Diabetic subjects may have abnormal sweating patterns such as inappropriate truncal sweating, or gustatory sweating (facial and truncal sweating induced by eating certain foods). Thermoregulatory sweat testing examines the geographic distribution of sweating. Quantitative sudomotor axon reflex testing (QSART) tests quantitative sweat output using a dehumidified sweat capsule; in diabetes, output may be reduced, absent, excessive, or "hung up" (persistent). The sympathetic skin response is an electrophysiologic surrogate for sweat gland activation. Other measures of sweat output include analysis of sweat droplet numbers (numbers of functioning sweat glands) and size; skin biopsy to analyze sweat gland innervation; and novel rapid sweat indicator methods available commercially. For patients with hypohidrosis or anhidrosis, caution regarding heat exposure should be advised. Moisturizers may be applied to dry feet and hands.

Autonomic neuropathy may cause small pupils with sluggish or absent pupillary reflexes accompanied by light intolerance. Pupils may be examined by pupillography to measure pupillary diameter, latency to contraction, and velocity of contraction and dilatation.

Patients with diabetes may have hypoglycemic unawareness because autonomic responses (e.g., sweating, tachycardia) and counter-regulatory hormones such as epinephrine fail to increase. Patients may not recognize their impairment and thus fail to take adequate protective measures.

CENTRAL NERVOUS SYSTEM COMPLICATIONS

Cognitive Dysfunction

A complication of diabetes mellitus that is frequently overlooked or under-reported is cognitive decline.[13] An association between diabetes mellitus and cognitive dysfunction was first described almost a century ago, and occurs with either type 1 or type 2 diabetes. Both have an elevated risk of dementia, cerebral atrophy, and the presence of white matter abnormalities. The impact may be most apparent during childhood or in late stages of life when neurodegeneration may predominate. For example, diabetic patients have an increased risk of development of Alzheimer disease (AD) as compared with nondiabetic subjects, possibly predated by early blood–brain barrier changes. Many AD patients also have glucose intolerance.

Children with type 1 diabetes have lower intelligence scores, lowered mental efficiency, and poor school performances when compared to classmates without diabetes. The younger the age of onset of the diabetes, the greater the cognitive impact. The exact role of hypoglycemic episodes is unclear. While some reports have speculated on the association between lifetime hypoglycemic episodes and cognitive impairment, more recent studies have not demonstrated such an association even though hypoglycemic events are known to cause hippocampal damage. Chronic hyperglycemia may accelerate neurodegeneration. Hyperglycemia in children with type 1 diabetes has also been shown to lead to altered white matter development.

In type 2 diabetes mellitus, there are several confounding factors that may influence cognition, such as obesity, dyslipidemia, hypertension, and stroke. Patients with prediabetes or impaired glucose tolerance may also have cognitive impairment, but to a lesser degree. An important comorbidity is depression, which may lead to synergistic effects on executive function.

Some domains of cognition are impacted more than others in diabetes—these include changes in attention, executive function, visual and verbal memory, processing speed, mental flexibility, and planning. In contrast, language and visuospatial construction ability do not appear to be compromised. Motor impairment, less commonly studied and confounded by the impact of polyneuropathy, appears to be linked to cognitive decline.

Changes present in the diabetic brain over time can be described pathologically as a diabetic leukoencephalopathy, characterized by cerebral atrophy, cognitive decline, and white matter abnormalities (Fig. 19-3).

Studies examining cognitive function in diabetics require additional factors to be considered, including glycemic control, duration of diabetes, and specific treatments used. It is well known that longer durations of diabetes and poor glycemic control are associated with greater microvascular end-organ complications in both type 1 and type 2 diabetes. An elevated HbA1c level, indicating more significant chronic hyperglycemia, is also associated with greater severity of impaired cognition in patients with type 2 diabetes. It is possible that cognitive dysfunction is partially reversible with improvements in glycemic control, although optimal target levels have not yet been established.

Cerebral Infarction and Vascular Dementia

Diabetes mellitus is a prominent risk factor for atherosclerosis and cerebral infarction. Diabetes is usually associated with lacunar infarction involving small penetrating arteries in addition to large-vessel infarction. As a result, patients with multi-infarct (or vascular) dementia have a greater prevalence of

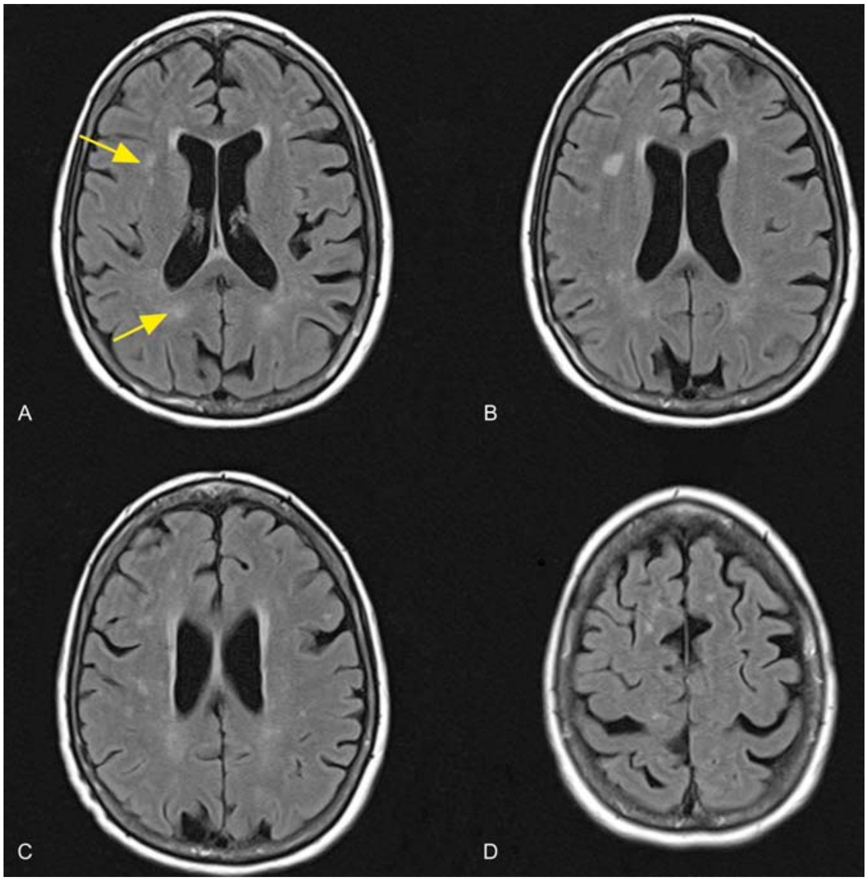

FIGURE 19-3 ■ Magnetic resonance imaging of the brain from a 62-year-old woman with type 2 diabetes mellitus for 12 years, who presented with mild ataxia of gait and polyneuropathy. These axial T2-weighted fluid-attenuated inversion recovery (FLAIR) sequences progress from caudal to rostral cuts, *A* to *D*, and show nonenhancing bilateral white matter hyperintensities (*arrows*) in *A*, also termed diabetic leukoencephalopathy.

diabetes than other patients with dementia. Vascular dementia is the second most common worldwide cause of dementia following AD, and both are rising in prevalence.

Alzheimer Disease

There has also been a longstanding association between diabetes and vascular dementia in longitudinal population-based studies, but the relationship between diabetes and AD has been recognized more recently. Depending upon the country, gender, and ethnicity of the population considered, AD generally comprises 50 to 70 percent of all causes of dementia. Reduced glucose tolerance, insulin resistance, and hyperinsulinemia are negatively correlated with memory and are associated with hippocampal atrophy. Diabetes is associated with neuropathologic markers of AD, including β-amyloid and tau accumulation.

Insulin resistance is related to an increased risk for cognitive decline and linked with a reduction in cerebral glucose metabolic rates and more subtle cognitive impairment. The major gene linked with AD, the apolipoprotein E gene (particularly the ε4 allelic variant) is associated with a greater atherosclerotic risk profile and higher risks of both vascular dementia and AD in patients with diabetes. Hyperinsulinemia's impact upon the brain includes downregulation of insulin-signaling pathways, including the degrading enzyme insulysin. Insulin inactivates glycogen synthase kinase 3 (GSK-3) through phosphoinositide (PI) 3-kinase (PI3K), subsequent Akt (also called protein kinase B) activation, and then Akt-mediated phosphorylation of GSK-3 isoforms, ultimately inhibiting GSK-3 activity. As such, insulin regulates tau protein phosphorylation. Insulin-mediated GSK-3 inhibition may therefore prevent tau protein hyperphosphorylation or reduce Aβ protein accumulation. Hyperinsulinemia or insulin resistance also promotes amyloidosis. As such, peripheral insulin increases measurable Aβ levels in CSF, potentially accelerating AD. Finally, insulin signaling influences neuronal senescence and life span; reduced hippocampal synaptic plasticity occurs both with peripheral and CNS insulin resistance and may be linked to hippocampal atrophy.

Pathogenic synergy exists with diabetic leukoencephalopathy and AD, in apolipoprotein processing and disruption of insulin signaling. The advanced glycation end-product (AGE) pathway[14] renders additional toxicity associated with greater oxidative stress and reduced nitric oxide bioavailability. AGEs propagate with hyperglycemia in diabetes as well as during aging, corresponding with an upregulation of the receptor for AGEs, called RAGE—a ubiquitous multiligand transmembrane receptor of the immunoglobulin superfamily of cell surface molecules. AGE-RAGE signaling initiates protein kinase pathways including proinflammatory gene activation and secondary immune responses including rises in NFκB, a stress responder.

NEUROPATHIC PAIN

Neuropathic pain can develop in the setting of diabetic polyneuropathy or mononeuropathies and may occur at any stage of these disorders. In diabetic polyneuropathy, neuropathic pain is typically described as nocturnal burning discomfort, allodynia, electric-like jolts, or a deep aching pain.

Pathophysiology

Altered excitability of axons, associated with early molecular alterations of both peripheral axons and the cell bodies of neurons in sensory ganglia, explains why patients may have prominent neuropathic pain despite only mild loss of nerve fibers. Changes in the distributions of sodium or calcium channels that promote abnormal ectopic discharges may initiate the pain cascade. Specific channels include upregulated $Ca_v3.2$ T-type calcium channels and sodium channels ($Na_v1.3$, $Na_v1.9$, and $Na_v1.7$). Other molecules involved in neuropathic pain may include bradykinin B1 receptors (BKB1-R), VR1 (vanilloid, TRPV1) receptors, TRPA1 (transient receptor potential cation channel, subfamily A, member 1), protein kinase C (PKC), and COX-2. Finally, changes at the level of the dorsal horn of the spinal cord or higher may also be implicated in the development of neuropathic pain. Overall, work by a number of investigators suggests that diabetic polyneuropathy is associated with multilevel changes in the neuraxis that promote pain, including alterations of primary sensory neurons and abnormal signaling through the dorsal horn of the spinal cord.

Treatment

The current state of the literature evaluating analgesic therapy for human diabetic polyneuropathy has been reviewed elsewhere.[15] There is evidence supporting the use of tricyclic antidepressants, gabapentin, pregabalin, duloxetine, and tramadol. However, opioids are no longer recommended for nonmalignant neuropathic pain. Gabapentin is excreted renally and thus downward dose revision is necessary in patients with renal failure.

Treatment guidelines have been published by the American Academy of Neurology, in association with other professional organizations and based on Class I evidence. Pregabalin was determined to lessen the pain of peripheral diabetic neuropathy and improve quality of life and sleep (recommendation level A). Gabapentin and sodium valproate were classified as probably effective and given a level B recommendation. A flag concerning the risk of birth defects was placed for sodium valproate. Other agents deemed probably effective (level B) were amitriptyline, venlafaxine, duloxetine, dextromethorphan, morphine sulfate, tramadol, oxycodone, capsaicin, isorbide dinitrate, and percutaneous electrical stimulation. Topiramate, desipramine, imipramine, fluoxetine, alpha lipoic acid, or the combination of nortriptyline and fluphenazine had insufficient evidence for or against their use. Oxcarbazepine, lamotrigine, lacosamide, clonidine, pentoxifylline, and mexiletine had evidence against their effectiveness (negative level B recommendation). Other guidelines have provided similar recommendations. More studies on the effectiveness of synthetic and naturally occurring cannabinoids is required before any concrete conclusions can be made.

SPECIFIC THERAPEUTIC AGENTS

Calcium channel $\alpha 2$-δ ligands include gabapentin and pregabalin. Gabapentin is initiated in low doses such as 300 mg at bedtime and increased to a maximum of 3,600 mg daily. It does not alter the metabolism of other drugs, but dose reduction is required in renal failure. Side effects include dizziness, fatigue, and cognitive dysfunction with initial use or higher doses, and lower limb edema. Pregabalin is started at 75 mg at bedtime, and titrated upwards using a twice-daily dosing schedule to a maximum of 600 mg daily; its side effects are similar to those of gabapentin.

Serotonin and norepinephrine reuptake inhibitors include venlafaxine, which is initiated at 37.5 mg per day and increased weekly to a maximum of 225 mg daily. Side effects include nausea, dizziness, drowsiness, hyperhidrosis, hypertension, and constipation. Duloxetine is started at 30 mg daily titrated up to a maximum of 120 mg daily, although 60 mg daily provides optimal outcomes. Adverse effects include hepatotoxicity, nausea, dry mouth, constipation, somnolence, hyperhidrosis, and decreased appetite. Amitriptyline is started at 10 to 25 mg at bedtime and increased to 100 to 150 mg. Side effects include next-day drowsiness, lethargy, dry mouth, constipation, and urinary retention. Amitriptyline may help with prominent nocturnal pain but requires caution in patients with cardiac disease or urinary retention.

Agents to treat local pain include lidocaine patches, other local anesthesia agents and capsacin. Some patients find these to be acceptable alternatives to oral medications.

  - *Pheochromocytoma and Neuroendocrine Tumors*

The most common endocrine disorders causing neurologic disease are thyroid disease and diabetes mellitus, which are addressed in Chapters 18 and 19. Nevertheless, sex hormone, pituitary, parathyroid, and adrenal disorders may have important neurologic implications or consequences and are therefore reviewed here, with emphasis on features relevant to neurologic practice.

SEX HORMONES AND THE NERVOUS SYSTEM

The effects of sex steroids on neurologic function in health and disease constitute a rich and rapidly expanding area of basic and clinical neuroscience. Sex steroids exert both organizational and activational effects within the nervous system. Organizational

effects refer to the irreversible differentiation of neural circuitry resulting from exposure to sex steroids during critical periods of brain development and are discussed in the previous edition of this book. The activational effects of sex steroids encompass a myriad of largely reversible neurophysiologic influences exerted by gonadal hormones on the mature nervous system. Such interactions are essential for regulation of the brain–pituitary–gonadal axis (Fig. 20-1) and the establishment of normal patterns of sexual, aggressive, cognitive, and autonomic behaviors. Furthermore, by impacting neurosteroidogenesis and the metabolism and release of various central neurotransmitters and neuromodulators, hormonal fluctuations associated with (1) specific phases of the menstrual cycle, (2) pregnancy, (3) the menopause, and (4) exposure to exogenous sex hormones may induce or modify a host of neurologic and neuropsychiatric disorders.

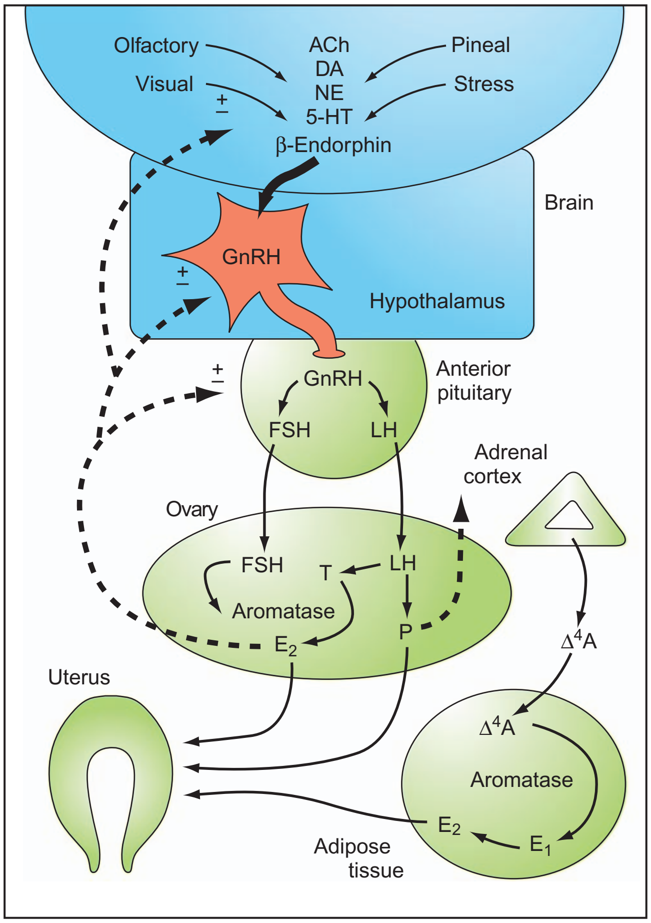

FIGURE 20-1 ■ The brain–pituitary–ovarian axis. Δ^4A, delta-4-androstenedione; ACh, acetylcholine; DA, dopamine; E_1, estrone; E_2, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; 5-HT, 5-hydroxytryptamine (serotonin); LH, luteinizing hormone; NE, norepinephrine; P, progesterone; T, testosterone.

Migraine

Although no gender difference in its prevalence is apparent before puberty, migraine is three times as common in adult women (18%) as in men (6%).[1,2] Approximately 60 percent of women with migraine experience perimenstrual exacerbations of their headaches (catamenial migraine). The late luteal-phase decline in plasma estradiol (but not progesterone) appears to play an important role in the precipitation of catamenial migraine. The frequency or severity (or both) of migraine attacks often diminishes with gestation, particularly in patients whose headaches are linked to the menstrual cycle. The absence of rhythmic estrogen "withdrawal" characteristic of the pregnant state is believed to be responsible for the reduction in migraine activity. Indeed, many women whose headaches are attenuated by pregnancy experience relapses at the time of parturition, when sex hormone levels fall precipitously. In some women, breastfeeding appears to protect against migraine recurrence. Occasionally, migraine arises for the first time or appears to worsen during gestation or the perimenopausal period. A first approach to the management of gestational migraine should be nonpharmacologic (e.g., relaxation training, biofeedback), especially during the first trimester when risks of teratogenicity and embryotoxicity are greatest. For severe attacks, acetaminophen with codeine or nonsteroidal anti-inflammatory drugs (NSAIDs) may have to be used. Further discussion is provided in Chapters 31 and 59. For status migrainosus in pregnancy, chlorpromazine, meperidine, morphine, or prednisone may need to be administered. Perimenopausal migraine often responds to standard estrogen replacement therapy, but this must be weighed against the risk of developing breast cancer in individual patients. Fluoxetine and venlafaxine may be beneficial in women with perimenopausal migraine and comorbid hot flashes.

An association between migraine and oral contraceptives is frequently encountered in clinical practice. Women often exhibit new onset or exacerbation of migraine while taking oral contraceptives. Attacks tend to manifest during the first few cycles (particularly on placebo days in accord with the estrogen withdrawal hypothesis) and usually, but not invariably, resolve on discontinuation of the medication. A qualitative change in the pattern of migraine is noted in some patients. For example, a migraineur may develop a focal prodrome for the first time while taking oral contraceptives. Women in this category may be at high risk of infarction in regions reflecting the distribution of their auras. Amelioration of migraine after exposure to oral contraceptives is sometimes observed, perhaps related at least in part to psychologic factors.

The pathophysiology of estrogen-related migraine is incompletely understood. Estrogens may act directly on vascular smooth muscle as well as modulate the activity of vasoactive substances at the neurovascular junction. In addition, by altering central prostaglandin, serotonin, opioid, prolactin, or calcitonin gene-related peptide metabolism, premenstrual changes in circulating estrogens may activate vasoregulatory elements in the brainstem or hypothalamus, which, in turn, may trigger symptomatic alterations in cerebrovascular tone.

First-line therapy for menstrual migraine should include the standard pharmacologic, dietary, and psychologic modalities employed in the general migraine population. Sumatriptan and related serotonin 5-HT_{1D} (presynaptic autoinhibitory) receptor agonists are equally effective for noncatamenial and menstrual migraine. Refractory cases of severe catamenial migraine may benefit from late luteal-phase therapy with prostaglandin inhibitors (e.g., naproxen, 250 to 500 mg orally twice daily) and mild diuretics. Hormonal interventions in catamenial migraine have been largely unsuccessful and are often complicated by unpleasant side effects. Oral contraceptives usually exacerbate migraine and probably should not be used in the treatment of this disorder. The use of estrogen implants has yielded contradictory results. The risk–benefit ratio accruing to long-term estrogen therapy must be carefully assessed before such treatment can be advocated for this relatively benign condition. The antiestrogen tamoxifen may either alleviate or precipitate catamenial migraine. The beneficial effect of tamoxifen may be due to inhibition of calcium uptake or prostaglandin E synthesis in these subjects. In several reports, danazol (200 mg twice daily for 25 days), a testosterone derivative used in the management of endometriosis, aborted or ameliorated premenstrual migraine for the duration of treatment; catamenial headaches resumed on its discontinuation. Continuous bromocriptine therapy (2.5 mg three times daily) results in a substantial decline of headache frequency in menstrual migraine. In addition to migraine, menstruation, pregnancy, and menopause may also influence cluster headache, other autonomic cephalalgias, and hemicrania continua.

Stroke

Oral contraceptives have been implicated as a significant risk factor in thromboembolic cerebral infarction, subarachnoid hemorrhage, and cerebral venous thrombosis.[2] In the late 1960s, case-control studies revealed a 6- to 19-fold increased risk of ischemic stroke in young women related to the use of oral contraceptives. Hypertension, migraine, and age older than 35 years are associated, but independent, risk factors for cerebral infarction in patients taking oral contraceptives. Cigarette smoking by women on oral contraceptives was found to increase further the likelihood of hemorrhagic but not thromboembolic stroke. Ingestion of lower-dose (30 μg) estrogen preparations appears to be responsible for a decline in rates of thromboembolic disease among users of oral contraceptives. In a population-based case-control study, the odds ratio of ischemic stroke in current users of low-dose estrogen contraceptives (20 to 35 μg) was only slightly higher compared with former users or women who were never exposed to oral contraceptives. However, the risk of stroke remains unacceptably high in low-dose oral contraceptive users if they smoke and are older than the age of 35. Recent evidence suggests that exposure to ultralow-dose oral contraceptives (containing <25 μg ethinyl estradiol) may not enhance stroke risk when used in normotensive nonsmokers. Although less often implicated than estrogens, progestins may contribute to the danger of cerebral infarction by promoting hypertension, hypercoagulability, and adverse serum lipoprotein levels.

Ischemic strokes in users of oral contraceptives have been localized to the carotid (usually the middle cerebral artery or its deep penetrating branches) and vertebrobasilar distributions. There is usually no radiologic or pathologic evidence of disseminated vascular disease in young women with oral contraceptive-related stroke. Cerebral thromboembolism resulting from estrogen-induced hypercoagulability is a likely etiology for such strokes. Estrogen increases plasma levels of fibrinogen and clotting factors VII, VIII, IX, X, and

XII. The steroid also enhances platelet aggregation and suppresses antithrombin III activity and the fibrinolytic system. A host of estrogen-regulated genes may impact the risk of ischemic stroke, either positively or negatively. Certain inherited prothrombotic conditions (e.g., G20210A prothrombin, factor V Leiden, or methylenetetrahydrofolate reductase C677T polymorphism) augment the risk of ischemic stroke substantially if present in oral contraceptive users. Sex hormone-induced hypercoagulability is thought to play an important role in the pathogenesis of cerebral venous thrombosis complicating pregnancy, the puerperium, and use of hormonal contraceptives.

Increased levels of endogenous free estradiol may be an indicator of atherothrombotic stroke risk in older postmenopausal women, particularly in those with greater central adiposity. Dyslipidemia, insulin resistance, inflammation, and several adipose-derived hormones (e.g., adiponectin, leptin, ghrelin) are potential mediators of this association. On the other hand, estrogens may mitigate atherosclerotic vascular disease by inhibiting NFκB signaling in macrophages and the production of proinflammatory cytokines such as IL-1β, IL-6, and tumor necrosis factor (TNF)-α.[2] Data concerning the impact of hormone replacement therapy (HRT) on stroke incidence and severity are conflicting, with reports of neutral, increased, and decreased stroke risk accruing from this intervention. In some observational studies, HRT-related stroke risk was significantly modified by the presence or absence of associated factors such as hypertension or smoking. Importantly, several large randomized controlled studies indicated that HRT with conjugated equine estrogen or 17β-estradiol, alone or combined with medroxyprogesterone acetate, does not protect against stroke (or coronary artery disease) in women with established vascular disease and may actually worsen outcomes in this high-risk population. In healthy women without prior cerebrovascular history, an increased risk of ischemic but not fatal or hemorrhagic stroke has been attributed to 17β-estradiol replacement therapy. The risk of ischemic stroke in women receiving HRT does not appear to be modified by age of hormone initiation or by temporal proximity to menopause.

HRT with transdermal low-dose estrogens alone or combined with micronized progesterone may be particularly favorable in minimizing risk of ischemic stroke. Interestingly, men with the common ESR1 c.454−397CC variant of the estrogen receptor-alpha (*ESR*a) gene may be more prone to ischemic stroke than men bearing other *ESR*a genotypes after adjusting for age, hypertension, diabetes, blood lipid levels, and smoking status.

The relative risks of subarachnoid hemorrhage in former users and current users of moderate- to high-dose oral contraceptives were four times those of the general population. The odds ratio for hemorrhagic stroke in current users of low-dose estrogen contraceptives (20 to 35 μg) in comparison with former users or nonusers is negligible. As in the case of ischemic stroke, cigarette smoking and age older than 35 years substantially increase the risk of subarachnoid hemorrhage in users of oral contraceptives. Female sex hormones may predispose to bleeding from both aneurysms and arteriovenous malformations, although the pathophysiologic mechanisms underlying these phenomena remain controversial. By analogy to their effects on endometrial spiral arteries, fluctuating sex hormone levels may compromise the integrity of cerebral arterial walls, rendering them more susceptible to rupture. During pregnancy, hemodynamic changes may facilitate engorgement and bleeding from cerebral arteriovenous malformations. In addition, sex hormones may exert direct trophic influences on these malformations, analogous to their effects on other highly vascularized lesions such as spider angiomas, gingival epulis, and meningiomas (discussed later). Rarely, subarachnoid hemorrhage is secondary to cyclic bleeding from hormone-sensitive ectopic endometriomas of the spinal canal.

Epilepsy

Normal reproductive processes may be disrupted by seizure disorders and their therapies. Abnormal limbic discharges may be responsible for the hyposexuality and increased prevalence of hypogonadotropic hypogonadism and polycystic ovary syndrome noted in patients with temporal lobe epilepsy.

As discussed in Chapter 31, anticonvulsant therapy in women of childbearing age may result in failure of oral contraceptives and in teratogenicity. Phenytoin, phenobarbital, primidone, ethosuximide, and carbamazepine have been implicated in oral contraceptive failure. These anticonvulsants induce the hepatic cytochrome P450 microsomal enzyme system, which, in turn, accelerates catabolism of endogenous and exogenous sex hormones. In addition, the anticonvulsants augment the synthesis of sex hormone-binding globulins, resulting in reduced levels of circulating free (active) hormone. Anticonvulsants may also promote the clearance of sex hormones by influencing sulfate conjugation and glucuronidation of the latter in the gut wall and liver. Oral contraceptive failure does not occur with valproic acid, which may actually inhibit cytochrome P450 enzymes, causing elevations in plasma steroid concentrations. Valproic acid, however, may cause hyperandrogenism and polycystic ovaries. Of the newer antiepileptic medications, lamotrigine, gabapentin, vigabatrin, levetiracetam, zonisamide, clobazam, and lacosamide do not induce the hepatic P450 microsomal enzyme system, and oral contraceptive failure is less likely to occur with concomitant use of these drugs. Topiramate and felbamate have modest effects on sex hormone pharmacokinetics and may affect contraceptive efficacy. Although breakthrough bleeding has been reported with tiagabine, the impact of this drug on ovarian hormone metabolism is believed to be minimal.

The course of epilepsy and its management may be greatly influenced by specific phases of the reproductive cycle and exposure to steroid contraceptives. A variety of seizure disorders have been documented to worsen around the time of ovulation or premenstrually (catamenial epilepsy) and during pregnancy. An increased risk of epilepsy is associated with menstrual irregularity around age 20. Curiously, left-sided temporal lobe seizures appear more likely to cluster at the onset of menses than right-sided temporal seizures, which tend to occur more randomly throughout the cycle. Data amassed from human and animal studies indicate that estrogens and progestins have epileptogenic and anticonvulsant properties, respectively. Estrogen augments glutamatergic and suppresses GABAergic neurotransmission, favoring epileptogenesis, whereas progesterone has the opposite effects. A rising estrogen—progesterone ratio during the late luteal phase may trigger catamenial seizure activity. Furthermore, the markedly elevated estrogen—progesterone ratio characteristic of the polycystic ovary syndrome may, in part, contribute to the relatively frequent association of this reproductive disorder with temporal lobe epilepsy. Exposure to oral contraceptives consisting of estrogen—progestin combinations does not appear to worsen seizure control significantly. However, spikes in circulating estrogen concentrations accruing from gonadotropin therapy for assisted reproduction may exacerbate seizures in women with epilepsy. Also of concern are interactions between enzyme-inducing anticonvulsants and hormones used for gender-affirming treatment in transgender persons. Management strategies for catamenial epilepsy include (1) premenstrual or periovulatory supplementation of anticonvulsant doses or addition of an adjunctive antiepileptic drug such as clobazam; (2) cyclic administration of acetazolamide, a mild diuretic with weak antiepileptic activity; and (3) progesterone supplementation by mouth or suppository. The allopregnanolone analogue ganaxolone (3α-hydroxy-3β-methyl-5β-pregnane- 20-one), a positive allosteric modulator of GABA-A receptors, may diminish epileptic activity in adults with partial-onset seizures and children with refractory infantile spasms. This neurosteroid appears to be well tolerated and, importantly, lacks hormonal activity.

With respect to gestational epilepsy, factors such as maternal sleep deprivation, stress, and inadequate anticonvulsant levels are probably more important than direct hormonal epileptogenesis. During pregnancy, serum levels of phenytoin, phenobarbital, and valproic acid may decrease by 30 to 40 percent of pregestational levels, with a lesser decline in carbamazepine. Primidone levels are reportedly stable during pregnancy, but the concentration of primidone-derived phenobarbital is reduced. Decreased drug compliance, bioavailability, and protein binding, as well as an increased volume of distribution and metabolic clearance, are factors contributing to the fall in anticonvulsant levels during pregnancy. The influences of the menstrual cycle and of oral contraceptive preparations on anticonvulsant disposition appear to be of minor clinical significance.

Movement Disorders

CHOREA

Pregnancy and steroid contraceptive therapy have infrequently been complicated by the acute or subacute development of choreiform movements of the face and extremities associated with limb hypotonia and pendular reflexes. Fever, dysarthria, and neuropsychiatric symptoms may complete the clinical picture. Gestational and oral contraceptive-related chorea have a close association with previous rheumatic fever and Sydenham chorea.

Estrogen-containing medications may elicit chorea in patients with a history of congenital cyanotic heart disease, Henoch–Schönlein purpura, systemic lupus erythematosus, and antiphospholipid antibody syndrome and exacerbate dyskinesias in chorea-acanthocytosis. Pharmacologic, epidemiologic, and pathologic evidence suggests that altered hormonal patterns characteristic of pregnancy and ingestion of oral contraceptives may unmask latent chorea by modulating dopaminergic neurotransmission in basal ganglia previously damaged by rheumatic or hypoxic encephalopathy. In most cases, chorea gravidarum and oral contraceptive-related dyskinesias resolve completely by the end of pregnancy or after discontinuation of the medication, respectively. As many as 20 percent of women experience recurrences of chorea with subsequent pregnancies. Patients with chorea gravidarum are at increased risk of later developing oral contraceptive-related dyskinesias, and vice versa.

In patients with suspected chorea gravidarum, appropriate clinical and laboratory investigations may be required to exclude other causes of chorea, such as acute rheumatic fever, systemic lupus erythematosus, hyperthyroidism, and Wilson disease. Chorea gravidarum is usually self-limited, and abortion or premature delivery is rarely indicated. Judicious use of neuroleptics or other medications may afford symptomatic relief in severe cases. Women with a history of gestational or oral contraceptive-induced chorea should probably minimize further exposure to any estrogen-containing medications.

PARKINSONISM

There are anecdotal reports in the early clinical literature of motor deterioration in idiopathic and neuroleptic-induced parkinsonism after exposure to exogenous estrogen. Furthermore, premenopausal women were reportedly more susceptible to drug-induced parkinsonism than men of similar age. These observations argued for a potentially antidopaminergic role of estrogen in this condition. Yet, in subsequent studies of premenopausal women with idiopathic Parkinson disease, motor symptoms were noted to worsen premenstrually when estrogen titers were falling, favoring a stimulatory influence of estrogen on striatal dopamine. Data from several studies suggest that postmenopausal estrogen replacement is beneficial in women with Parkinson disease. In other studies, postmenopausal estrogen therapy either had no significant dopaminergic effect or was associated with worsening motor scores. Epidemiologic studies suggested that early menopause (natural or surgical) may be a risk factor for the development of Parkinson disease and that the latter may be offset by postmenopausal estrogen replacement. However, larger prospective studies have disclosed no evidence of a beneficial effect of exogenous or endogenous estrogens on the risk of developing Parkinson disease. Exposure to oral contraceptives may be a risk factor for the disease, and polymorphisms of the estrogen receptor-β gene (an important mediator of estrogenic effects on the nigrostriatal pathway), although not associated with an overall risk of contracting Parkinson disease, may impact the age of symptom onset. Several studies have documented that exposure to the antiestrogen tamoxifen may substantially augment the risk of contracting Parkinson disease in women with breast cancer. Of potential therapeutic relevance, CSF and plasma concentrations of allopregnanolone are reportedly low in idiopathic Parkinson disease and this neurosteroid stimulates neurogenesis in the substantia nigra, modulates dopamine release, and improves motor control in animal models of the disease.[2]

WILSON DISEASE

Wilson disease is an inborn error of copper metabolism that is characterized by hepatic cirrhosis and degenerative changes in the basal ganglia. Patients exhibit decreased serum ceruloplasmin levels, increased plasma levels of nonceruloplasmin copper, and reduced biliary excretion of the heavy metal. Movement disorders, seizures, and psychosis result from the toxic effects of excessive copper deposition in neural tissues. In normal individuals, serum ceruloplasmin and copper levels increase during pregnancy and after administration of estrogen or estrogen–progestogen contraceptives. The rise in ceruloplasmin resulting from exposure to oral contraceptives is responsible for the green-tinged serum occasionally noted in these women. In patients with Wilson disease, increased serum ceruloplasmin levels occur during pregnancy and after treatment with exogenous estrogens. Effects on serum copper, however, are inconsistent. Normalization of serum ceruloplasmin levels by estrogen administration has no therapeutic benefit, and such exposure sometimes leads to neurologic deterioration. Exposure to hormonal contraceptives may yield "falsely normal" ceruloplasmin levels in patients with Wilson disease, resulting in a delay in diagnosis. Whether sex hormones similarly raise blood ceruloplasmin concentrations in other conditions featuring low levels of the protein, such as hypoceruloplasminemia and acquired copper deficiency, remains to be determined.

OTHER MOVEMENT DISORDERS

A broad spectrum of movement disturbances may be influenced by prior or current sex steroid exposure. Included are cases of posthypoxic and hereditary myoclonus, dominantly inherited myoclonic dystonia, tardive dyskinesia, hemiballismus, drop attacks, familial episodic ataxia, Gilles de la Tourette syndrome, the neuroleptic malignant syndrome, essential tremor, restless legs syndrome, and progressive supranuclear palsy.[3]

Nervous System Neoplasms

MENINGIOMAS

Meningiomas occur more frequently in women than men and are rarely diagnosed before puberty or during the senium, corresponding to the time of maximal gonadal activity. They are more common in patients with hormone-dependent breast carcinoma and in obese women, perhaps because of higher circulating estrogen levels derived from the aromatization of androstenedione to estrone in adipocytes. Meningiomas have been documented clinically and radiologically to undergo relatively rapid expansion during pregnancy, followed by spontaneous regression postpartum. Some women suffer exacerbations of symptoms in the luteal phase of the menstrual cycle. These fluctuations in tumor size have been attributed to steroid-induced fluid retention by the lesion, increased vascular engorgement of the tumor, and direct trophic effects of gonadal hormones on meningioma cells. Although there is an increase in the incidence of meningioma in women receiving HRT, this should not influence the practice of HRT as the overall frequency of meningiomas in this population remains low.

Numerous investigators have demonstrated the presence of progestin- and, to a lesser extent, estrogen- and androgen-binding proteins in a significant number of human meningioma specimens. These observations suggest that progestins and possibly other gonadal steroids may directly modify the growth and differentiation of these tumors. The presence of progestin receptors may indicate a more favorable prognosis because progesterone receptor-negative meningiomas have been associated with a greater tendency for brain invasiveness, higher mitotic indices and necrosis, and shorter disease-free intervals. Although the antiestrogen tamoxifen does not appreciably affect tumor size or neurologic status in patients with inoperable meningiomas, the antiprogestin RU486 has been reported to induce stabilization or regression of meningiomas, suggesting that antiprogesterone therapy may be useful in the management of these tumors. However, the effects of progestins and RU486 on meningioma growth in vitro are contradictory, and patients chronically treated with RU486 may require glucocorticoid replacement to counteract its antiglucocorticoid effects. Of note, gender-affirming treatment with estrogens, progestogens, or cyproterone acetate (a progestin with antiandrogen activity) may promote meningioma growth in transgender women.

GLIOMAS

There are anecdotal reports of astrocytomas enlarging during pregnancy, only to shrink spontaneously in the puerperium. As in the case of meningiomas, certain human gliomas may selectively bind estrogens, progestins, and androgens. Some may also contain enzymes (e.g., 17β-oxidoreductase and aromatase) that catalyze steroid hormone interconversions. The origin of putative steroid receptors in glial cell tumors is obscure, although significant numbers of normal astrocytes in certain brain regions possess estrogen receptors. Astroglial tumors predominantly express estrogen receptor-β, and expression levels reportedly decline with increasing histologic grade of malignancy. High-dose tamoxifen therapy may result in clinical and radiologic stabilization of astrocytomas and glioblastoma multiforme in some patients. These benefits are more likely to be due to the inhibitory effects of tamoxifen on protein kinase C or its role as a radiosensitizer than to any accruing antiestrogenic activity. Human oligodendrogliomas have also been reported to contain sex steroid receptors and could theoretically be subject to hormonal manipulations.

OTHER TUMORS

Acoustic neuromas, pituitary adenomas, and breast cancer metastases to the nervous system may also be responsive to sex hormones. Sex steroid receptors have also been reported in hemangioblastomas, anaplastic ependymomas, malignant lymphomas, melanomas, renal cell carcinomas, medulloblastomas, and primitive neuroectodermal tumors, suggesting that the natural history of these neoplasms may be influenced by sex hormones and their antagonists.

Multiple Sclerosis

Multiple sclerosis (MS) is an immune-mediated demyelinating disorder of the central nervous system (CNS) that often occurs during the reproductive years. An association between specific *ESR1* gene polymorphisms and MS has been reported in some studies but not others and may be population dependent.

Epidemiologic studies have indicated that the overall effect of age at menarche, pregnancies, and breastfeeding on MS-related morbidity is nil.[4] As discussed in Chapter 31, subsequent studies involving larger patient cohorts have amply demonstrated a tendency for MS exacerbation during the first 3 postpartum months that is counterbalanced by significant suppression of disease activity in the third trimester. Indeed, the approximately 70 percent reduction in the relapse rate of MS in the third trimester is more robust than that accruing from interferon-β, glatiramer acetate, or intravenous immunoglobulin therapy. Immunomodulation that is necessary to prevent rejection of the semiallogenic fetus is probably responsible for the dampening of third-trimester disease activity in MS and other immune-mediated conditions. Factors that have been implicated in gestational immunosuppression include estradiol, progesterone, human chorionic gonadotropin, human placental lactogen, cortisol, 1,25-dihydroxyvitamin D_3, α-fetoprotein, pregnancy-associated glycoprotein, "blocking antibodies," immune complexes, and interleukin-10. If necessary, intravenous steroids can be used for MS attacks in pregnancy. Interferon-β should be discontinued 3 months before planned conception and should not be used during pregnancy or while breastfeeding.

Earlier age at puberty may be a predisposing factor for MS in girls but not boys. Although the risk of developing MS does not appear to be impacted by oral contraceptive use, the latter may delay the onset of the disease. The disease-modifying therapies dimethyl fumarate and fingolimod do not appear to diminish the effectiveness of hormonal contraception. Less is known regarding the potential impact of cladribine and anti-MS biologics on sex steroid metabolism. Finally, there are early studies reporting potentially beneficial effects of oral estriol in women with MS.

Alzheimer Disease

Alzheimer disease is a common dementing illness characterized by progressive neuronal degeneration, gliosis, marked depletion of acetylcholine and other neurotransmitter disturbances, and the accumulation of senile (amyloid) plaques and neurofibrillary tangles in discrete regions of the basal forebrain, hippocampus, and association cortex. By the turn of the millennium, there were promising reports suggesting that estrogens play an important role in normal human cognition, have a salutary effect on the manifestations of Alzheimer disease, and may even protect against the development of this neurodegenerative disorder in women. Fundamental research indicates that estrogens exert trophic influences on cholinergic neurons of the rodent basal forebrain, induce dendritic spines (synapses) and functional *N*-methyl-D-aspartate (NMDA) receptors (important for memory) in adult rat hippocampus, and induce massive neuritic growth in rodent hypothalamic explants. In addition, estrogens were shown to manifest antioxidant properties, reduce the deposition of fibrillar β-amyloid, modulate apolipoprotein E expression, suppress inflammatory responses implicated in neuritic plaque formation, increase cerebral blood flow and glucose utilization (which are deficient in subjects with Alzheimer disease) and stabilize microRNA expression patterns and mitochondrial bioenergetics.[5] There is also accumulating evidence that estrogens improve cognitive behaviors in rats and monkeys; that psychometric performance in women is influenced by the menstrual cycle phase; that transgender hormone therapy affects cognition in transsexual men and women; and that estrogen replacement therapy augments verbal memory scores in normal menopausal women. Moreover, early clinical studies suggested that estrogen replacement therapy may improve cognitive performance, especially language function, verbal memory, and attention, in menopausal women with Alzheimer disease, and enhance the likelihood of a beneficial response to acetylcholinesterase inhibitors in affected women. In several studies, postmenopausal estrogen replacement therapy appears to be associated with a significantly decreased risk of developing Alzheimer disease. There was some indication that postmenopausal estrogen replacement therapy protected against the development of dementia in women with Parkinson disease and that androgen (testosterone) or estrogen treatment conferred cognitive benefits in elderly men with Alzheimer disease or mild cognitive impairment. Lower postmenopausal estradiol levels have also been associated with increased risk of dementia in persons with Down syndrome.

The results of other large, randomized, placebo-controlled prospective trials evaluating the potential benefits of sex HRT in preventing the dementia of Alzheimer disease have been disappointing. Age-adjusted cognitive function scores are no different in women with coronary artery disease who received estrogen and progestin than in placebo-treated controls. Some studies have even demonstrated a slightly higher risk of dementia with HRT compared with placebo-treated controls. Of note, certain polymorphisms of the follicle-stimulating hormone receptor may confer protection against the disease in women (but not men).

The third Canadian Consensus Conference for the Diagnosis and Treatment of Dementia (2006) recommended against the use of estrogen/progestin replacement therapy for reducing the risk of dementia in postmenopausal women. It was also concluded that there is insufficient evidence for or against prescription of androgen replacement for cognitive dysfunction in elderly men. Since these recommendations were published, it has been hypothesized that there may be a critical perimenopausal "window" during which HRT may protect against the development of Alzheimer disease.[5] Importantly, the purportedly salutary influences of estrogen on cognition and hippocampal volumes may be offset in aging women bearing one or two copies of the apolipoprotein E ε4 allele. Regarding androgens, higher serum levels of bioavailable testosterone in late life predict a diminished risk of developing Alzheimer disease in men, perhaps due to androgen-induced down-modulation of brain β-amyloid deposition. Prospective clinical trials amply powered to determine the efficacy of androgen treatment in forestalling dementia in men (and possibly women) may be warranted.

Neurosteroidogenesis has also been implicated in the pathophysiology of Alzheimer disease. There are reports of reduced levels of DHEA-S in the plasma and cerebrospinal fluid and allopregnanolone concentrations in the prefrontal cortex of persons with Alzheimer disease. Allopregnanolone may contribute to cognitive well-being insofar as it suppresses neuroinflammation (microglial activation), diminishes β-amyloid pathology, increases hippocampal neurogenesis, and reverses learning and memory deficits in animal models of Alzheimer disease.

Neuropsychiatric Disorders

THE PORPHYRIAS

The porphyrias are characterized by the excessive production of porphyrins and porphyrin precursors resulting from specific enzymatic defects in the heme biosynthetic pathway. Neurologic manifestations, when present, include seizures, neuropsychiatric symptoms, and sensorimotor and autonomic neuropathies. Estradiol and other steroids with a 5β configuration induce the enzyme δ-aminolevulinic acid synthase and may thereby precipitate porphyric crises. Oral contraceptives increase urinary excretion of this enzyme in normal individuals, and it has been suggested that asymptomatic relatives of patients with porphyria should avoid oral contraceptives. In many women with acute intermittent porphyria, cyclic attacks of variable severity occur during the late luteal phase or, less commonly, at ovulation. New-onset acute intermittent porphyria has also been reported as a result of controlled ovarian hyperstimulation for in vitro fertilization. Paradoxically, some patients exhibit prolonged remissions after suppression of ovarian cyclicity with oral contraceptives.

Although acute treatment with gonadotropin-releasing hormone (GnRH) agonists, such as d-His or leuprolide, stimulates the pituitary–ovarian axis, chronic administration of these agents downregulates gonadotrope GnRH receptors, resulting in long-term suppression of pituitary–ovarian function. d-His administration (5 μg subcutaneously daily) yielded complete remission of severe premenstrual acute intermittent porphyria for the duration (8 months) of therapy in a single patient; similar benefits were observed in subsequent cases of catamenial acute intermittent porphyria and hereditary coproporphyria in response to GnRH analogue therapy. Side effects of long-term GnRH treatment include hot flashes, diminished breast size, and bone demineralization. GnRH analogues, unlike sex steroids, do not appear to induce porphyrin accumulation in chick embryo hepatic cell culture and provide a rational approach to the management of catamenial porphyria.

PREMENSTRUAL SYNDROME

The premenstrual syndrome (or premenstrual dysphoric disorder) occurs in approximately 30 percent of women during their reproductive years. Common neuropsychiatric symptoms include headache, fatigue, depression, irritability, increased thirst or appetite, and craving for sweet or salty foods. Symptoms typically begin toward the end of the luteal phase of the cycle and usually, but not invariably, resolve with the onset of flow. The pathophysiology of this disorder remains obscure. An increased luteal-phase estrogen–progesterone ratio, hyperprolactinemia, disturbances of the renin–angiotensin–aldosterone axis, hypothyroidism, and abnormal secretion of opioid peptides are among the causes considered for this enigmatic condition.

Numerous hormonal and nonhormonal therapies—including natural progesterone, oral contraceptives, bromocriptine, GnRH agonists, diuretics, drospirenone, prostaglandin inhibitors, vitamin B_6, calcium supplements, *Vitex agnus castus* (chasteberry), selective serotonin reuptake inhibitors, and lithium—are prescribed for the management of premenstrual syndrome. In many cases, the efficacy of these treatments remains uncertain. Induction of "artificial menopause" with a GnRH agonist (d-Trp-Pro-NEt-Gn-RH, 50 μg/day subcutaneously) relieves both physical and neuropsychiatric symptoms in women with rigorously defined premenstrual syndrome; prolonged hypoestrogenemia resulting from the long-term use of these agents may predispose to osteoporosis. Such therapy should probably be reserved for patients with incapacitating symptoms, and low-dose estrogen replacement may have to be considered when the duration of treatment exceeds several months. Continuous daily administration of levonorgestrel 90 μg/ethinyl estradiol 20 μg is well tolerated and possibly useful in controlling the physical, psychologic, and behavioral symptoms of the premenstrual syndrome.

DEPRESSION AND PSYCHOSIS

Depression and other major affective disorders may surface in relation to the menstrual cycle, the puerperium, and menopause. Approximately 15 percent of women experience postpartum depression, whereas 50 to 80 percent report milder dysphoria ("maternal blues"). In patients with postmenopausal depression, mood elevation and anxiolysis often occur promptly in response to estrogen replacement. Paradoxically, oral contraceptives may precipitate depression in susceptible individuals. Estrogen has also been implicated in the pathogenesis of anorexia nervosa because of the high preponderance of this condition in women and the potent anorexic effects of estrogen in animals.

Psychotic disorders characterized by extreme agitation, hallucinations, paranoid delusions, incoherent speech, and mood lability may arise during the postpartum period, may recur consistently during the late luteal phase of the cycle, and may complicate withdrawal of estrogen replacement therapy in transgendered women. Such disorders may be refractory to conventional therapies (e.g., neuroleptics, lithium, electroconvulsive treatment) but may respond well to specific hormonal interventions, including the use of oral contraceptives, intramuscular progesterone, and danazol. "Menopause" induced by GnRH analogues may also be of considerable benefit in the management of cyclical psychosis. Transdermal estradiol has been shown to be an effective adjunctive therapy for women of childbearing age with treatment-resistant schizophrenia. Furthermore, adjuvant therapy with tamoxifen reduces the frequency of manic episodes in patients with bipolar disease, and the estrogen receptor modulator raloxifene ameliorates cognitive and psychologic deficits in men and women with schizophrenia. Estrogen receptor-α polymorphisms have been associated with symptoms of autism in Chinese Han children, although little is known concerning the clinical effects of sex hormone manipulation in persons with autistic spectrum disorders.

Sleep Disorders

Estrogen and progestin replacement may shorten mean sleep latencies, extend the duration of rapid-eye-movement sleep periods, and diminish nocturnal movement arousals, thereby improving sleep in hypogonadal women. The GABA-active metabolites allopregnanolone and pregnanolone may mediate the reduction in vigilance during wakefulness observed after the administration of progesterone to healthy men. Progestins may also provide stimulatory drive to brainstem respiratory centers in subjects with central sleep apnea and thereby improve hypoventilation. The hypocapnic apnea threshold is lower in women than men, and testosterone administration increases this threshold in premenopausal women. In men, obstructive sleep apnea may correlate with low serum testosterone levels. Menopause has been associated with attenuation of circadian rhythmicity and an increase in sleep-disordered breathing. Estrogen plus progesterone has been shown to decrease the prevalence of nocturnal arousals, breathing irregularities, periodic limb movements, hot flashes, and bruxism.

Intracranial Hypertension

Progesterone suppresses post-traumatic cerebral edema and intracranial hypertension in rodents. This progestational effect has been attributed to reduction in blood–brain barrier permeability and inhibition of cerebrospinal fluid production by the choroid plexus. Estrogens, by contrast, appear to enhance cerebral endothelial cell permeability and post-traumatic brain edema in female rats. Estrogenic attenuation of the blood–brain barrier may also play a role in the pathogenesis of pseudotumor cerebri (idiopathic intracranial hypertension) in humans and explain the robust female predilection for this disorder. Idiopathic intracranial hypertension may be over-represented in women with the polycystic ovarian syndrome and hyperandrogenism, and in female-to-male transgender persons receiving intramuscular testosterone. Data concerning the risk of pseudotumor cerebri in women exposed to hormonal contraception are conflicting.[6]

Neuromuscular Diseases

Catamenial Sciatica

Ectopic endometrial tissue (endometriosis) is hormone sensitive and undergoes epithelial sloughing and hemorrhaging at the time of menses. Ectopic endometrial tissue may destroy lumbar vertebrae, producing back pain, invade the lumbosacral plexus in the retroperitoneal space, and implant within the sheath of the sciatic nerve. In this last instance, radicular pain in the distribution of the nerve usually begins 2 to 3 days before the onset of menses and may continue for a variable duration after cessation of flow (catamenial sciatica). In addition to pain, there is often numbness, weakness, and loss of ankle reflexes. In contrast to far more common discogenic radiculopathy, endometriotic sciatica is less likely to respond to bed rest, and the imaging findings are usually unimpressive. There may be evidence of endometriosis elsewhere, and surgical exploration of the sciatic nerve may be required for diagnosis. In positive cases, the nerve appears blue, and a dark hemorrhagic fluid is expressed after incision of the sheath. Biopsy specimens reveal characteristic glandular elements. Symptoms of catamenial sciatica may show dramatic improvement with standard therapy for endometriosis, including danazol, progestins, GnRH agonist, and in refractory cases, bilateral oophorectomy.

Other Neuromuscular Disorders

Endogenous and administered sex hormones (mainly estrogens) may influence the natural history of Bell palsy, recurrent brachial plexopathy, and carpal tunnel syndrome. Abnormally high estrogen levels have been reported in male patients with amyotrophic lateral sclerosis, Kugelberg–Welander disease, bulbospinal muscular atrophy (Kennedy syndrome), Duchenne muscular dystrophy, and the Crow–Fukase syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes [POEMS syndrome], usually associated with plasma cell dyscrasias). It is unclear whether hyperestrogenemia plays any significant role in the pathogenesis of these neuromuscular disorders. Initial results suggesting that the GnRH agonist leuprorelin improves swallowing in patients with bulbospinal muscular atrophy could not be confirmed in subsequent phase 3 studies. Dysfunction of testicular peritubular myoid cells and corpus cavernosum smooth muscle contributes to the hypergonadotropic hypogonadism and impotence that complicate myotonic dystrophy in men.

PITUITARY GLAND

The endocrine and nervous systems interact in intricate ways, and disorders in one system may cause dysfunction of the other in diverse ways. For example, small anterior pituitary tumors produce symptoms principally as the result of hormonal excess, but large tumors cause symptoms of either hypersecretion or hyposecretion as well as dysfunction of adjacent cranial nerves or cerebral structures. The protean clinical features of hormonal excess and deficiency states include both central and peripheral nervous system dysfunction.

The complex anatomy of the sellar region influences the clinical features of pituitary disorders.[7,8] The pituitary gland, or hypophysis, sits in a bony depression in the posterior sphenoid bone called the sella turcica, bounded anteriorly by the tuberculum sellae and anterior clinoid process and posteriorly by the dorsum sellae. Dural reflections border the pituitary superiorly and laterally. The diaphragma sellae forms the roof of the sella turcica and lies beneath the optic chiasm. Adjacent bilaterally is the cavernous sinus, through which passes the internal carotid artery and cranial nerves III, IV, V (upper two divisions), and VI. In addition the cavernous sinus serves to drain the ophthalmic and middle and inferior cerebral veins.

The anterior pituitary, or adenohypophysis, derives embryologically from Rathke pouch, of ectodermal origin, and has blood supplied by the hypophyseal-portal system. Hormones secreted by the anterior pituitary include prolactin, growth hormone (GH), adrenocorticotropic hormone (ACTH), thyrotropin (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The hypothalamus controls anterior pituitary hormone secretions through various hypophysiotropic substances, most of which are peptides (Table 20-1).[8] The hypophyseal-portal system provides the basis for feedback loops that regulate the hypothalamic–pituitary axis.

The posterior pituitary, known also as the neurohypophysis or pars nervosa, derives from a neuroectodermal extension of diencephalon that fuses with Rathke pouch. Also of neuroectodermal origin is the infundibulum linking the pituitary to the hypothalamus at the median eminence, which also forms the floor of the third ventricle. The inferior hypophyseal artery, a branch of the intracavernous carotid, supplies the neurohypophysis. Neurohypophyseal hormones include oxytocin and antidiuretic hormone (ADH) or arginine vasopressin.

The juxtaposition of the pituitary gland to hypothalamus, third ventricle, intracavernous carotid arteries, and cranial nerves related to vision, extraocular movements, and mid- and upper facial sensation accounts for many of the neurologic manifestations of lesions in and around the sella. Endocrine disturbances arising from excess or insufficient secretion of one or more pituitary hormones may also cause neurologic as well as systemic symptoms and signs, and laboratory abnormalities. Advances in neuroimaging have greatly facilitated assessment of sellar and parasellar lesions.[7] A detailed discussion of the increasingly complex array of stimulation and inhibition studies used to assess the integrity of specific elements of the hypothalamic–pituitary axis is provided elsewhere.[8] However, a basic understanding of pituitary hormone physiology is essential to evaluating patients with mass lesions in and around the gland and it is reviewed here after a discussion of the neurologic symptoms and signs resulting from these lesions.

TABLE 20-1 ■ Anterior Pituitary and Hypothalamic Hormones

Pituitary Hormone	Hypothalamic Factor
Prolactin	Dopamine (inhibitory)
Growth hormone (GH)	Growth hormone-releasing hormone (GHRH) Somatostatin (inhibitory)
Adrenocorticotropin (ACTH)	Corticotropin-releasing hormone (CRH)
Thyrotropin (TSH)	Thyrotropin-releasing hormone (TRH)
Luteinizing hormone (LH) and follicle-stimulating hormone (FSH)	Gonadotropin-releasing hormone (GnRH)

Sellar and Parasellar Lesions

Pituitary adenomas are the most common mass in the sellar region and account for up to 25 percent of intracranial neoplasms. Previous classification schemes based on histologic staining properties have given way to categorization based on hormone secretion.[8,9] Pituitary adenomas are also classified by size. Microadenomas (Fig. 20-2A), lesions that are 10 mm or smaller, typically spare adjacent neural or vascular structures and generally come to medical attention during evaluation for symptoms and signs of hormone oversecretion. Lesions larger than 10 mm, known as macroadenomas, or ≥40 mm, known as giant adenomas (Fig. 20-2B), also may present with manifestations of hormone excess (~two-thirds of pituitary adenomas) or may impair normal glandular function, resulting in hypopituitarism. When macroadenomas compress adjacent neural or

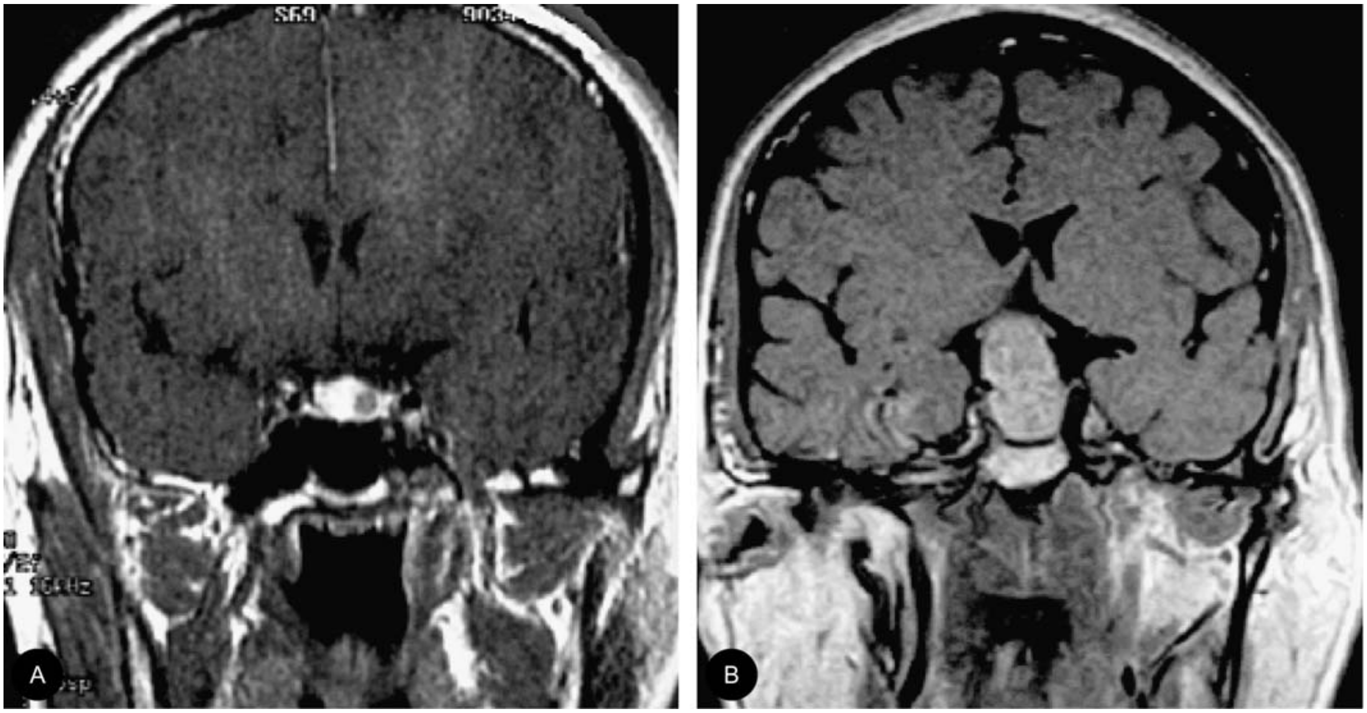

FIGURE 20-2 ■ Neuroimaging of pituitary adenoma. *A*, Microadenoma. Gadolinium-enhanced T1-weighted magnetic resonance imaging (MRI) shows a small focus of decreased enhancement compatible with microadenoma in a young woman with galactorrhea-amenorrhea. *B*, Macroadenoma. Large sellar lesion, subsequently shown to be a nonsecretory adenoma, in a gadolinium-enhanced T1-weighted MRI obtained in a middle-aged man with progressive visual loss.

vascular structures, neurologic dysfunction, such as headache, visual loss, ophthalmoparesis, and facial sensory symptoms, may develop.[7–9] Adenoma size does not correlate with headache, which may have features similar to migraine or trigeminal autonomic cephalgia. Macroadenomas extending superiorly may compress the optic chiasm, nerves, or tracts. Bitemporal hemianopia is the classic consequence, although monocular visual loss or junctional scotoma also may occur. Because adenomas grow slowly, patients may not appreciate visual deficits until they are quite advanced. Third ventricular extension occasionally causes acute or chronic hydrocephalus. Lateral extension, with subsequent cavernous sinus involvement, disturbs extraocular motility and sensation in the upper and middle face. Very large lesions involving inferior frontal or medial temporal lobes are rare but may cause cognitive impairment, behavioral changes, or seizures. A few pituitary tumors extend inferiorly, causing epistaxis or CSF rhinorrhea.

Pituitary adenomas account for 90 percent of masses in the sellar region, with other pituitary tumors, nonpituitary neoplasms, metastases, infectious and inflammatory disorders, vascular lesions, and cysts accounting for the rest (Table 20-2).[7] Craniopharyngiomas arise from epithelial cell rests of Rathke pouch. Among malignant lesions, pituitary carcinomas are quite rare, and metastases to the pituitary are recognized more frequently at autopsy than during life.

Among more common disorders, primary empty sella is often associated with an incompetent diaphragma sellae, which allows arachnoid and CSF to herniate into the sella. Typically an incidental finding on neuroimaging studies, primary empty sella syndrome is not usually associated with endocrinopathy. Secondary empty sella occurs after spontaneous or treatment-induced regression of pituitary disease. Other important non-neoplastic sellar lesions include granulomatous processes, such as tuberculosis or sarcoidosis, and vascular lesions such as aneurysms of the intracavernous carotid artery.

Magnetic resonance imaging (MRI) before and after gadolinium enhancement, with high-resolution thin sections in the sagittal and coronal planes, is the test of choice for pituitary-region imaging. On T1-weighted images, high signal intensity in the posterior pituitary is referred to as the “bright spot” and is

TABLE 20-2 ■ Differential Diagnosis of Sellar Masses

Neoplasms

- Pituitary origin
  - Anterior: pituitary adenoma or carcinoma
  - Posterior: granular cell tumor, stalk or posterior lobe astrocytoma
- Nonpituitary origin
  - Craniopharyngioma
  - Germ cell tumor
  - Meningioma
  - Glioma (hypothalamic, optic nerve, or chiasm)
  - Skull base: chordoma, giant cell tumor, fibrous dysplasia
- Others
  - Lipoma
  - Hemangioblastoma
  - Sarcoma
  - Schwannoma
  - Paraganglioma
  - Esthesioneuroblastoma
- Metastatic
  - Carcinoma
  - Melanoma
  - Hematopoietic malignancies

Vascular lesions

- Intracavernous carotid aneurysm
- Cavernous sinus thrombosis
- Pituitary apoplexy

Cysts

- Rathke cleft cyst
- Arachnoid cyst
- Epidermoid
- Dermoid

Inflammatory disorders

- Granulomatous: sarcoidosis, tuberculosis, syphilitic gumma, giant cell granuloma
- Pituitary abscess
- Lymphocytic hypophysitis
- Histiocytosis
- Mucocele

Empty sella syndrome

Pituitary hypertrophy

- Puberty (in girls)
- Pregnancy
- Chronic primary hypothyroidism

believed to represent ADH in neurosecretory vessels.[7] Pituitary adenomas typically enhance less intensely than normal glandular tissue (Fig. 20-2A). In patients who cannot undergo MRI, precontrast and postcontrast computed tomography (CT) images through the area can be obtained. A consequence of modern neuroimaging is detection of the asymptomatic pituitary mass, the so-called pituitary "incidentaloma."[9]

Anterior Pituitary

PROLACTIN

Prolactin acts on mammary tissue to promote lactation and inhibit cyclic gonadotropin secretion. Hypothalamic control of prolactin secretion occurs primarily by inhibition, and thus pituitary stalk disruption from lesions other than prolactinomas may elevate serum prolactin levels, although rarely above 200 μg/L (normal <25 μg/L).[8] Dopamine is the major inhibitory factor. Accordingly, neuroleptics and other dopamine antagonists can cause mild hyperprolactinemia, although the risk may be lower for some atypical antipsychotics; dopaminergic drugs are therefore used therapeutically to lower prolactin levels.[8,9] Prolactin-releasing factors are less well understood, although thyrotropin-releasing factor (TRH) plays a role. Consequently, in primary hypothyroidism, when TRH is elevated, the resulting hyperprolactinemia and pituitary enlargement may cause diagnostic confusion with prolactinoma.[9] The differential diagnosis of hyperprolactinemia (Table 20-3) also includes pregnancy, lactation, and chest wall stimulation.[8,9] Serum prolactin may be modestly increased in the first hour after a generalized tonic-clonic or complex partial seizure. However, recent studies of prolactin levels in patients with psychogenic nonepileptic spells suggest that elevated levels have limited usefulness in the differentiation of epileptic from nonepileptic seizures.

Amenorrhea-galactorrhea in women and impotence and decreased libido in men should prompt consideration of hyperprolactinemia. In the absence of venipuncture stress, an elevated serum prolactin level establishes the diagnosis, and further evaluation should include medication history and laboratory screening for chronic kidney disease and hypothyroidism. Prolactinomas account for approximately 50 percent of hormonally active pituitary adenomas.[9] Prolactin levels exceeding 250 μg/L suggest prolactinoma, with levels above 500 μg/L diagnostic of macroprolactinoma. Values lower than this may be seen with any type of macroadenoma due to stalk compression or as a consequence of the "hook effect," whereby the radioimmunoassay used to determine serum prolactin

TABLE 20-3 ■ Differential Diagnosis of Hyperprolactinemia

Physiologic
Pregnancy, lactation
Metabolic
Primary hypothyroidism, chronic kidney disease, cirrhosis, adrenal insufficiency
Medications—Neuroleptics, tricyclic antidepressants, SSRIs, verapamil, metoclopramide
Estrogens
Neurogenic
Chest wall injury, herpes zoster, breast stimulation, spinal cord lesion
Pituitary disease—acromegaly, Cushing disease
Prolactinoma, other pituitary adenomas or tumors, stalk section, granulomatous infiltration
Hypothalamic/Stalk Disease
Neoplastic, vascular, inflammatory, post-irradiation, severe head trauma
Seizures, stress, macroprolactinemia, idiopathic

returns a falsely low value in severe hyperprolactinemia.[8,9] Performing the assay with diluted serum samples reveals the true, markedly elevated prolactin level and should be requested when prolactin levels are not markedly elevated in a patient with a macroadenoma.

Amenorrhea-galactorrhea and infertility bring women to early medical attention, and thus microprolactinomas predominate. Symptoms of hypogonadism in men—impotence, loss of libido, and infertility—may not as reliably trigger measurement of serum prolactin level. Consequently, macroprolactinomas are more common in men, classically presenting with headache or visual impairment. Medical therapy with dopamine agonists decreases prolactin levels, reverses hypogonadism, and shrinks approximately 75 percent of macroprolactinomas and an even higher percentage of microprolactinomas.[9] Cabergoline is better tolerated and more effective than bromocriptine, and is thus the preferred drug. Surgery is typically reserved for patients with acute visual impairment or who do not improve or tolerate therapy with dopaminergic agents. As is the case for medical therapy, surgical outcomes are better for patients with microadenomas than macroadenomas. Trans-sphenoidal approaches are favored, although large, invasive tumors may require bifrontal craniotomy. Regardless of whether the treatment plans include medication, surgery, or both, patients require monitoring with serial clinical assessment, prolactin levels, visual field testing, and neuroimaging.[9] Radiation therapy is used primarily when medical and surgical approaches have been unsuccessful. Newer radiotherapy techniques may be safer or more effective than conventional radiotherapy.[10]

GROWTH HORMONE

Secretion of GH, a 191-amino-acid polypeptide, is regulated by stimulatory (GH-releasing hormone) and inhibitory (somatostatin) hypothalamic factors. Secretory dynamics are complex; factors that influence pulsatile GH secretion include age, nutritional state, and sleep. GH stimulates skeletal growth and exerts a variety of metabolic effects, including glucose intolerance. The action of GH is mediated by its receptors in liver, bone, and fat, as well as by induction of insulin-like growth factor I (IGF-I).

Excessive circulating GH before epiphyseal fusion in children leads to gigantism. In adults, sustained GH excess causes acromegaly, which results from pituitary hypersecretion in nearly all cases. Coarsened facial features and enlargement of hands and feet may only be recognized in retrospect and are an infrequent presenting complaint. The diverse systemic manifestations include hyperhidrosis, reproductive dysfunction, skin tags, colonic polyps, arthropathy, hypertension, hyperlipidemia, diabetes, and sleep apnea.[9] Neurologic symptoms include proximal weakness and compression of neural structures by bony and soft tissue overgrowth causing, for example, carpal tunnel syndrome.[8–10] Macroadenomas are identified in most cases, and symptoms of an expanding sellar mass may bring patients to clinical attention. The pulsatile nature of GH secretion limits the diagnostic utility of random GH determination, hence elevated serum IGF-1 level establishes the biochemical diagnosis of acromegaly. Autonomous GH secretion may be demonstrated by lack of appropriate GH suppression during an oral glucose tolerance test. Other important diagnostic tests include neuroimaging studies, visual field testing, serum prolactin level, and evaluation for panhypopituitarism and complications of acromegaly, in particular cardiovascular and bony disease, and colonic polyps.

Cosmetic disfigurement and chronic pain impair quality of life, and patients with untreated acromegaly risk premature death from diabetes, hypertension, cardiovascular disease, and colon cancer. Normalizing GH and IGF-1 is the therapeutic goal, and decreases long-term mortality. Trans-sphenoidal resection is the primary treatment of choice for microadenomas and macroadenomas. Expert pituitary neurosurgeons can normalize GH and IGF levels with reduction or elimination of tumor mass in 80 to 90 percent of microadenomas and 40 to 60 percent of macroadenomas. Options for adjunctive medical therapy include the dopamine agonist cabergoline and somatostatin analogues octreotide, lanreotide, or pasireotide, alone or in combination. The GH receptor antagonist pegvisomant can normalize IGF-1 levels in many patients, but does not have any effects on tumor growth or size. Medical therapy is usually used after surgery to control GH and IGF-1 levels, or, in selected cases, to shrink large tumors before planned surgery or when surgery is not possible. Conventional radiotherapy, stereotactic radiosurgery, or repeat surgical resection may be necessary if GH levels remain elevated.

Adrenocorticotropic Hormone and Cushing Disease

ACTH is a 39-amino-acid peptide derived from pro-opiomelanocortin, a precursor molecule that also gives rise to β-endorphin and β-lipotropin. Corticotropin-releasing hormone (CRH), secreted by the hypothalamus, controls ACTH release. ACTH stimulates adrenal steroidogenesis in a circadian pattern. ACTH and cortisol levels are highest in the morning and lowest in late evening; psychologic or physiologic stress also activates the pituitary–adrenal axis.

Cushing disease is due to ACTH hypersecretion from a pituitary adenoma and is a common cause (65 to 70%) of endogenous hypercortisolism.[9,11] Clinical features include central obesity, dorsocervical fat pad ("buffalo hump"), hypertension, bruising, purple abdominal striae, thin skin, facial plethora, hyperpigmentation, acne, hirsutism, osteoporosis, menstrual disorders, impotence, decreased libido, and infections. Cushing disease is associated with an increase in mortality. Laboratory findings include hypokalemia, hyperglycemia, and peripheral leukocytosis. Neurologic manifestations include myopathy, headache, neuropsychiatric disturbances including particularly mood disorders and cognitive impairment, and less commonly spinal epidural lipomatosis with resulting radiculopathy or myelopathy.[9,11]

Diagnosis depends on demonstrating endogenous hypercortisolism and then localizing the source of excess ACTH secretion to the pituitary. Recommended screening tests include urinary free cortisol, late-night salivary cortisol, or either the 1-mg overnight or longer low-dose (2 mg/day for 48 hours) dexamethasone suppression test. The 24-hour urinary free cortisol measurement has lower sensitivity and specificity and may yield false-positive results. Pregnancy, depression, alcoholism, morbid obesity, glucocorticoid resistance, and poorly controlled diabetes mellitus can cause hypercortisolism without Cushing syndrome, as can stress (including hospitalization or intense exercise), and malnutrition. A second screening test is often needed. Dexamethasone testing can be confounded by agents that alter steroid clearance, including some antiepileptic drugs. Distinguishing pituitary from ectopic ACTH secretion can be difficult, and inferior petrosal sinus sampling aids diagnosis in centers experienced in its use. Brainstem infarctions or hemorrhages are rare but serious complications of this procedure. Most tumors in Cushing disease are microadenomas and, in up to half of patients, not apparent on MRI.

Trans-sphenoidal surgery is the treatment of choice, with remission rates of 65 to 95 percent for microadenomas and recurrence rates of 10 to 20 percent at 10 years.[9] Remission rates are lower for macroadenomas, which recur earlier and more frequently than smaller tumors. Transient or permanent adrenal insufficiency frequently develops postoperatively. Among options available for patients with persistent hypercortisolism after surgery are repeat surgery, conventional radiotherapy or stereotactic radiosurgery, and medical therapy. Ketoconazole, metyrapone, mitotane, and etomidate inhibit adrenal steroidogenesis. Agents which target the pituitary include the somatostatin analogues (e.g., pasireotide) and the dopamine agonist cabergoline. Bilateral total adrenalectomy can be performed laparoscopically and is another treatment option; however, it obligates permanent adrenal replacement therapy and carries the risk of Nelson syndrome, in which an ACTH-secreting pituitary adenoma enlarges rapidly due to loss of corticosteroid inhibition.

Thyroid-Stimulating Hormone

Pituitary adenomas secreting TSH cause hyperthyroidism and are rare, with an estimated incidence of one case per million. Clinical manifestations are those of hyperthyroidism (Chapter 18), with goiter in most cases, as well as features referable to an enlarging pituitary mass, as most are macroadenomas. Concomitant prolactin or GH hypersecretion occurs in some patients and hence galactorrhea-amenorrhea or features of acromegaly may co-exist. TSH is inappropriately normal or elevated for the high peripheral thyroid hormone levels, distinguishing these lesions from Graves disease or toxic goiter. Individuals with thyroid hormone resistance have elevated laboratory studies suggesting central hyperthyroidism, but generally lack clinical manifestations of hyperthyroidism. For TSH-secreting pituitary tumors, surgical resection is the preferred primary therapy. If thyroid hormones remain elevated postoperatively, radiotherapy, radiosurgery, or somatostatin analogues may be used as adjunctive therapy. Thyroidectomy or antithyroid drugs such as methimazole or propylthiouracil risk increasing tumor growth by interfering with feedback inhibition.

Clinically Nonfunctioning Pituitary Adenomas

Most pituitary tumors that are unaccompanied by clinical evidence of hormonal hypersecretion are gonadotroph cell adenomas, which inefficiently secrete gonadotropins or discordantly secrete their α, FSH-β, or LH-β subunits.[8,9] With the paucity of endocrine symptoms, most are macroadenomas or incidentalomas detected as incidental findings on neuroimaging obtained for other indications. Presenting features are those of a large pituitary mass: headache, visual dysfunction, and hypopituitarism due to compression of normal pituitary or the portal system. Serum prolactin, assessment of anterior pituitary function, and visual field testing should accompany neuroimaging studies. Surgery is the primary therapy of choice for patients with macroadenoma with symptomatic mass effects, with additional radiotherapy for significant residual tumor or recurrence.[10] Nonsecreting microadenomas rarely grow in size and can be monitored with serial MRI scans. If adenomas abut the optic nerves, visual fields should be monitored at regular intervals.

The clinical and therapeutic features of pituitary adenomas are summarized in Table 20-4.

Pituitary Apoplexy

Headache and visual loss, variably accompanied by oculomotor dysfunction, nausea, vomiting, altered mentation, and meningismus, constitute the classic clinical features of pituitary apoplexy, caused by pituitary hemorrhage or infarction. The presenting syndrome may be fulminant, resembling subarachnoid hemorrhage, but subacute or even asymptomatic forms have been recognized increasingly. Headache, visual loss (frequently decreased acuity or bitemporal hemianopia), and diplopia are common, and most patients have impairment of at least one anterior pituitary hormone. Acute adrenal insufficiency may be fatal, hence empiric corticosteroid replacement should be given to all patients with pituitary apoplexy. Hypogonadism and hypothyroidism are common, as is hyponatremia.

Pituitary apoplexy often occurs in adenomas, including those that have been clinically silent, and the risk of symptomatic apoplexy is higher in patients with macroadenomas. Although most cases develop without obvious cause, reported precipitating factors include anticoagulation, trauma, dynamic hormone testing of pituitary function, radiation, and dopamine agonist treatment or its cessation. Sheehan syndrome refers to ischemic pituitary necrosis after postpartum hemorrhage and hypotension.

The differential diagnosis of pituitary apoplexy includes subarachnoid hemorrhage, bacterial meningitis, cavernous sinus thrombosis, and upper brainstem infarction or hemorrhage. Sellar MRI is the neuroimaging study of choice, although CT may be diagnostic when MRI is unavailable or contraindicated. CSF shows nonspecific abnormalities. Transsphenoidal decompression should be undertaken in patients with significant visual field deficit, loss of visual acuity, or deteriorating mental status. Surgery may also help to preserve pituitary function. Once the acute illness has resolved, patients should be monitored for hypopituitarism, with hormone replacement instituted as needed.

Posterior Pituitary

Magnocellular neurons of the hypothalamic supraoptic and paraventricular nuclei synthesize precursor polypeptides, which ultimately are cleaved to form the posterior pituitary hormones oxytocin and ADH.[12] Oxytocin mediates the “let-down” reflex of milk

TABLE 20-4 ■ Diagnosis and Management of Pituitary Adenomas

Type of Adenoma	Presenting Symptoms	Predominant Tumor Type	Primary Therapy	Adjunctive Therapy	Comments
Prolactin-secreting	Children: delayed puberty Women: amenorrhea-galactorrhea, infertility Men: headache, visual loss, impotence	Women: microadenoma Men: macroadenoma	Dopamine agonists	Surgery, radiotherapy, radiosurgery	Most common pituitary adenoma
GH-secreting	Children: gigantism Adults: acromegaly	Macroadenoma	Surgery	Somatostatin analogues, GH receptor antagonist, dopamine agonists, radiotherapy, radiosurgery	Increased mortality, improves with treatment
ACTH-secreting	Central obesity, hypertension, purple striae, bruising, osteoporosis, cognitive and mood changes, myopathy	Microadenoma	Surgery	Steroidogenesis inhibitors, somatostatin analogues, dopamine agonists, radiotherapy, radiosurgery	Untreated disease associated with increased mortality
TSH-secreting	Hyperthyroidism, goiter	Macroadenoma	Surgery	Somatostatin analogues, radiotherapy, radiosurgery	Rare
Nonsecreting	Headache, visual loss, hypopituitarism Incidental finding on CT or MRI obtained for other indications (usually microadenoma)	Macroadenoma	Surgery (serial imaging for microadenomas)	Radiotherapy, radiosurgery	Most secrete gonadotroph subunits

ACTH, adrenocorticotropic hormone; GH, growth hormone; TSH, thyrotropin.

expulsion in response to suckling. ADH facilitates tubular water resorption, thus controlling renal free water clearance and, in concert with hypothalamic thirst mechanisms, regulates water balance and osmolality. Deficient or inappropriate ADH secretion may complicate cerebral disorders or their treatment and lead to neurologic disturbances.

Diabetes Insipidus

Diabetes insipidus is characterized by excessive renal water loss due to ADH (arginine-vasopressin) deficiency. Awake patients present with thirst, polydipsia, and polyuria. ADH hyposecretion leads to central diabetes insipidus, and deficient renal response to adequate circulating ADH levels causes nephrogenic diabetes insipidus. Both types of diabetes insipidus have congenital and acquired forms (Table 20-5) and must be distinguished from excessive water drinking, in which polyuria is appropriate to water intake. Awake patients with diabetes insipidus can often increase their fluid intake sufficiently to compensate for urinary losses. Patients who cannot maintain adequate water intake to balance polyuria develop hypernatremia, volume contraction, and encephalopathy. Brain shrinkage in severe

TABLE 20-5 ■ Causes of Diabetes Insipidus

Central Causes

- Acquired
  - Trauma and neurosurgery
  - Parasellar pathology
    - Neoplasms
    - Granulomatous disorders
    - Vascular lesions
    - Autoimmune: lymphocytic hypophysitis, autoimmune hypothalamic disease
  - Cerebral infection
  - Hypoxic-ischemic brain injury
  - Stroke
  - Pregnancy
  - Idiopathic
- Congenital/familial
  - Septo-optic dysplasia
  - Laurence–Moon–Biedl syndrome
  - Wolfram syndrome
  - ADH mutations

Nephrogenic causes

- Acquired
  - Metabolic
    - Hypercalcemia
    - Hypokalemia
  - Drugs
    - Lithium
    - Antibiotics: demeclocycline, amphotericin B, foscarnet
    - Others: colchicine, loop diuretics
  - Chronic renal parenchymal disease
    - Autoimmune
    - Amyloidosis
    - Sickle cell anemia
  - Postobstructive uropathy
- Congenital/familial
  - ADH receptor mutations
  - Aquaporin-2 mutations

ADH, antidiuretic hormone.

hypertonic encephalopathy may lead to intracerebral hemorrhage.

Common acquired causes of central diabetes insipidus include trauma, cerebral hypoxia-ischemia, and neoplastic, granulomatous, and inflammatory disorders of the sellar region. Transient diabetes insipidus is not uncommon after head trauma or neurosurgery. Most acquired nephrogenic causes are metabolic or toxic, including hypokalemia, hypercalcemia, and lithium. Diagnosis depends on demonstrating an inability to appropriately concentrate urine and is suggested by passage of large amounts of dilute urine. However, polyuria alone is not sufficient to make the diagnosis. In critically ill patients with increased intracranial pressure, for example, polyuria may reflect osmotic diuresis from mannitol therapy, rather than diabetes insipidus. Low urine osmolality in the presence of polyuria and hypertonicity in serum indicates inability to concentrate urine in severe diabetes insipidus, but the diagnosis can be challenging in milder disease. Water deprivation tests, monitoring urine and serum osmolality in the presence of dehydration, are sometimes necessary, but are not without risk, especially in children. The response, after water deprivation, to exogenously administered desmopressin (DDAVP), the ADH analogue, indicates whether the diabetes insipidus is central or nephrogenic. One diagnostic approach to distinguish pituitary diabetes insipidus from primary polydipsia, the AVP-MRI method, can be performed on an outpatient. If plasma ADH is low, when urine osmolarity is low, brain MRI can determine if the posterior pituitary bright spot is absent or small, indicating pituitary diabetes insipidus. If the bright spot is normal or enlarged, it may indicate primary polydipsia.

For both the central and nephrogenic disorders, correcting the water deficit is an important therapeutic goal. Desmopressin can be given parenterally, intranasally, or orally and is the treatment of choice for central diabetes insipidus. In the nephrogenic disorder, the underlying cause should be eliminated; in addition, thiazide diuretics, which enhance sodium excretion, should be prescribed and an adequate fluid intake assured.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Diagnosis of the syndrome of inappropriate antidiuretic hormone secretion (SIADH) depends on the demonstration of decreased effective plasma osmolality, increased urinary osmolality, increased urinary sodium excretion (with normal salt and water intake), euvolemia, normal adrenal and thyroid function, and absence of recent diuretic therapy. Neurologic manifestations of SIADH are those of hyponatremia including encephalopathy and seizures, when the electrolyte disturbance is severe or acute. Milder degrees of hyponatremia impair performance on tests of attention and may predispose patients to falls and fractures. Neurologic causes of SIADH include head trauma, neurosurgery, brain tumor, CNS infection, stroke, hydrocephalus, and acute intermittent porphyria. Ectopic ADH production may occur from systemic malignancies or in association with pulmonary disease. Among the many drugs associated with SIADH are carbamazepine, antidepressants, neuroleptics, antineoplastic agents, and thiazide diuretics. The causes of SIADH are summarized in Table 20-6.

Osmotic demyelination syndrome, a rare but often devastating cerebral disorder associated with rapid correction of hyponatremia of any cause, has helped inform the optimal management of SIADH and other hyponatremic states. Fluid restriction and treatment of the underlying cause are mainstays of therapy, but patient adherence with the former is usually poor. Hypertonic saline and diuretics such as furosemide may be necessary for patients with seizures or those who are otherwise severely symptomatic. Demeclocycline, which induces nephrogenic diabetes insipidus, is occasionally used. More recently, vasopressin receptor antagonists (the "vaptans") are available and are under investigation as second-line treatment for SIADH.

Cerebral salt wasting, occurring in the setting of intracranial disease, is defined as hyponatremia resulting from renal sodium loss. It causes hypovolemia, in contrast to the euvolemia of SIADH, from which it must be distinguished. Rational management consists of water and sodium repletion, rather than fluid restriction, as is standard in SIADH. There are a number of unsettled issues relating to cerebral salt wasting including the difficulty of accurately determining volume status, the frequency with which the syndrome occurs, the necessity for the presence of co-existing cerebral disease, and whether it properly should be renamed renal salt wasting.

TABLE 20-6 ■ Causes of the Syndrome of Inappropriate ADH Secretion

Neurologic Disease
Head trauma or neurosurgery
Stroke
Cerebral infection: meningitis, encephalitis, brain abscess
Brain tumors
Others: hydrocephalus, delirium tremens, acute intermittent porphyria, Guillain–Barré syndrome
Pulmonary Disease
Infection: pneumonia, tuberculosis, empyema
Acute respiratory failure
Others: asthma, cystic fibrosis, pneumothorax, positive-pressure ventilation
Drugs
Psychotropic agents: antipsychotics, antidepressants
Chemotherapy: vinca alkaloids, cyclophosphamide, ifosfamide
Hormones: vasopressin, desmopressin, oxytocin
Others: carbamazepine, clofibrate, amiloride, thiazides
Neoplastic Ectopic ADH Production
Carcinoma: nasopharyngeal, bronchogenic, duodenal, pancreatic, endometrial, prostatic
Others: thymoma, lymphoma, mesothelioma, Ewing sarcoma
Other
Surgery
AIDS
Prolonged exercise

ADH, antidiuretic hormone; AIDS, acquired immunodeficiency syndrome.

Hypopituitarism

Hypothalamic and intrinsic pituitary disorders may lead to impaired secretion of anterior or posterior pituitary hormones (Table 20-7). Because prolactin, unlike other anterior pituitary hormones, is primarily regulated by inhibition, large mass lesions or other processes that disrupt the pituitary stalk can elevate prolactin levels. Prolactin levels in the resulting "stalk syndrome" will be elevated, but not to levels seen with prolactinomas. Pituitary adenomas, even when large, usually spare posterior pituitary function. Thus, the triad of diabetes insipidus, hyperprolactinemia, and deficiency of one or more anterior pituitary hormones suggests hypothalamic dysfunction or disruption of the hypothalamic–pituitary stalk.

Hypopituitarism spans a broad clinical spectrum from the acute crisis of pituitary apoplexy to the indolent and easily missed fatigue, decreased sexual interest and function, loss of body hair, and cold intolerance of a nonsecreting adenoma that has grown large enough to cause deficiencies of multiple hormones. GH deficiency causes growth failure in children and accelerated atherosclerosis and osteoporosis in adults. Hypoadrenalism due to ACTH deficiency is usually less severe than in intrinsic adrenal disease, owing to preserved mineralocorticoid secretion. Gonadotropin deficiency causes loss of libido and impotence. Thyroid dysfunction resulting from TSH deficiency is generally less severe than primary

hypothyroidism. Neuropsychiatric abnormalities and myopathic weakness are features of hypothyroidism and hypocortisolism.

Pituitary tumors or the consequences of their treatment account for some cases of hypopituitarism. Hypopituitarism exceeds 25 percent after traumatic brain injury and has been associated with cognitive impairment, metabolic abnormalities, and reduced quality of life.

PARATHYROID GLANDS

The two pairs of parathyroid glands lie behind the thyroid, secreting parathyroid hormone (PTH). PTH increases serum calcium through direct effects on kidney and bone as well as by indirect effects on gastrointestinal absorption. PTH secretion, in turn, is regulated by ionized calcium concentration in extracellular fluid. The C cells of the thyroid secrete calcitonin, which inhibits bone resorption, thus opposing PTH activity and lowering serum calcium levels. Vitamin D and its metabolites also influence absorption of calcium and other minerals and are sometimes used to treat parathyroid disorders.

Primary Hyperparathyroidism

Primary hyperparathyroidism most commonly results from PTH oversecretion by a solitary parathyroid adenoma and is a common cause of hypercalcemia.[13] Primary hyperparathyroidism is not rare, and the diagnosis is frequently made in patients with few or no symptoms. The classic triad of nephrolithiasis, osteitis, and peptic ulcer disease (“stones, bones, and abdominal groans”) characteristic of advanced primary hyperparathyroidism, is rarely seen today.

Common symptoms include fatigue and subjective weakness, although diverse central and peripheral nervous system syndromes have been reported. Neuropsychiatric syndromes include impaired memory, personality changes, affective disorders, delirium, and psychosis. Elderly patients may be particularly vulnerable. The association of hyperparathyroidism with cognitive disorders remains controversial. The degree of hypercalcemia does not always correlate with clinical severity, although neurologic manifestations typically improve with treatment of the endocrine disorder. Parkinsonism and a syndrome resembling motor neuron disease, reversing with parathyroid surgery, have been described. Myelopathy has been reported from compression by “brown tumors” seen in osteitis fibrosa cystica or on a presumed metabolic basis with normal spine MRI. Neuromuscular symptoms include proximal weakness, muscle pain and stiffness, and paresthesias and typically respond to parathyroidectomy.

Hypercalcemia, usually with concomitant hypophosphatemia, and elevated levels of immunoreactive PTH suggest the diagnosis. Distinguishing malignancy-associated hypercalcemia, with or without ectopic PTH secretion, from primary hyperparathyroidism can be challenging. Parathyroidectomy relieves symptoms and normalizes serum calcium levels in mild as well as severe disease. In patients with mild symptoms or those who are not surgical candidates, cinacalcet and bisphosphonates are options.

Hypoparathyroidism

Hypoparathyroidism results from decreased PTH secretion, causing hypocalcemia. PTH deficiency occurs most commonly after thyroidectomy or other neck surgery, including parathyroidectomy.[14] Hypoparathyroidism may also develop as a feature of autoimmune endocrinopathies and inherited disorders such as Kearns–Sayre syndrome and DiGeorge syndrome. Other causes include glandular destruction from infiltrative processes or radiation. Severe magnesium depletion impairs both PTH secretion and its peripheral action. PTH resistance, referred to as pseudohypoparathyroidism, may develop as a consequence of circulating antagonists, abnormal receptors, or defects in receptor-linked enzyme activity.

Diverse central and peripheral nervous system disorders may occur, primarily owing to hypocalcemia. Dementia and psychosis have been described, with varying degrees of improvement after correction of serum calcium concentration. Seizures, usually generalized, may occur and, because their response to antiepileptic drugs is often unsatisfactory, are best managed by correction of serum calcium. Intracranial calcification, most commonly in the basal ganglia and cerebellum, develops in many hypoparathyroid patients, most of whom are asymptomatic. Diverse extrapyramidal syndromes, with or without associated intracranial calcification, have been described including parkinsonism, choreoathetosis, hemiballismus, and torticollis. Further discussion is provided in Chapter 58. Tetany is the classic peripheral nervous system manifestation of hypocalcemia and may be difficult to distinguish from seizures. Findings on examination include Trousseau and Chvostek signs and carpopedal spasm. Clinically significant autonomic dysfunction is rare; the electrocardiogram may demonstrate a prolonged QT interval. Less common neurologic syndromes include myopathy, peripheral neuropathy, sensorineural hearing loss, and intracranial hypertension.

ADRENAL GLANDS

The paired adrenal glands, situated atop the kidneys, consist of the medulla, derived from neuroectoderm, and the cortex, derived from mesoderm. Their distinct embryologic origins parallel their different endocrine functions. Adrenal medullary chromaffin cells secrete catecholamines, principally epinephrine, regulated by cholinergic preganglionic sympathetic neurons. Adrenal cortical cells secrete sex hormones, corticosteroids, and mineralocorticoids regulated by the hormones ACTH and angiotensin II. This complex neural, endocrine, and metabolic integration allows the adrenal gland to fulfill its critical role in coordinating energy homeostasis and stress responses.

Adrenal Cortex

PRIMARY ALDOSTERONISM

Aldosterone, the major mineralocorticoid in humans, promotes sodium retention and potassium excretion and is primarily controlled by the renin-angiotensin system. In primary aldosteronism, hormone production is inappropriately elevated, most commonly from bilateral adrenal hyperplasia or an aldosterone-secreting adenoma. The resulting volume expansion causes hypertension, which may be treatment-resistant. Hypokalemic alkalosis is a useful clue to the diagnosis when present and when severe can lead to muscle weakness, paresthesias, tetany, or paralysis. The association of hypokalemia and refractory hypertension in ischemic or hemorrhagic strokes should prompt an assessment of the renin-angiotensin system to rule out primary aldosteronism.

CUSHING SYNDROME

Although Cushing disease refers specifically to excess circulating corticosteroids induced by an ACTH-secreting pituitary adenoma, Cushing syndrome is a more general term for hypercortisolism and its associated clinical features, regardless of whether steroid excess is exogenous or endogenous. Corticosteroid treatment for neurologic disorders is usually parenteral or oral, and clinicians are familiar with the importance of monitoring for medical and neurologic complications.

In patients with suspected Cushing syndrome who are not taking corticosteroids, diagnosis is directed toward demonstrating hypercortisolism and defining the source of corticosteroid excess beginning with the same screening tests as for Cushing disease, followed by additional confirmatory blood tests and imaging. ACTH-dependent causes of hypercortisolism are the most common endogenous form and include Cushing disease.

TABLE 20-8 ■ Differential Diagnosis of Hypercortisolism

Non-Cushing Hypercortisolemia
Obesity
Major depression
Alcoholism
Pregnancy
Glucocorticoid resistance
Diabetes mellitus
Others (usually without clinical features of Cushing syndrome): acute illness, malnutrition, elevated cortisol-binding globulin
Exogenous
Corticosteroid or ACTH administration
Endogenous
ACTH-dependent
Pituitary ACTH production (Cushing disease) Ectopic ACTH production: carcinoid or other neuroendocrine tumors Ectopic CRH syndrome
ACTH-independent
Adrenal adenoma or carcinoma Adrenal macronodular hyperplasia McCune–Albright syndrome

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Adrenal lesions such as hyperplasia, adenoma, or carcinoma account for many of the ACTH-independent forms. The differential diagnosis of hypercortisolism is outlined in Table 20-8. Treatment depends on the specific underlying cause and may include steroidogenic inhibitors.

ADRENAL INSUFFICIENCY

With exogenous corticosteroids responsible for many cases of hypercortisolism, it is not surprising that rapid withdrawal of these agents is a common cause of adrenal insufficiency. Acute adrenal failure may be fatal and should be considered in patients with unexplained hypotension. When adrenal insufficiency develops more gradually, systemic manifestations include fatigue, weight loss, loss of libido, hypotension, nausea, vomiting, dry skin, loss of axillary and pubic hair, and limb pain.[15] The low specificity of these symptoms and lower frequency of more specific symptoms such as salt craving and hyperpigmentation mean that diagnosis of adrenal insufficiency is often delayed. Cerebral symptoms include apathy, depression, confusion, and, occasionally, paranoia and psychosis. Myalgias, myopathic weakness, cramping, and hyperkalemic periodic paralysis may develop occasionally.

TABLE 20-9 ■ Causes of Adrenal Insufficiency

Primary (Addison disease)
Autoimmune adrenalitis
Infection: meningococcemia, tuberculosis, cytomegalovirus
Metastases
Adrenal infarction or hemorrhage
Adrenoleukodystrophy and other inherited disorders
Drugs: steroidogenesis inhibitors
Secondary
Corticosteroid administration
Pituitary disease or surgery

Primary adrenal insufficiency, or Addison disease, results from glandular dysfunction or destruction, acutely or chronically, by hemorrhage, infection, autoimmune disorders, surgery, metastases, steroidogenesis inhibitors, or hereditary disorders.

Inherited causes with their own neurologic features include adrenomyeloneuropathy and adrenoleukodystrophy, which are X-linked disorders characterized by accumulation of very-long-chain fatty acids. Adrenal disease may antedate neurologic symptoms or occur in isolation, and the diagnosis should be considered in young men with Addison disease.

Secondary adrenal insufficiency results from ACTH deficiency, due to hypothalamic or pituitary lesions, surgery, or suppression of the hypothalamic–pituitary–adrenal axis by exogenous corticosteroids. The differential diagnosis of adrenal insufficiency is outlined in Table 20-9.

The basal morning cortisol and synthetic corticotropin stimulation test usually constitute the initial steps in evaluating suspected adrenal insufficiency. Steroid replacement is lifesaving in acute adrenal failure and relieves symptoms in chronic states.

Adrenal Medulla

PHEOCHROMOCYTOMA AND NEUROENDOCRINE TUMORS

Pheochromocytoma is a rare catecholamine-secreting tumor that arises from adrenal chromaffin cells. Most are sporadic, but pheochromocytomas also occur as a part of inherited disorders, including neurofibromatosis type 1 and von Hippel–Lindau disease. Extra-adrenal chromaffin cell tumors ("paragangliomas") are typically nonsecretory when they occur in the head and neck and occasionally cause cranial neuropathies. More commonly, paragangliomas occur along the sympathetic chain and secrete catecholamines, with clinical features similar to pheochromocytoma. A classic cause of secondary hypertension, these tumors also present with paroxysmal headache, diaphoresis, anxiety, tremor, dizziness, or flushing, in varying combinations. They may also present acutely, with ischemic or hemorrhagic stroke, reversible cerebral vasoconstriction syndrome, seizure, or delirium. Included in the extensive differential diagnosis are anxiety disorders, panic attacks, migraine, hyperthyroidism, menopausal symptoms, effects of sympathomimetic drugs, and dysautonomia. Recommended initial testing for pheochromocytoma or paraganglioma is measurement of urine or plasma fractionated metanephrines, with phlebotomy performed supine and with additional restrictions on antecedent smoking, caffeine intake, and exercise. CT or MRI, increasingly supplemented with functional imaging, localize the tumor, which is usually managed surgically.

Other neuroendocrine tumors may cause neurologic symptoms related to secretion of other biogenic amines or peptides. Flushing, which may raise concern for dysautonomia, is a feature of carcinoid tumors—neoplasms of the gastrointestinal tract or lung which secrete serotonin, dopamine, prostaglandins, and other molecules. Pancreatic neuroendocrine tumors may secrete insulin, causing hypoglycemic symptoms; GHRH, causing acromegaly; or ACTH, causing Cushing syndrome.

This chapter provides an overview of disorders that have both neurologic and cutaneous manifestations, the latter often reducing what would have been a broad differential diagnosis into a single entity. Because the emphasis is on diagnosis by a neurologist, the presentation is organized around familiar neurologic syndromes rather than pathologic or dermatologic entities. This approach is complementary to those based on traditional pathophysiologic categories, such as genetic, autoimmune, and infectious disorders. Patients present to the neurologist with signs and symptoms, not with biopsies.

Usually a disease cannot be related to either a single cutaneous sign or a single neurologic syndrome. With a goal of minimal repetition but a comprehensive presentation, the text is limited to important representative diseases. Each is described only once, grouped with its most characteristic clinical presentation where possible. Secondary manifestations are mentioned in passing or in tables. Details are necessarily limited, but are supplemented with more comprehensive tables and, where applicable, annotation with the code number in the continuously updated Online Mendelian Inheritance in Man (OMIM).[1] The discussion is limited to disorders that permit survival to adulthood.

TUMORS

Earlier classifications of neurocutaneous disorders described phakomatoses, disorders that were thought

Aminoff's Neurology and General Medicine, Sixth Edition.

to affect exclusively structures arising from the embryonic ectoderm: the skin, eyes, and nervous system. This designation was originally applied to two autosomal dominant disorders associated with tumors: neurofibromatosis type I and tuberous sclerosis.[2] However, the category gradually expanded to encompass a wide variety of other neurologic disorders, including Sturge–Weber syndrome, which is not associated with tumors, and von Hippel–Lindau syndrome, associated with tumors but not with cutaneous lesions. Furthermore, many of these disorders involved tissues with mesodermal and endodermal origins as well. Phakomatosis has outlived its utility as a diagnostic category.

Numerous disorders are associated with tumors, cutaneous manifestations, and neurologic disease. In many cases the tumors themselves are responsible for the cutaneous or neurologic symptoms, but in others they are independent manifestations of a more complex syndrome.

Neurofibromatosis Type I

Neurofibromatosis type I (NF1; von Recklinghausen disease), an autosomal dominant disorder (OMIM 162200), is characterized by café-au-lait spots, fibromatous dermal tumors, and Lisch nodules of the iris as well as neoplasms of both the peripheral and the central nervous system (CNS). The earlier designation as peripheral neurofibromatosis (strictly speaking, a misnomer) served to distinguish this disorder from the genetically and clinically distinct central neurofibromatosis, now neurofibromatosis type II (NF2; OMIM 101000), as well as schwannomatosis 1 (SWNTS1, OMIM 162091) and 2 (SWNTS1, OMIM 615670).

NF1 is the most common single-gene disorder of the nervous system, affecting 1 in 3,500 individuals. It results from heterozygosity for a mutant form of a large gene on chromosome 17q11.2 that encodes a cytoplasmic protein with multiple regulatory functions. The NIH consensus criteria permit unequivocal diagnosis of NF1 even without demonstration of the genetic mutation, by clinical observation of at least two of the following: (1) the presence of six or more café-au-lait macules with a diameter of ≥ 5 mm in children younger than 6 years and ≥ 15 mm in older people (Fig. 21-1); (2) two or more neurofibromas of any type or one plexiform neurofibroma; (3) axillary or inguinal region freckling; (4) optic pathway glioma; (5) two or more Lisch nodules (whitish tumors of the iris); (6) dysplasia of the sphenoid bone or thinning of the cortex of long bones with or without pseudarthrosis; and/or (7) a first-degree relative exhibiting these changes.

The familiar café-au-lait spots are present at birth, as are plexiform neurofibromas and focal bone dysplasias, but axillary freckling, optic gliomas, Lisch nodules, and neurofibromas appear later in childhood. Of these, axillary freckling is the most diagnostically reliable, being present in all individuals with NF1 by the end of puberty. Café-au-lait spots alone are not diagnostic of NF1 because fewer than five spots are found frequently in individuals who are well. Café-au-lait spots as an isolated trait can be transmitted as an autosomal dominant (OMIM 114030) or as occasional features in other heritable disorders including tuberous sclerosis, the microcephalic disorders Nijmegen breakage syndrome (ataxia telangiectasia variant VI, OMIM 251260), X-linked Russell–Silver syndrome (OMIM 312780), Turcot mismatch repair cancer syndrome (OMIM

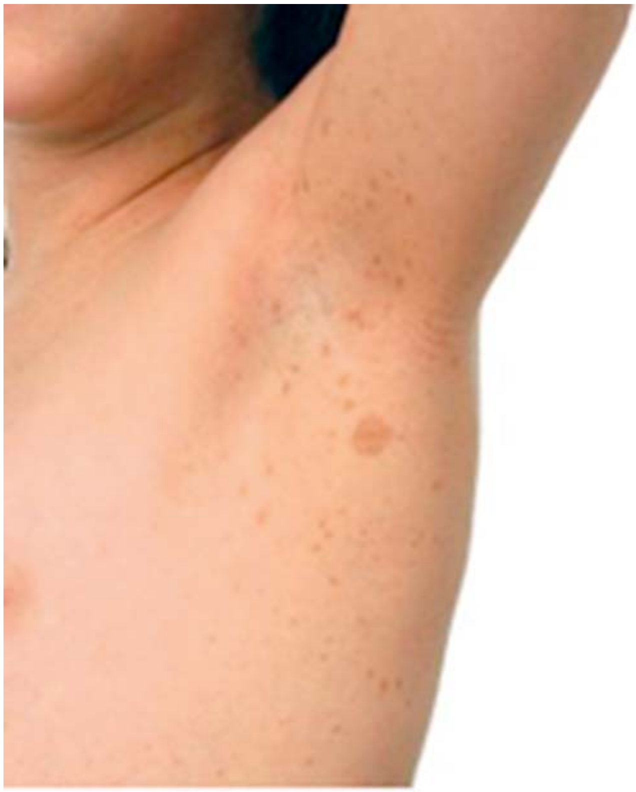

FIGURE 21-1 ■ Neurofibromatosis type I: axillary freckling—a cluster of freckle-sized café-au-lait macules. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012, with permission.)

276300; polyposis coli, rhabdomyosarcomas, medulloblastomas, ependymomas and other gliomas), the rare Westerhof growth retardation syndrome (OMIM 154000), and perhaps most famously in McCune–Albright polyostotic fibrous dysplasia (OMIM 174800). The old clinical pearl that the rough border of McCune–Albright café-au-lait spots distinguishes them from the smooth borders seen in NF1 is not reliable.

Malignant neoplasms or benign tumors of the nervous system occur in 45 percent of individuals with NF1. Optic nerve gliomas develop in 15 percent. However, neurologic involvement most often results from benign neurofibromas in the root entry zone of peripheral nerves, causing radiculopathy or compression of the spinal cord. Plexiform neurofibromas, which can be nodular or diffuse, arise from nerve trunks. Diffuse plexiform neurofibromas are usually congenital and undergo transformation in about 4 percent of cases into malignant peripheral nerve sheath tumors that are severely painful, tender, and hard. The more common dermal neurofibromas are usually innocent, permitting conservative management in asymptomatic people. The incidence of non-neural tumors is also increased modestly, especially rhabdomyosarcomas of the urogenital tract and myelogenous leukemia.

In addition, there are neurologic sequelae not related to tumors. The most significant of these are poorly characterized T2 hyperintensities in the centrum semiovale (unidentified bright objects), the density of which correlates with mild cognitive impairment. In addition to these neurologic, ocular, and cutaneous manifestations, there may also be cardiovascular, gastrointestinal, and orthopedic manifestations.

Neurofibromatosis Type II

This genetically distinct autosomal dominant disorder (OMIM 101000; also known as NF2, bilateral acoustic neurofibromatosis, or BANF) is characterized by tumors of the eighth cranial nerve in the cerebellopontine angle, meningiomas, and schwannomas of the dorsal roots of the spinal cord. It is less common than NF1 by an order of magnitude, affecting 1 in 25,000 live births in association with heterozygosity for a mutant form of merlin, a critical regulator of cell–cell adhesion, transmembrane signaling, the actin cytoskeleton, and resultant inhibition of proliferation. It is encoded on chromosome 8. Other mutations of this gene result in a clinically related but distinct Mendelian disorder, congenital cutaneous schwannomatosis 1 (OMIM 162091) or in some familial predispositions to meningiomas (OMIM 607174). Typically, NF2 presents in young adults, but hearing loss has been reported as early as age 6. Proposed diagnostic criteria for definite NF2 are bilateral vestibular schwannomas; or a family history of NF2 in one or more first-degree relatives plus (1) unilateral vestibular schwannomas at age less than 30 years, or (2) any two of the following: meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract. Bilateral acoustic neuromas occur in less than 5 percent of most series. The cutaneous manifestations are also distinct from that of NF1. Café-au-lait spots are present in about 40 percent of individuals, but only about 1 percent have six, the minimum seen in NF1. There are three types of cutaneous tumors: (1) discrete well-circumscribed, slightly raised, roughened areas of skin often pigmented and accompanied by excess hair, which are seen in about one-half of affected individuals; (2) subcutaneous well-circumscribed, nodular tumors located on peripheral nerves seen in about one-third; and (3) violaceous papillary skin neurofibromas, similar to those seen in NF1, in about one-fifth. One-third of NF2 patients have no cutaneous lesions.

Tuberous Sclerosis

This autosomal dominant neurocutaneous disorder was originally described as a phakomatosis, as had been NF1. It is characterized by hamartomas in multiple organ systems, including the brain, skin, heart, kidneys, and lung. The characteristic brain lesions, named tubers because of their fancied resemblance to potatoes, are benign, but some 5 to 15 percent of affected individuals also develop malignant brain neoplasms, most frequently subependymal giant cell astrocytomas. These often develop at the foramen of Monro or elsewhere on the wall of the lateral ventricle or the retina. More frequent neurologic presentations are learning difficulties, behavioral problems, autism, or epilepsy, often the severe West syndrome. The characteristic skin lesions are pale "ash leaf spots," present in 90 percent of affected individuals. These are difficult to spot on light-skinned individuals unless examined with an ultraviolet Wood light (Fig. 21-2). Such an examination will also facilitate the recognition of smaller confetti-like

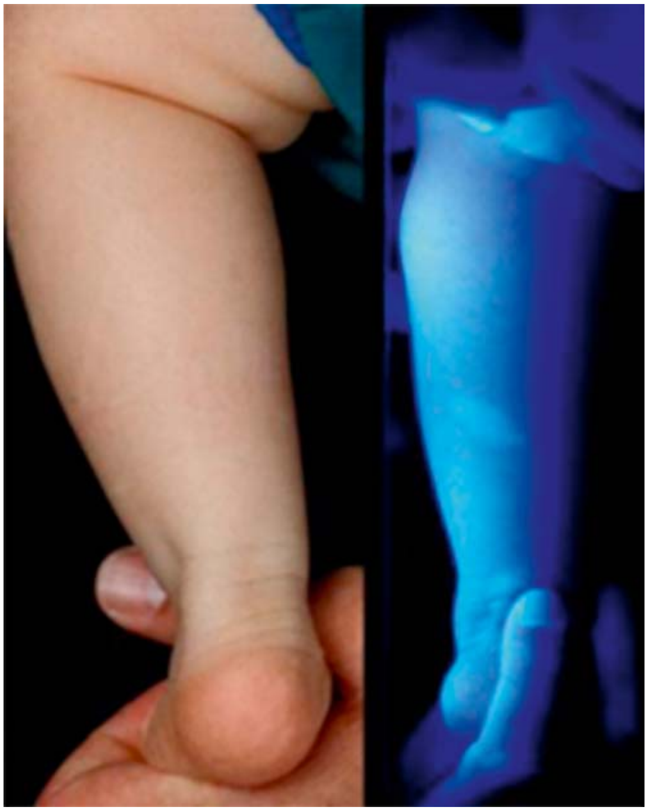

FIGURE 21-2 ■ Tuberous sclerosis: ash leaf spot in Wood light. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012, with permission.)

hypopigmented patches that are present in about one-third of patients, but only rarely in normal individuals. In addition to these flat hypopigmented lesions and occasional café-au-lait spots, there are three kinds of distinctive raised cutaneous lesions: shagreen patches (Fig. 21-3), periungual fibromas (Fig. 21-4), and facial angiofibromas. The latter can be mistaken for acne on casual inspection. There are also systemic manifestations: usually asymptomatic cardiac rhabdomyomas, present at birth and regressing in childhood, but sometimes associated with arrhythmias; renal cysts, angiolipomas, and carcinomas; and pulmonary lymphangioleiomyomas.

Tuberous sclerosis (TSc) can result from mutation of either of two genes. About 70 percent of cases (TSc 2, OMIM 613254) result from heterozygous mutation of tuberin encoded on chromosome 16p13.3, the remainder (TSc 1, OMIM 191100) from mutations of the gene encoding hamartin on chromosome 9q34.13. Unlike the case for the phenotypically distinct NF1 and NF2, each of which results from disruption of either of two independent, noninteracting proteins, TSc 1 and TSc 2 are practically indistinguishable clinically. This is as would be predicted by the known interaction of hamartin and tuberin to form a single complex, the activity of which is disrupted by mutation of either subunit.

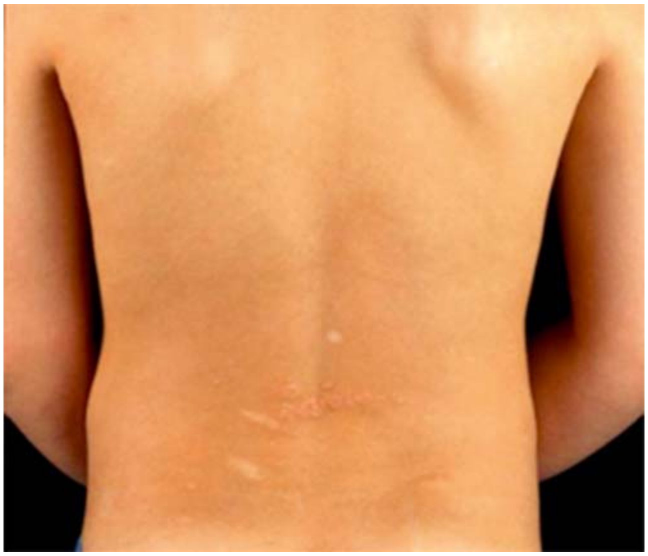

FIGURE 21-3 ■ Tuberous sclerosis: ash leaf spot and shagreen patch. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012, with permission.)

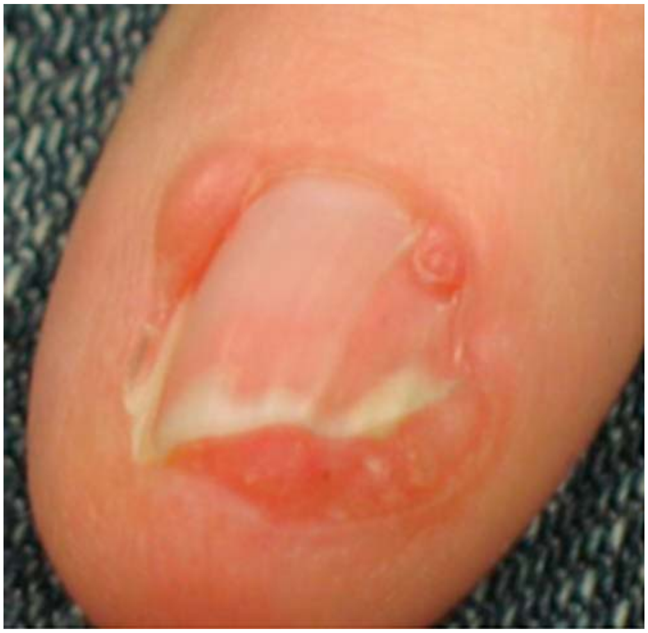

FIGURE 21-4 ■ Tuberous sclerosis: nail-fold fibroma. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012.)

This complex regulates the activity of the downstream pathway of the mammalian target of rapamycin (mTOR), which is disrupted by mutation in another neurocutaneous disorder, the Cowden multiple hamartoma syndrome (OMIM 158350).

Melanoma

Melanoma is the most lethal of skin cancers, largely because of its propensity for early and highly neurotropic metastasis.[3] In most instances, involvement of the nervous system by melanoma is by metastasis from a primary cutaneous lesion first to a local regional lymph node, then to the lung whence it metastasizes further to brain, bone, or liver. Unlike the usual solitary brain metastases from more common primaries such as lung, breast, and kidney, brain metastases of melanoma are characteristically multiple. The other two types of primary cutaneous neoplasms, the more common basal cell carcinoma and the more invasive squamous cell carcinoma, do not metastasize to the brain.

Furthermore, tumors of the nervous system (including gliomas, medulloblastomas, ependymomas, meningiomas, and acoustic neurilemmomas) have an increased likelihood as secondary tumors in patients with cutaneous melanoma as well as in their family members. The molecular bases underlying these associations are only partially understood.

An increased incidence of cutaneous melanomas is seen in a more complex heritable neurocutaneous syndrome, xeroderma pigmentosa (OMIM 610651). This autosomal recessive disorder is characterized by increased sensitivity to sunlight as well as widespread neurologic involvement. Signs include microcephaly, mental retardation, ataxia, ventriculomegaly, cerebellar atrophy, basal ganglia calcification, and disordered central and peripheral myelination.

In addition to those syndromes in which melanoma originates in the skin, there is also the rare neurocutaneous melanosis (OMIM 249400), in which there is a primary melanoma of the CNS in over 50 percent of cases, but no malignant melanoma in the periphery. In this disorder there are large multiple pigmented skin nevi (> 20 cm) (Fig. 21-5), as well as cranial nerve palsies from histologically benign melanocytic invasion of the meninges, Dandy–Walker malformation, and suprasellar calcifications. Death usually occurs in childhood.

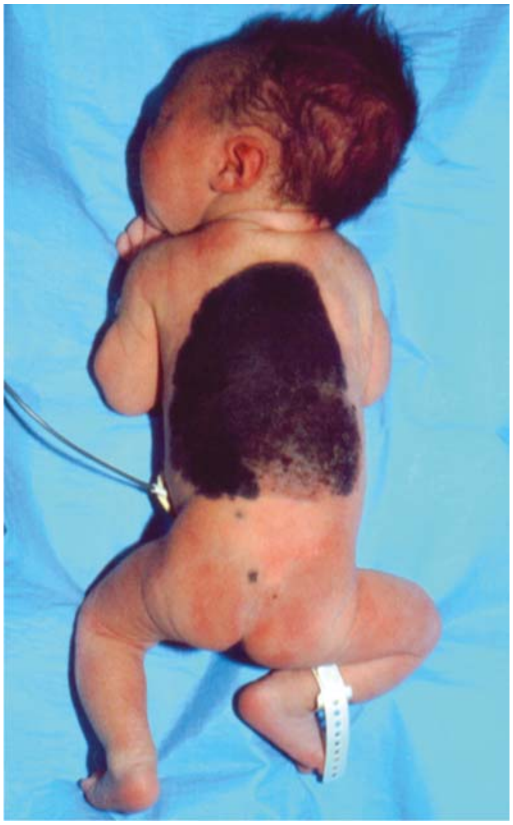

FIGURE 21-5 ■ Neurocutaneous melanosis. (From Jones, K: Smith's Recognizable Patterns of Human Malformation. Saunders, Philadelphia, 2005, with permission.)

STROKE

A number of neurocutaneous disorders are associated with either ischemic or hemorrhagic stroke, or both. The underlying mechanisms range from intrinsic vascular disease to cardiac or paradoxical embolization and to coagulopathies or platelet disorders, as summarized in Table 21-1.

Fabry Disease

Fabry disease is an X-linked neurocutaneous disorder (OMIM 301500) characterized by stroke, peripheral neuropathy, and progressive renal and cardiac failure. These sequelae occur both in hemizygous males as well as in heterozygous females, albeit later and usually, but not invariably, with less severity. A pathognomonic whorl-like corneal dystrophy is seen with equal severity in both sexes. Affected males are easily recognized by a purpuric skin rash: discrete angiokeratoma, most prevalent between the knees and nipples. Females,

TABLE 21-1 ■ Ischemic or Hemorrhagic Stroke with Cutaneous Manifestations

Disease	Cutaneous Lesions	Neurologic Features
Antiphospholipid syndrome	Livedo reticularis	Ischemic stroke, chorea, neuropsychiatric symptoms, relapsing-remitting central vasculitis, myelopathy
Behçet disease	Erythema nodosum, genital and oral aphthous ulcers	Brainstem meningoencephalitis, dural sinus thrombosis, ischemic stroke, peripheral neuropathy (rare)
Bone fragility with contractures, arterial rupture, and deafness (OMIM 612394)	Ecchymoses, blistering of fingers, toes, pinnae	Cerebral hemorrhage, developmental delay
Cerebral cavernous malformations; CCM (OMIM 116860, 603284)	Angiomas, hyperkeratotic cutaneous vascular lesions	Small, localized intracranial hemorrhages
Diabetes mellitus	Necrobiosis lipoidica diabeticorum, poorly healing ulcers	Lacunar stroke, peripheral neuropathy, retinopathy, metabolic coma
Endocarditis	Petechiae, Janeway lesions, Osler nodes, splinter hemorrhages	Septic embolic strokes
Fabry disease (OMIM 301500)	Angiokeratoma starting at the umbilicus and knees, spreading to buttocks and scrotum	Ischemic stroke, seizures, peripheral neuropathy, autonomic dysfunction, acral paresthesias, painful crises
Factor XIII subunit A deficiency (OMIM 613225)	Ecchymoses	Intracranial hemorrhage
Glanzmann thrombasthenia (OMIM 273800)	Easy bruisability, purpura	Intracranial hemorrhage
Hemolytic-uremic syndrome (OMIM 235400)	Erythematous necrotic skin lesions	Seizures, coma, hemiparesis, cognitive defects, visual defects, dysphasia
Hereditary hemorrhagic telangiectasia of Osler—Weber—Rendu (OMIM 187300, 600376, 601101, 610655)	Telangiectasia	Ischemic and hemorrhagic stroke
Homocystinuria due to cystathionine β-synthase deficiency (OMIM 236200)	Malar flush, livedo reticularis, hypopigmentation	Ischemic stroke, seizures, mental retardation, psychiatric disorders, depression, personality disorder
Familial hypercholesterolemia (OMIM 143890)	Xanthomas, xanthelasma	Ischemic thromboembolic stroke
Hereditary neurocutaneous angiomas (OMIM 106070)	Large irregular flat hemangiomas	Spinal angiomas and cerebral thin-walled angiomas
Hyper-IgE recurrent infection syndrome, autosomal recessive (OMIM 243700)	Severe eczema, atopic dermatitis, recurrent skin abscesses	Ischemic infarctions, subarachnoid hemorrhage
Malignant atrophic papulosis (OMIM 602248)	Multiple asymptomatic papules with atrophic white centers surrounded by telangiectatic lesions	Ischemic infarctions
Prothrombin deficiency, congenital (OMIM 613679)	Ecchymoses, easy bruising	Intracranial hemorrhage
Pseudoxanthoma elasticum (OMIM 264800)	Pseudoxanthoma, multiple papules, peau d'orange, angioid streaks, subcutaneous calcification usually in blood vessels	Stroke, retinopathy
Pseudoxanthoma elasticum, forme fruste (OMIM 177850)	Small, yellow papules, peau d'orange, elastosis perforans serpiginosa	Cerebral hemorrhage, retinopathy
Schimke-type immuno-osseous dysplasia (OMIM 242900)	Hyperpigmented macules	Moyamoya, cerebral infarctions

(Continued)

TABLE 21-1 ■ (Continued)

Disease	Cutaneous Lesions	Neurologic Features
Systemic lupus erythematosus	Photosensitivity, malar rash, telangiectasia, discoid lupus, patchy alopecia, mucosal ulcers, angioneurotic edema, Raynaud phenomenon, subcutaneous nodules, palpable purpura, gangrene, erythema multiforme	Ischemic and hemorrhagic stroke, encephalopathy, chorea, peripheral neuropathies
Takayasu arteritis	Palpable purpura	Ischemic stroke
Thrombophilia due to protein C deficiency, autosomal dominant (OMIM 176860)	Warfarin-induced skin necrosis	Cerebral thrombosis
Thrombocytopenia—absent radius syndrome (OMIM 274000)	Nevus flammeus on forehead, dysseborrheic dermatitis	Intracranial hemorrhage, absent corpus callosum, spina bifida

having two X chromosomes, are twice as likely to have the pathogenic mutation of α-galactosidase (also commonly known as ceramide trihexosidase). Nevertheless, affected female heterozygotes frequently remain undiagnosed because they rarely have the characteristic cutaneous lesions, even though they can have severe neurologic, cardiac, and renal manifestations.

Stroke is a late manifestation of the vascular deposition of lipid in Fabry disease. It was underappreciated until survival was prolonged by renal transplantation and, now, by enzyme-replacement therapy. A painful small-fiber neuropathy with autonomic dysfunction and episodic severely painful abdominal crises, reminiscent of those of the hepatic porphyrias, occurs early in the disease. Other early manifestations are small infarctions in the retina and kidneys. The latter lead to renal failure, which had previously caused death of affected hemizygotes by the third decade.

Although Fabry disease is also referred to as angiokeratoma diffusum, these skin lesions are not pathognomonic. They are also manifestations of other Mendelian neurocutaneous disorders associated with mental retardation: aspartylglucosaminuria (OMIM 208400; seizures), fucosidosis (OMIM 230000; seizures and peripheral neuropathy), lysosomal beta A mannosidosis (OMIM 248510), Ramon syndrome (OMIM 266270; a posterior cerebral leukoencephalopathy), Kanzaki disease (OMIM 609242, adult-onset mild cognitive impairment), and Bannayan—Riley—Ruvalcaba syndrome (OMIM 153480; megaencephaly, meningioma, pseudopapilledema).

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), an autosomal dominant disorder also known eponymously as Osler—Weber—Rendu syndrome, is a vascular dysplasia that gives rise to hemorrhagic and ischemic strokes. These arise from a diverse set of peripheral as well as central vascular abnormalities, ranging from ischemic strokes and brain abscesses from paradoxical emboli passing through pulmonary venous malformations to intracerebral vessels, and subarachnoid hemorrhages from cerebral arteriovenous malformations. It is important to search for previously unsuspected pulmonary arteriovenous malformations before assuming local vascular pathology as a cause of stroke, because these pulmonary lesions can be effectively obliterated by embolization. The mucocutaneous telangiectasias for which the disorder is named are most often found on the tongue, lips, palate, fingers, face, conjunctiva, trunk, nail beds, and fingertips. Similar systemic vascular malformations are responsible for frequently problematic recurrent epistaxis, hepatic cirrhosis, and gastrointestinal hemorrhage later in life. Depending on the vascular anatomy, there may be either a polycythemia or an anemia.

This disorder is genetically heterogeneous. HHT type 1 (OMIM 187300) results from heterozygosity for a mutation of the gene on chromosome 9q34.11 encoding endoglin, a homodimeric membrane glycoprotein expressed mostly on the vascular endothelium, a component of the transforming growth factor-β receptor complex; HHT type 2 (OMIM 600376), from heterozygosity for mutation of the gene on chromosome 12q13.13 encoding activin receptor-like kinase 1; and HHT type 5 (OMIM 615506) from heterozygous mutation in the *GDF2* gene (OMIM 605120) on chromosome 10q11 encoding growth/differentiation factor 2. HHT type 3 (OMIM 601101) has been mapped to chromosome 5q31.3-q32 and HHT type 4 (OMIM 610655) to chromosome 7p14. The genes mutated in the latter two entities have not yet been identified.

Homocystinuria

Homocystinuria is a feature of several different neurologic disorders, only one of which, homocystinuria due to cystathionine β-synthase deficiency (OMIM 236200), is associated either with cutaneous lesions or with stroke. In this disorder cutaneous hypopigmentation, malar flush, and livedo reticularis are not as striking as the Marfan-like disproportionate tall stature and ectopia lentis, which provide the most evident clues to diagnosis. Neurologic features include ischemic thromboembolic strokes in about 25 percent of homozygotes, as well as mild mental retardation, seizures, and a variety of psychiatric disturbances that include personality disorders and depression. Diagnosis is critical, because over half of affected individuals respond to simple treatment with pyridoxine, vitamin B_6. Furthermore, even pyridoxine nonresponders benefit from dietary modification to reduce methionine and increase cysteine as well as supplementation with betaine.

The classic syndrome associated with homozygosity for mutations in the gene cystathionine β-synthetase is rare, but heterozygotes—encountered more commonly—are also at greater risk of ischemic stroke than the general population. Lacking the characteristic cutaneous or systemic signs, these individuals can only be detected by biochemical or genetic screening. As is always the case with rare autosomal recessive disorders, the vast majority of heterozygotes will not have an affected homozygous relative to prompt suspicion of the diagnosis.

Endocarditis

Septic emboli leading to ischemic or hemorrhagic stroke or intracranial hemorrhage from rupture of mycotic aneurysms occur in 40 percent of individuals with bacterial endocarditis.[4] In developed countries, acute endocarditis commonly occurs because of unhygienic self-administration of intravenous drugs; infections of surgically implanted artificial cardiac valves are another important cause. In the developing world, secondary infection of unrepaired congenital valvular abnormalities or those damaged by rheumatic fever are also an important contributor to infective endocarditis.

The classic cutaneous findings associated with infective endocarditis are subungual splinter hemorrhages, Janeway lesions, and Osler nodes. Splinter hemorrhages (1- to 3-mm, red to reddish-brown, longitudinal hemorrhages appearing under the nail plate) are commonly seen also as a response to repetitive trauma in otherwise healthy individuals, such as manual laborers or elderly individuals using walkers. In addition they have been reported as occasional findings in antiphospholipid syndrome, another neurocutaneous syndrome associated with stroke.

The more diagnostic Janeway lesions are nontender, large, irregular, flat macules that appear on the palms or the soles, frequently on the planar surface of a toe. These are culture-positive sites of septic emboli. In contrast, Osler nodes are tender, purple, slightly raised nodules ranging in size from 1 to 10 mm. These are typically seen on the tips or sides of toes or fingers. Unlike the Janeway lesions, they are sites of vasculitis, not embolization. Both of these lesions can appear on the thenar or hypothenar eminences.

The presence or absence of neurologic complications dictates the optimal timing of surgery for both native and prosthetic valve endocarditis, as do cardiac function and the control of the infection. In the absence of embolic events or rapidly deteriorating cardiac function, cardiac surgery is best delayed for 1 or 2 weeks of antibiotic treatment before subjecting the patient to the risks of surgery, not the least of which is cardiac bypass and attendant anticoagulation. However, if there is a stroke or transient ischemic attack, and intracranial hemorrhage has been excluded by scanning, surgery is recommended without delay.

Antiphospholipid Syndrome

The twin hallmarks of antiphospholipid antibody syndrome are either a thrombotic event, such as a stroke, or a complication of pregnancy seen in association with high titers of certain antibodies. Sometimes misleadingly referred to as lupus anticoagulants, these are thought to induce hypercoagulability by neutralizing anionic phospholipids on endothelial cells and platelets, predisposing to both arterial and venous thromboses.[5] This syndrome can be seen either as a primary abnormality or in the setting of a number of different neurocutaneous disorders: primary inflammatory diseases such as systemic lupus erythematosus, systemic sclerosis, Behçet disease, Sjögren syndrome, and rheumatoid arthritis, or infections such as syphilis, Lyme borreliosis, and human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS). In some instances, antiphospholipid syndrome has been shown to be a familial trait (OMIM 107320).

Cutaneous manifestations may be the initial clinical manifestation of the antiphospholipid syndrome. These include livedo reticularis, most commonly on the lower extremities; acrocyanosis, a Raynaud-like phenomenon; necrotizing vasculitis, with cutaneous ulceration and necrosis; erythematous macules; purpura, ecchymoses, and subungual splinter hemorrhages; and rarely, Degos malignant atrophic papulosis. The combination of livedo reticularis with multiple strokes has been designated as Sneddon syndrome. Antiphospholipid antibodies are associated with several neurologic syndromes, including stroke, transverse myelitis, and chorea. Many of these might be plausibly attributed to focal ischemia.

Takayasu Arteritis

Stroke in a young woman of Asian descent should prompt consideration of Takayasu arteritis (aortic arch syndrome or pulseless disease).[6] The differential diagnosis of aortitis includes mycotic aneurysms, syphilis, mycobacterial infections, endocarditis, as well as various autoimmune disorders, including Behçet disease, ankylosing spondylitis, sarcoidosis, and Sjögren syndrome.[7] The cutaneous manifestation of Takayasu arteritis is erythema nodosa, which occurs at an early phase in the disease. Fever and synovitis also develop prior to the large-vessel vasculopathy that defines the disorder. Neurologic involvement results from ischemic stroke from inflammation or stenosis of a proximal carotid or vertebral artery. Such strokes occur in about 20 percent of affected individuals. More commonly, involvement of the subclavian arteries leads to claudication and pulse asymmetries or frank loss of palpable pulses in the upper extremities.

The etiology of Takayasu arteritis appears to be autoimmune, with modest associations both to HLA-B52 and to elevations of serum levels of certain matrix metalloproteinases (OMIM 207600). The latter normalize after clinical improvement resulting from treatment with immunosuppressants.

MENINGITIS AND MENINGOENCEPHALITIS

A large number of disorders can present both dermatologic abnormalities and meningitis or meningoencephalitis, which can be acute, subacute, relapsing-remitting, or chronic. A few characteristic disorders are presented in detail, the others are included in Table 21-2.

Meningococcal Meningitis

Meningococcal meningitis is a fulminant disorder with a high mortality rate and serious sequelae (sensorineural hearing loss, seizures, motor deficits, hydrocephalus, cognitive abnormalities, and behavioral problems) in treated survivors. Fever, headache, and meningeal irritation develop over the course of 24 hours. The distinguishing feature of meningococcal disease is the concomitant evolution of a rapidly evolving petechial rash, usually over the trunk and lower extremities, but which can also develop on the face, mucous membranes, and arms (Fig. 21-6).[8] These cutaneous lesions can coalesce or develop into vesicles or bullae. In contrast, the cutaneous lesion associated with meningitis from infection with *Haemophilus influenzae*, previously the most common type of bacterial meningitis in children, is typically a solitary indurated area on the face, neck, upper chest, or arm. The meningococcal rash must also be distinguished from that of other disorders in Table 21-2, notably Rocky Mountain spotted fever.

In the 10 to 30 percent of cases of meningococcemia that develop too rapidly to seed the choroid plexus and meninges, the prognosis is even worse than in those cases with meningitis. Early treatment at the first recognition of the short febrile prodome and rash is critical. Although most cases of meningococcemia, either with or without meningitis, occur in children, young adults in cramped quarters, including college students and military recruits, are also at risk.

The incidence of some meningococcal infections has been reduced significantly by the introduction of a vaccine, as has the incidence of the other two most common types of acute bacterial meningitis, resulting from infection with *H. influenzae* or *Streptococcus*

TABLE 21-2 ■ Meningitis with Cutaneous Manifestations

Disorder	Cutaneous Lesions	Neurologic Features
Adams–Oliver aplasia cutis congenita type III (OMIM 614814)	Scalp defect at the vertex, cutis marmorata telangiectatica, hemangioma	Acute bacterial meningitis from scalp defect
AIDS	Seborrhea, herpes zoster, tinea corporis, *S. aureus* infection, molluscum contagiosum, Kaposi sarcoma, cryptococcosis	Transient meningitis during seroconversion
Amyloidosis V (Meretoja, Finnish) (OMIM 105120)	Cutis laxa	Cranial and peripheral neuropathies
Behçet disease	Erythema nodosum, genital and oral aphthous ulcers, papules, purpura, pustules, dermatographia, pyoderma	Chronic or recurrent meningitis, meningoencephalitis, dural sinus thrombosis
Blastomycosis	Hyperplastic granulomatous microabscesses	Rarely, chronic meningitis or cerebral abscess
Brill–Zinser epidemic typhus	Macular rash	Meningoencephalitis
Chagas disease	Romana sign, inflammation of lacrimal glands, erythema multiforme	Encephalitis
Coccidioidomycosis	Erythema nodosum, draining sinus, subcutaneous cellulitis	Meningitis common
Cryptococcosis	Macules and nodules (in 10–15% of cases)	Chronic meningitis
Haemophilus influenzae infection	Typically a single indurated area on face, neck, upper chest, or arm	Acute purulent meningitis
Histiocytic reticulosis (autosomal recessive) (OMIM 267700)	Purpura, jaundice, erythroderma	Chronic aseptic meningitis, neuropathy
Leptospirosis	Scleral conjunctival injection, maculopapular rash of trunk (in 50% of cases), jaundice	Subacute meningitis
Leukemia	Erythema nodosum, Sweet syndrome (acute febrile neutrophilic dermatosis–painful raised red plaques, commonly on face and extremities)	Meningeal leukemia is common form of relapse, especially in acute lymphocytic leukemia
Listeriosis	Generalized erythematous papules or petechiae in infants; veterinarians with tender red papules on hands	Subacute meningitis
Lyme borreliosis	Target lesion	Early aseptic meningitis, polyneuropathy, delayed demyelinating disease
Lymphoma	Erythema nodosum	Subacute meningitis, cerebral or vertebral metastases
Lymphoma, cutaneous (T cell)	Scaly erythematous patches, leonine facies, poikiloderma, hypopigmented and hyperpigmented patches with atrophy and telangiectasia	Subacute meningitis, vertebral metastases
Meningococcemia	Petechiae, usually on extremities and trunk; initially can mimic a viral exanthem	Fulminant meningitis
Murine typhus	Axillary rash, macular rash of upper abdomen, shoulders, chest	Headache, encephalopathy, and nuchal rigidity without meningitis
Neurocutaneous melanosis	Melanosis; large multiple pigmented skin nevi (>20 cm), no malignant melanoma other than CNS; primary CNS melanoma in over 50% of cases	Meningeal enhancement secondary to melanosis of pia-arachnoid, cranial nerve palsies, Dandy–Walker malformation, suprasellar calcification
Reticulosis, familial histiocytic	Purpura, jaundice, erythroderma	Chronic meningitis, peripheral neuropathy

(Continued)

TABLE 21-2 ■ (Continued)

Disorder	Cutaneous Lesions	Neurologic Features
Rocky Mountain spotted fever	Progressive rash begins on the fourth day of fever with pink macules on wrists, ankles, forearms; after 6–18 hours, on palms and soles, then centrally after 1–3 days; after 2–4 days, nonblanching petechiae	Vasculitic meningoencephalitis, choreoathetosis, deafness, hemiplegia
Sarcoidosis	Dry skin, hypohidrosis, cicatricial alopecia; *acute*: erythema nodosum, vesicles, maculopapular rash; *chronic*: lupus pernio, plaques, scars, keloids	Chronic meningitis with cranial neuropathies, peripheral neuropathy, proximal myopathy, hypothalamic involvement
Sjögren syndrome	Purpura, Raynaud phenomenon, xerostomia, candidiasis	Aseptic meningitis, sensory neuronopathy, dural sinus thrombosis
Syphilis	*Primary*: chancre. *Secondary*: maculopapular nonpruritic scaling rash (acral), patchy alopecia, condyloma lata, mucous patches, erythema multiforme, hyperpigmentation on healing, split papules, palm and sole lesions	Aseptic meningitis, late meningovascular syphilis, tabes dorsalis
Tuberculosis	Cutaneous tuberculosis is rare; primary tuberculous chancre; warty tuberculous verrucosa cutis from reinfection, postprimary lupus vulgaris, scrofuloderma, erythema nodosum, erythema multiforme	Chronic meningitis, Pott disease of vertebrae, CNS tuberculomas
Varicella zoster (chickenpox)	Vesicles with oral lesions	Meningitis with cerebellar ataxia
Vogt–Koyanagi–Harada	Vitiligo-type macules, poliosis and alopecia in convalescent third phase	Meningoencephalitis in first phase of illness, preceding uveitis
Yersinia pestis (bubonic plague)	Erythema multiforme, bubos then petechiae and ecchymoses	Meningitis can complicate all three types: bubonic, bubonic-septicemic, pneumonic

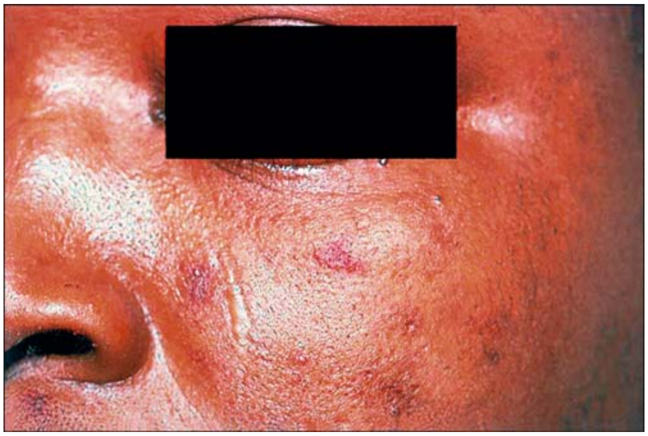

FIGURE 21-6 ■ Early cutaneous lesions of meningococcemia. (From Tyring S, Lupi O, Hengge U: Tropical Dermatology. Courtesy of Dr. Luc Van Kaer. Churchill Livingstone, New York, 2005, with permission.)

pneumoniae. There are now three quadrivalent vaccines against the causative organism *Neisseria meningitidis*, targeting serogroups A, C, W-135, and Y. There are also serogroup-independent vaccines that are effective against serogroup B but, currently, none is effective against serogroup X. Worldwide, meningococcal infections remain one of the leading causes of meningitis in children.

Lyme Borreliosis

The characteristic "target lesion" (*erythema chronicum migrans*) that spreads centrifugally from the site of a prolonged bite by a tick infected with the spirochete *Borrelia burgdorferi* is pathognomonic of early-stage Lyme disease. This cutaneous lesion first develops within a few days to weeks after the infecting bite by the tiny tick, *Ixodes dammini*. The characteristic cutaneous lesion is so named because of the fancied resemblance to a target. The erythematous circumference of the lesion advances over the course of days to weeks up to a diameter of 5 cm, leaving behind a trailing central area of clearing and a persistent erythematous papule at the very center, the site of the original tick bite (Fig. 21-7). This lesion develops in about 85 percent of infected individuals, facilitating clinical diagnosis for the subsequent syndrome of migratory arthralgias and later neurologic dysfunction. However, a high degree of clinical suspicion and the use of a serologic test are necessary for diagnosis in the substantial minority of patients that do not develop the characteristic target lesion.

Although neurologic signs can develop while the erythema migrans is still present, typically they do not appear until the cutaneous signs have resolved, after 6 to 12 months of migratory arthralgia that occasionally evolves into arthritis with an effusion in a large joint. The most common neurologic syndrome, affecting about 70 percent of untreated individuals, is a mild aseptic meningitis, with a mononeuritis multiplex or typical cranial nerve palsies. The latter include unilateral or bilateral facial palsies or lesions of the oculomotor, trigeminal, abducens, or eighth cranial nerve. Alternatively there may be a painful radiculopathy or plexitis. Other lesions reported less frequently include a myositis, patchy demyelination mimicking multiple sclerosis, or myelopathy with radiculopathies that could be mistaken for amyotrophic lateral sclerosis. Some untreated patients later develop an indolent diffuse encephalopathy. Further discussion is provided in Chapter 39.

Syphilis

As in Lyme borreliosis, dermatologic and neurologic manifestations are also temporally discordant in syphilis, which is related to infection with *Treponema pallidum*. The cutaneous manifestations are limited to the painless, indurated, rubbery genital chancre of primary syphilis in the days after infection, and the flat copper-colored lesions of the palms and soles, patchy alopecia, and mucous membrane patches seen in secondary syphilis, 2 to 4 months later (Figs. 21-8 and 21-9). Secondary syphilis is associated with a mild meningitis, sometimes with involvement of cranial nerves, typically the optic, facial, or acoustic.

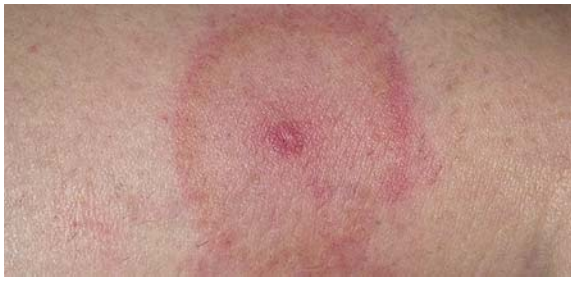

FIGURE 21-7 ■ Large 5-cm targetoid patch with central clearing, bright-red expanding border and central bite inflammation, characteristic of the erythema migrans rash of Lyme disease. (From Habif T, Campbell J, Chapman MS, et al: Dermatology DDX Deck. Saunders, Philadelphia, 2006, with permission.)

In contrast, cutaneous lesions will have resolved by the time of meningovascular syphilis, peaking 4 to 7 years after infection, and the neurologic manifestations of late-stage syphilis, namely the dementia (general paresis of the insane) and tabes dorsalis (Chapter 39). Thus the only exception to the temporal discordance of cutaneous and neurologic manifestations is their invariable association in secondary syphilis, in prenatal syphilis, and the rare occurrence of cutaneous nodules in late syphilis.

Fortunately, the late stages of syphilis have become quite rare. There had also been a period of diminishing prevalence of primary and secondary syphilis, but since 2000 there has been a steady increase of

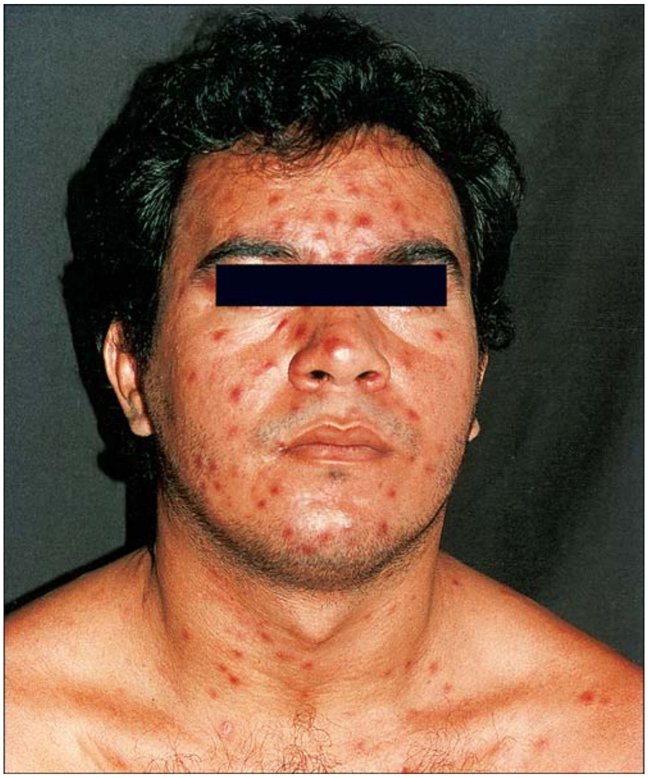

FIGURE 21-8 ■ Secondary syphilis: disseminated papular lesions. (From Tyring S, Lupi O, Hengge U: Tropical Dermatology. Courtesy of Dr. Luc Van Kaer. Churchill Livingstone, New York, 2005, with permission.)

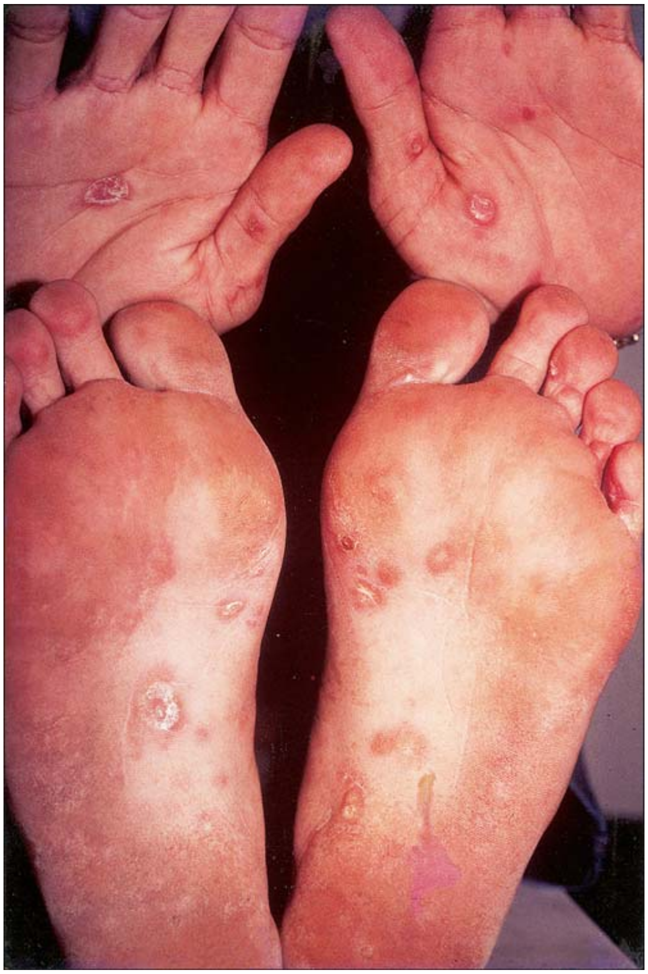

FIGURE 21-9 ■ Secondary syphilis: hyperkeratotic lesions on palms and soles. (From Tyring S, Lupi O, Hengge U: Tropical Dermatology. Courtesy of Dr. Luc Van Kaer. Churchill Livingstone, New York, 2005, with permission.)

incidence up to 16.9 per 100,000 in men and 2.3 per 100,000 in women, with a concomitant rise of congenital syphilis. Much of this increase has occurred in association with HIV-AIDS, which has also contributed to an altered natural history, including an occasional novel presentation that mimics that of herpes simplex encephalitis (but is responsive to treatment with penicillin), with focal lesions in the temporal lobe and status epilepticus or periodic lateralized discharges in the electroencephalogram.

Careful studies have also brought to light previously under-recognized syndromes of otologic syphilis, characterized by early sensorineural hearing loss and occasionally by vestibular dysfunction as well; and of ocular syphilis, mostly an early posterior uveitis affecting the choroid, retina, and pigmentary retinal epithelium. Involvement of the uveal tract also characterizes several other neurocutaneous disorders. Uveomeningitis is an occasional presentation of sarcoid, Behçet disease, and systemic lupus erythematosus, described in the following sections. It is also typical of the rare Vogt–Koyanagi–Harada syndrome, in which a prodromal meningoencephalitis precedes uveitis as well as the characteristic dermatologic findings of leukoderma with symmetric patches of vitiligo (involving the head, neck, shoulders, and eyelids), alopecia, and poliosis.

Sarcoidosis

Both the cutaneous and neurologic manifestations of sarcoidosis (discussed in Chapter 49) are notoriously variable, complicating early diagnosis.[9] Indeed, only 20 to 30 percent of patients with sarcoid have cutaneous lesions, and only 3 to 10 percent have neurologic manifestations. The most typical neurologic presentation is that of a mild aseptic meningitis, with or without cranial nerve palsies. Typically these are unilateral or bilateral facial nerve palsies, but optic, auditory or vestibular neuropathies may occur as well. A wide variety of other neurologic manifestations also occur (Chapter 49).

The cutaneous manifestations of sarcoid are more frequent but are also highly variable. There can be acute lesions such as erythema nodosum, vesicles, and maculopapular rash. These annular lesions, papules, or nodules are either skin-colored, violaceous, or brownish-red, often appearing on the face. Chronic lesions include lupus pernio (large, bluish red, dusty, violaceous infiltrated nodules and plaques, which generally appear on the cheeks, ears, fingers, and nose), plaque, scars, and keloids. The rare angiolupoid form of sarcoidosis consists of orange-red or reddish-brown soft, well-demarcated lesions.

Behçet Disease

This poorly understood inflammatory disease is characterized by a triad of recurrent oral and genital ulceration and uveitis, most commonly seen in populations along the old “Silk Road.” The majority of patients have additional cutaneous abnormalities including papillopustular lesions, erythema nodosum, and a pathergy reaction (pustulation at the site of trauma). The classic triad forms the basis of the current criteria for diagnosis, which is entirely clinical: recurrent oral ulceration (at least three times in a year) plus two of the following: (1) recurrent genital ulceration; (2) ocular lesions (uveitis, retinal vasculitis, or cells in the vitreous); and (3) skin lesions (erythema nodosum, pseudofolliculitis). Other common manifestations are arthritis, present in up to half of individuals; subcutaneous thrombophlebitis in about a quarter; and, in Japan, gastrointestinal lesions that affect about one-third. In contrast, neurologic complications affect only 10 percent or less of patients with Behçet disease, either as parenchymal or neurovascular disease. These two categories are not mutually exclusive; both parenchymal and neurovascular disease can affect a substantial minority of these patients. The pathology of the parenchymal disease is a "perivasculitis" rather than a vasculitis. There are infiltrates of polymorphonuclear leukocytes, eosinophils, lymphocytes, and macrophages without infiltration of blood vessel walls or necrosis of endothelial cells. The typical MRI picture of brainstem meningoencephalitis is that of a unilateral T2-enhancing lesion of the upper brainstem. Less frequent manifestations of parenchymal disease are seizures, transverse myelopathy, diffuse encephalopathy, or, much less commonly, an optic neuropathy. In some instances, the MRI appearance may resemble that of a glioma. Movement disorders and peripheral neuropathy are rare. Although venous occlusion is common, stroke resulting from arterial occlusions is rare, occurring in about 1 percent. Intracranial venous sinus thrombosis presents as increased intracranial pressure, a presentation that also sometimes occurs in the absence of radiographically demonstrable sinus or venous occlusion.

This disorder usually presents in young men, aged 20 to 40 years, but women are also affected, albeit less often. Most patients respond to treatment with corticosteroids, although about 20 percent are left with significant residual neurologic impairment and 10 percent succumb within a decade of diagnosis. Some practitioners supplement treatment of sinus thrombosis with anticoagulants after ruling out a pulmonary aneurysm, whereas others find corticosteroid treatment to be adequate. The course may be monophasic, relapsing remitting, or, most ominously, progressive.

INTERMITTENT ENCEPHALOPATHIES

Intermittent nonfocal impairment of the CNS culminating in psychiatric disturbance, confusion, delirium, stupor, or coma may result from trauma, infection, inflammation, and a wide variety of metabolic insults, some with cutaneous manifestations, as summarized in Table 21-3. Indeed, two of the most common—diabetic coma and intoxication with alcohol—are associated with cutaneous manifestations well known to most practicing physicians. The focus of this section is therefore on less common and perhaps less well-known neurocutaneous intermittent encephalopathies.

Systemic Lupus Erythematosus

Cutaneous abnormalities (malar, discoid, or photosensitive rash; Fig. 21-10) are present in at least 80 percent of these patients, with malar rash topping the list of the 17 classification criteria published by the Systemic Lupus International Collaborating Clinics, of which four are necessary for diagnosis. The others are features readily recognizable as immunologic abnormalities: serologic findings in the blood; arthritis; serositis of pleura or pericardium; glomerulonephritis or proteinuria; and hemolytic anemia, lymphopenia, or thrombocytopenia.[10] Rounding out the list are the nonspecific neurologic symptoms, including psychosis, which can be a presenting feature before the development of signs more typically associated with autoimmune disease. Because lupus typically presents between the ages of 15 and 25, which is also the peak age of onset of schizophrenia, a disorder considerably more prevalent than lupus, many patients are hospitalized in psychiatric wards before the true nature of their disease is recognized, often by appreciation of cutaneous abnormalities.

Although common, psychiatric signs and symptoms of a diffuse encephalopathy are but one of many less common but not infrequent manifestations of CNS lupus, others being seizures; aseptic meningitis; stroke (most commonly ischemic, either embolic from marantic endocarditis or mural cardiac thrombi after myocardial infarction, or from carotid atherosclerosis); chorea; relapsing-remitting disease resembling multiple sclerosis; and movement disorders. In addition, there is the more localized posterior reversible encephalopathy syndrome (PRES), a disorder with reversible subcortical vasogenic brain edema caused by endothelial dysfunction that presents with headaches, seizures, altered mental status, cortical blindness, vomiting, and focal deficits. Although occurring with other autoimmune disorders, this rare encephalopathy is encountered most commonly in association with systemic lupus. Systematic clinical trials have yet to be performed, but a favorable clinical response seems to follow control of blood pressure and seizures and elimination of

TABLE 21-3 ■ Intermittent Encephalopathy with Cutaneous Manifestations

Disorder	Cutaneous Lesions	Neurologic Features
Alcoholism	Telangiectasia	Intoxication, delirium tremens, neuropathy, Wernicke–Korsakoff syndrome, Marchiafava–Bignami syndrome
Coproporphyria (OMIM 121300)	Photosensitivity	Peripheral neuropathy, crises of abdominal pain and mental changes
Ethylmalonic encephalopathy (OMIM 602473)	Petechiae	Pyramidal and extrapyramidal signs, ataxia, seizures, hyperintense lesions in basal ganglia on MRI
Diabetes mellitus	Poorly healing skin ulcers, necrobiosis lipoidica diabeticorum	Diabetic ketoacidosis, nonketotic hyperglycemic coma, insulin-induced hypoglycemic coma, lacunar stroke, neuropathy, retinopathy
Hemolytic-uremic syndrome, 1–6 (OMIM 235400, 612922–612926)	Purpura	Coma, seizures, hemiparesis, visual disturbances
Holocarboxylase synthetase deficiency (OMIM 253270)	Skin rash	Irritability, lethargy, coma, seizures, hypotonia, developmental delay, hypertonia
Hydroxykynureninuria (OMIM 236800)	Light-sensitive rash	Intermittent, nonprogressive, ataxic encephalopathy
Letterer–Siwe disease (OMIM 246400)	Diffuse papulovesicular rash, scaly petechial dermatitis, intertriginous denudation, seborrhea, stomatitis	Encephalopathy
Methylmalonic aciduria and homocystinuria, CBLF type (OMIM 277380)	Reticulated pigmentation and rashes	Encephalopathy, hypotonia, lethargy, developmental delay, ataxia
Murine typhus	Macular rash	Headache, encephalopathy, and nuchal rigidity
Propionic acidemia (OMIM 606054)	Dermatitis acidemica	Acute encephalopathy, axial hypotonia, limb hypertonia, psychomotor retardation, cerebral atrophy, dystonia, cerebellar hemorrhage, ischemic stroke of basal ganglia
Shaken baby syndrome	Ecchymoses, purpura	Subdural hematomas, subarachnoid hemorrhage, parenchymal lacerations
Systemic lupus erythematosus	Photosensitivity, malar rash, telangiectasia, discoid lupus, patchy alopecia, mucosal ulcers, angioneurotic edema, Raynaud phenomenon, subcutaneous nodules, palpable purpura, gangrene, erythema multiforme	Encephalopathy, ischemic and hemorrhagic stroke, chorea, multifocal demyelination, peripheral neuropathies
Thrombotic thrombocytopenic purpura	Purpura	Rapidly evolving encephalopathy
Variegate porphyria (OMIM 176200)	Photosensitivity, blistering, skin fragility with chronic scarring of sun-exposed areas and postinflammatory hyperpigmentation	Crises with neuropsychiatric symptoms, abdominal pain, motor neuropathy

immunosuppressive drugs. The peripheral nervous system is also a frequent site of involvement with compressive neuropathies, most commonly carpal tunnel syndrome, affecting about 30 percent of patients, and a distal symmetric axonal neuropathy, sometimes with dysautonomia, about 20 percent. In about 1 percent or less, acute or chronic demyelinating neuropathies, mononeuritis multiplex, or cranial mononeuropathies occur.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) (Fig. 21-11) is a fulminant disorder that may be lethal if untreated.[11] Its clinical hallmark is rapid progression through confusion and obtundation to coma in the setting of thrombocytopenia resulting in cutaneous purpura, fever, Coombs-negative hemolytic anemia with fragmentation of erythrocytes, and renal

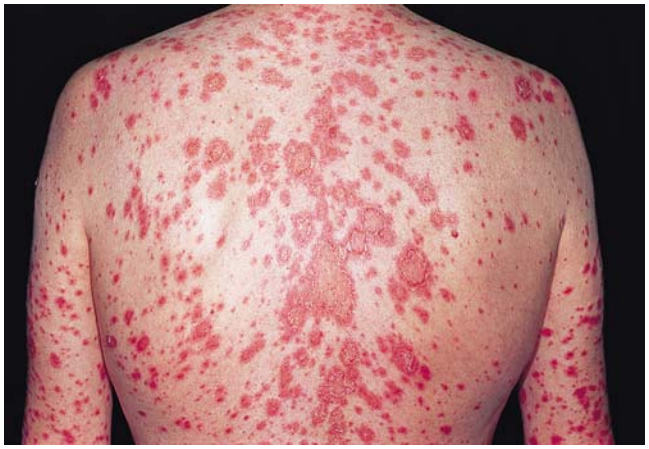

FIGURE 21-10 ■ Systemic lupus erythematosus. (From Callen J, Jorizzo J, Bolognia J, et al: Dermatological Signs of Internal Disease. Saunders, Philadelphia, 2009, with permission.)

failure. Unlike lupus, this is not a vasculitis but a manifestation of pathologic aggregations of platelets. The adult-onset form is triggered by endothelial injury in various clinical settings: HIV-AIDS, pregnancy, metastatic cancer, or high-dose chemotherapy, or as a drug reaction. Most frequently there is an autoantibody-mediated depletion of an enzyme (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13, or ADAMTS13, also known as von Willebrand factor-cleaving protease or VWFCP) that cleaves very high-molecular-weight complexes of von Willebrand factor, which can cause platelet adhesion and thrombosis. There is also a rare congenital familial TTP that is an autosomal recessive disorder (OMIM 274150) resulting from homozygosity for mutations of the ADAMTS13 gene encoded on chromosome 9q34.2. The congenital form, also known as Schulman–Upshaw syndrome, is associated with neonatal jaundice and a propensity to recurrences that require treatment with fresh frozen plasma.

Either form can be treated with plasmapheresis and exchange transfusion to remove the uncleaved high-molecular-weight complexes of von Willebrand factor and to replenish ADAMTS13. When needed, prophylaxis to prevent relapse of the acquired forms with autoantibodies to ADAMTS13 can also be obtained with corticosteroids, cyclosporine, or rituximab, an antibody directed at CD20, a cell-surface antigen of antibody-secreting B lymphocytes. Prompt recognition and treatment of this formerly lethal disorder results in recovery without residual neurologic or renal dysfunction, but mortality is still estimated at 10 to 20 percent.

The disorder must be distinguished from the similar hemolytic-uremic syndrome, of which there are several heritable susceptibility syndromes (OMIM 235400, 612922–612926). This disease occurs in children under age 3, usually after a prodromal diarrheal illness resulting from serotoxin-producing *Escherichia coli*, and is not always associated with encephalopathy. Six genes have been identified that confer susceptibility to this less-threatening disorder, all of them related to the complement system, a quite distinct mechanism from that underlying TTP.

Porphyria

The porphyrias are a family of genetically unrelated disorders resulting from mutations that disrupt heme metabolism. Clinically they can be divided into the hepatic porphyrias, which have neurologic but no cutaneous manifestations, and the cutaneous porphyrias, in which the opposite is true. Thus, none are neurocutaneous disorders, with the exception of variegate porphyria (OMIM 176200; heterozygous mutation of the protoporphyrinogen oxidase gene on chromosome 1q23.3, encoding the penultimate enzyme in the heme biosynthetic pathway) and coproporphyria (OMIM 121300; heterozygous mutation of the coproporphyrinogen oxidase gene on chromosome 3q11.2-q12.1). In both of these disorders, there is increased photosensitivity of the skin, and in variegate porphyria, fragility of the skin with blistering and chronic scarring of sun-exposed areas, followed by postinflammatory hyperpigmentation. In both, certain drugs induce a delirious encephalopathic crisis with psychotic symptoms, as well as neuropathic abdominal pain, constipation, and vomiting. In addition to the peripherally mediated abdominal crises there is a severe interictal peripheral neuropathy, which in variegate porphyria includes bulbar involvement as well as symmetric motor impairment in the extremities.

Both of these disorders violate the general rule of thumb that hereditary enzyme deficiencies are recessive disorders. In both, heterozygosity for a single mutant allele is sufficient to give rise to the disease phenotype, accounting for the unusual pattern of dominant inheritance for a metabolic disorder.

DEMENTIA

Certain neurocutaneous disorders lead to a progressive loss of cognitive ability. Two important examples are described in greater detail in the following paragraphs.

HIV-AIDS

Cognitive impairment, ranging in severity from mild HIV-1-associated neurocognitive disorder (HAND) to a severe progressive dementia, as well as a peripheral neuropathy, continue to be significant neurologic manifestations of HIV-AIDS, despite the availability of combination antiretroviral therapy.[12] The incidence of severe AIDS-related dementia has decreased, as have a number of adventitious infections of the nervous system in AIDS patients, including progressive multifocal encephalopathy, tuberculosis, toxoplasmosis, and infection with cytomegalovirus. However, the incidence of milder cognitive impairment persists, for reasons not yet understood. These and other neurologic aspects of HIV-AIDS are discussed in Chapter 43. Cutaneous manifestations have always been a hallmark of HIV-AIDS, affecting an estimated 85 percent of patients. A major clue in the early history of our understanding of AIDS was the high frequency of an unusual rapidly growing cutaneous tumor, atypical Kaposi sarcoma, in young homosexual men. Cutaneous herpes zoster or, more rarely, disseminated cryptococcal infection with cutaneous lesions resembling molluscum contagiosum may also be AIDS-defining events in HIV-positive individuals. The most common cutaneous manifestation, however, is seborrheic dermatitis, a chronic inflammation of the scalp and face, and, less commonly, intertriginous areas such as axillae and groin. Other cutaneous manifestations are virally mediated verruca vulgaris and molluscum contagiosum, recurrent staphylococcal infections, and tinea corporis.

Cockayne Syndrome

Cockayne syndrome (OMIM 216400) is an autosomal recessive disorder of “cachectic dwarfism” and significant cutaneous and neurologic abnormalities, with progressive dementia and multiple systemic abnormalities, that usually results in death in early adolescence, but with occasional survival to young adulthood. Other CNS abnormalities include microcephaly, calcifications of the basal ganglia, patchy subcortical demyelination, normal-pressure hydrocephalus, sensorineural hearing loss, pigmentary retinopathy, optic atrophy, ataxia, nystagmus, and peripheral neuropathy.

The syndrome is a consequence of homozygosity for mutations in a DNA-repairing enzyme, excision-repair cross-complementing, group 8 (ERCC8) on chromosome 5q12.1 (Cockayne syndrome A, OMIM 216400) or ERCC6 on chromosome 10q11.23 (Cockayne syndrome B, OMIM 133540). The resulting deficit confers increased sensitivity to ultraviolet irradiation, but not to x-irradiation. In a striking contrast with ataxia telangiectasia and xeroderma pigmentosa, other neurocutaneous disorders resulting from defects in DNA repair, there is no increased susceptibility to infections or malignancy.

SEIZURE DISORDERS

A great many neurocutaneous syndromes are associated with seizures. Three syndromes frequently included by some authors under a broadened definition of phakomatosis are discussed here in greater detail.

Sturge–Weber Syndrome

The characteristic feature of the Sturge–Weber syndrome (OMIM 185300) is the congenital port wine stain (Fig. 21-12), typically in the distribution of one of the branches of the trigeminal nerve. If

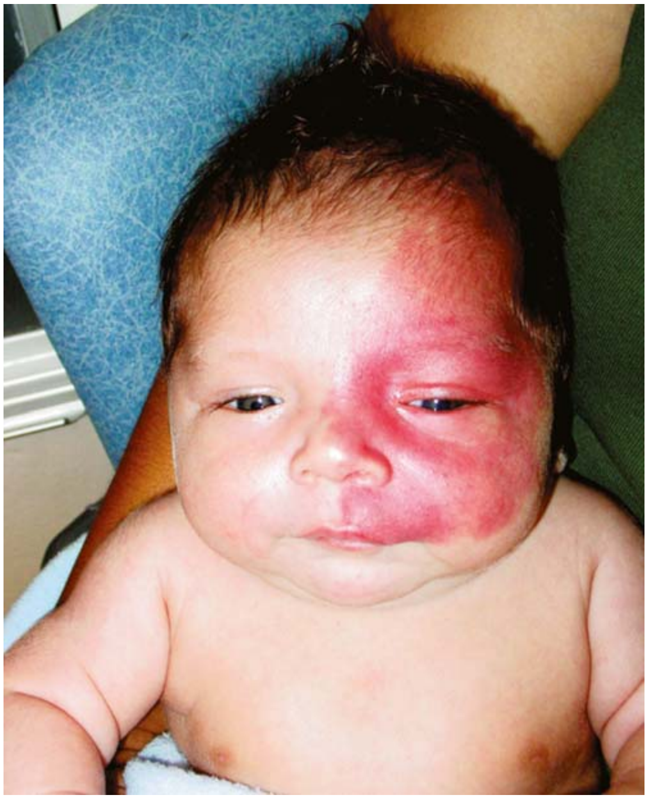

FIGURE 21-12 ■ Sturge–Weber syndrome: port-wine stain. (From Jones K: Smith's Recognizable Patterns of Human Malformation. Saunders, Philadelphia, 2005, with permission.)

this cutaneous lesion overlies the first division, there is a 75 percent chance that there will be a corresponding leptomeningeal venous malformation overlying focal deep cortical calcifications. This is often visible on skull radiographs as a "tram sign," the two tracks of which follow the contours of the calcified gyri.

Sturge–Weber syndrome is believed to result from somatic mosaicism for a mutation in the *GNAQ* gene (OMIM 600998) on chromosome 9q21-2, vertical transmission from parent to child never having been observed. The most common neurologic manifestation is epilepsy, typically partial complex seizures. The age of onset of seizures varies from birth to young adulthood. Often these seizures cannot be managed satisfactorily with anticonvulsants and therefore lead to consideration of surgery.

Unlike the classic phakomatoses with which it has occasionally been classified, Sturge–Weber syndrome is not associated with tumors of the nervous system or elsewhere. However, clinically significant neurologic involvement accompanies epilepsy in a significant proportion of affected individuals. Developmental delay and requirement for special education are typical of many patients with Sturge–Weber syndrome, but not for those who do not experience seizures. In contrast, the majority of individuals in both groups experience behavioral and emotional disturbances, as well as impediments to gainful employment, albeit to a greater degree in those with seizures. The major non-neurologic sequela is glaucoma, with onset as early as birth and as late as the fifth decade.

Incontinentia Pigmenti (Bloch–Sulzberger Disease)

Incontinentia pigmenti (OMIM 308300) is an X-linked dominant disorder that is lethal in utero to males, and is therefore only seen in those living female heterozygotes who preferentially inactivate the X chromosome bearing the mutant *NEMO* gene on Xp28 (a regulatory kinase of an inhibitor of the kappa light polypeptide gene enhancer in B cells) by lyonization. There is selective loss of cells expressing the X chromosome with the mutant gene at the time of birth, a process that continues until completion in young adulthood, at which time only cells expressing the normal X chromosome remain. This gradual elimination of cells expressing the mutant gene appears to be temporally correlated with the course of the characteristic cutaneous disorder, which occurs in four stages: (1) within hours to days of birth, lines of erythema develop into inflammatory vesicles that last from weeks to months; (2) these lesions then develop into verrucous, wart-like patches that persist for months; (3) hyperpigmentation develops, very gradually becoming pale and finally disappearing by age 20 years; and (4) dermal scarring develops in the final stage (Figs. 21-13 and 21-14). Hair loss may affect the scalp and other parts of the body, and there may be lined or pitted nails and toenails.

Seizures are the most common neurologic manifestation, occurring in about 70 percent of affected women, followed by various motor impairments (40%), cognitive impairment (30%), and microcephaly (7%). Structural abnormalities detectable by brain scanning include focal atrophy, infarcts, and lesions of the corpus callosum.

Classic Bloch–Sulzberger disease, as described above, had previously been called incontinentia pigmenti type II (IP2), IP1 being a term erroneously

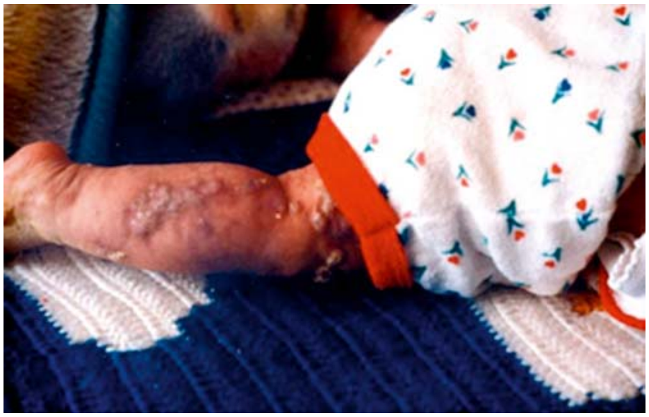

FIGURE 21-13 ■ Incontinentia pigmenti (Bloch–Sulzberger) stage 3: the beginning of hyperpigmentation. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012, with permission.)

assigned by earlier investigators to some cases of hypomelanosis of Ito (OMIM 300337), which does not represent a distinct entity but is rather a manifestation of many different states of mosaicism. The hypopigmented skin lesions in hypomelanosis have been described as the "negative pattern" of the hyperpigmented lesions of incontinentia pigmenti. Neurologic abnormalities, typically seizures, are quite variable but can include severe mental retardation. The most prominent neuroanatomic abnormalities are histologically benign cortical heterotopias. It is best that the IP1/IP2 terminology be discarded, these disorders being both clinically and genetically distinct.

Linear Sebaceous Nevus Syndrome

Another dominant-lethal neurocutaneous syndrome associated with epilepsy that survives only by somatic mosaicism is the linear sebaceous nevus syndrome (OMIM 163200), also known as the Schimmelpenning–Feuerstein–Mims syndrome (Fig. 21-15). The characteristic sebaceous nevi typically present in the first year of life and persist through adulthood, and are often the site of secondary lesions such as basal cell carcinomas, hemangiomas, hypopigmentation, trichoblastoma, syringocystadenoma papilliferum, and central giant cell granuloma. Neurologic involvement (most commonly seizures, but also mental retardation, ophthalmoplegia, hemimegencephaly, attention deficit disorder) is only present in about 7 percent of individuals, who can present with any of a large variety of systemic abnormalities including coarctation of the aorta, horseshoe kidney, phosphaturia,

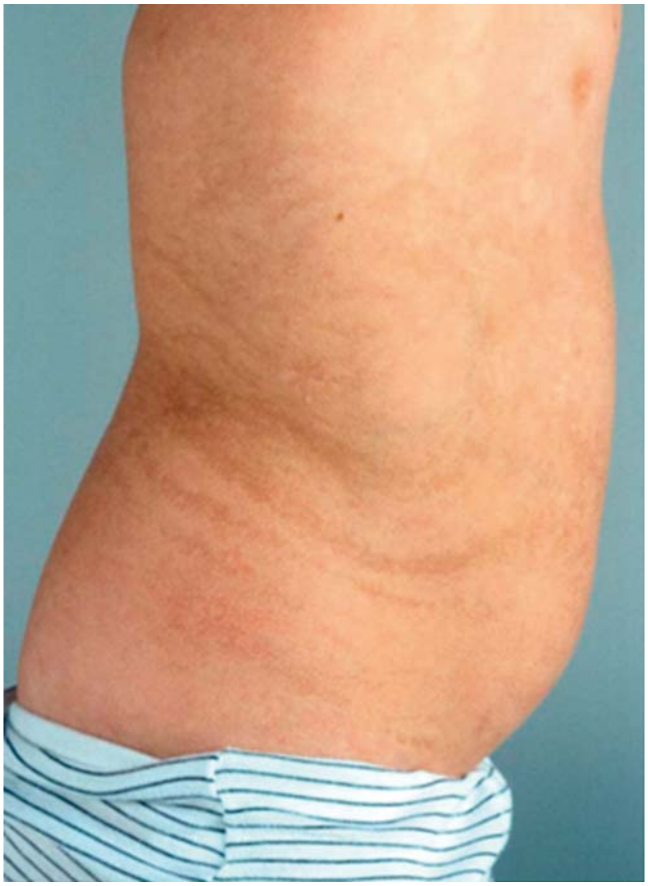

FIGURE 21-14 ■ Incontinentia pigmenti (Bloch–Sulzberger) stage 4: hypopigmentation on the trunk. (From Kurlemann G: Neurocutaneous syndromes. Handb Clin Neurol 108:513, 2012, with permission.)

osteopenia with fractures, and short stature. This disorder results from a mutation in either of two RAS genes: *KRAS* (V-Ki-Ras2 kirsten rat sarcoma viral oncogene homolog gene on chromosome 12p12.1) or *HRAS* (V-Ha-Ras Harvey rat sarcoma viral oncogene homolog gene on chromosome 11p15.5).

ATAXIA

Neurocutaneous disorders in which ataxia is a prominent feature are listed in Table 21-4. Four representative disorders are described in the following paragraphs.

TABLE 21-4 ■ Ataxia with Cutaneous Manifestations

Disorder	Cutaneous Lesions	Neurologic Features
Acrodermatitis enteropathica, zinc-deficiency type (OMIM 201100)	Bullous, pustular dermatitis of extremities; oral, anal, and genital areas dermatitis; impaired wound healing	Lethargy; ataxia; tremors; emotional lability
Angiomatosis, diffuse corticomeningeal, of Divry & van Bogaert (OMIM 206570)	Cutis marmorata; telangiectasia	Seizures; dementia; ataxia; dysarthria; pseudobulbar symptoms; emotional lability
Ataxia-telangiectasia (OMIM 208900)	Cutaneous telangiectasia; café-au-lait spots; progeric and sclerodermatous changes	Hyporeflexia; dysarthria; ataxia; choreoathetosis; seizures; oculomotor abnormalities
Biotinidase deficiency (OMIM 253260)	Seborrheic dermatitis; skin infections	Seizures; ataxia; developmental delay
Celiac disease; CD (OMIM 212750)	Dermatitis herpetiformis; follicular keratosis	Peripheral neuropathy; ataxia; anxiety; depression; cerebral calcification
Cerebrotendinous xanthomatosis (OMIM 213700)	Tuberous xanthoma; xanthelasma	Dementia; spasticity; ataxia; pseudobulbar palsy; psychiatric symptoms; leukoencephalopathy
Cowden disease (OMIM 158350)	Multiple facial papules; acral keratosis; palmoplantar keratosis; multiple skin tags; facial trichilemmomas; subcutaneous lipomas	Mild to moderate mental retardation; Lhermitte—Duclos disease; appendicular ataxia; cerebellar gangliocytoma; meningioma
Dyskeratosis congenita, autosomal dominant, 3 (OMIM 613990)	Reticular pigmentation pattern; leukoplakia; dry skin	Speech delay; learning difficulties; intracranial calcifications; ataxia; cerebellar hypoplasia
Flynn—Aird disease (OMIM 136300)	Skin atrophy, chronic ulceration	Seizures; dementia; ataxia; peripheral neuropathy
Hartnup disorder (OMIM 234500)	Photosensitive dermatitis	Intermittent ataxia; seizures; hypertonia; hyperreflexia; emotional instability; psychosis
Hemophagocytic lymphohistiocytosis (OMIM 267700, 603553)	Purpuric rashes	Seizures; meningitis; encephalitis; ataxia; coma; increased intracranial pressure; delayed psychomotor development
Hydroxykynureninuria (OMIM 236800)	Light-sensitive rash	Intermittent nonprogressive ataxic encephalopathy
Neuroblastoma (OMIM 256700)	Bluish skin nodules	Paraneoplastic opsoclonus, myoclonus, and/or ataxia; spinal cord compression
PHACE association (OMIM 606519)	Hemangioma, facial, plaque-like	Developmental delay; Dandy—Walker malformation; seizures; migraine headaches (ipsilateral to facial hemangioma); cerebral infarction
Plasminogen deficiency, type I (OMIM 217090)	Juvenile colloid milium; small papules on sun-exposed areas	Dandy—Walker malformation; macrocephaly; adult onset of symptoms has been reported
Refsum disease (OMIM 266500)	Ichthyosis	Ataxia; peripheral neuropathy; retinitis pigmentosa; sensorineural deafness; anosmia
Renal tubulopathy, diabetes mellitus, and cerebellar ataxia (OMIM 560000)	Mottled pigmentation of photoexposed areas; episodic cold-triggered erythrocyanosis of toes and fingers	Myoclonic jerks; ataxia; hypotonia; psychomotor regression
Revesz syndrome (OMIM 268130)	Fine, reticulate skin pigmentation (trunk, palm, and soles)	Psychomotor retardation; cerebellar hypoplasia; ataxia; cerebral calcifications; hypertonia; progressive neurologic deterioration
Spinocerebellar ataxia 34 (OMIM 133190)	Erythrokeratodermia; papulosquamous erythematous plaques; hyperkeratosis	Spinocerebellar ataxia; mild spasticity; dysarthria

Ataxia Telangiectasia

Also known as Louis–Bar syndrome (OMIM 208900), the cardinal features of this autosomal recessive disorder are cerebellar ataxia, cutaneous telangiectases, immune defects, and a predisposition to malignancy (Fig. 21-16). The invariable, progressive neurologic disorder, chiefly ataxia, begins at birth, often initially causing diagnostic confusion because the characteristic oculocutaneous telangiectasias do not appear until 3 to 5 years of age. The ataxia is initially truncal and only later appendicular. It is associated with a characteristic oculomotor apraxia. A large-fiber neuropathy becomes evident in late childhood and spinal muscular atrophy evolves in early adulthood. About 10 percent of individuals also develop a more complex movement disorder, with choreoathetosis that can be severe.

Major issues in clinical management include a strong predisposition to malignancy (chiefly leukemia and lymphoma, but also others), as well as impairment of both humoral and cellular immunity, often manifested by frequent sinopulmonary infections. A marked hypersensitivity to ionizing radiation is a fundamental feature of this disorder: the need to minimize exposure requires significant modification of radiotherapeutic dosages and the use of radiologic monitoring.

Affected individuals are homozygous for mutation of the ataxia-telangiectasia mutated (*ATM*) gene, consisting of 66 exons encoding a phosphatidylinositol 3-kinase that repairs certain types of DNA damage, on chromosome 11q22.3. As such, it fits the classic definition of an autosomal recessive disorder. However, heterozygotes for *ATM* mutations, who cannot be identified by routine clinical examination and who vastly outnumber manifesting homozygotes, have a significantly increased sensitivity to radiation as well as increased propensity to certain types of malignancy. As such, they represent a larger concern to public health than do the rare, unfortunate homozygotes.

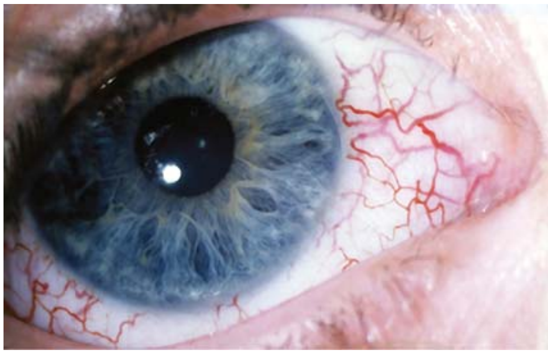

FIGURE 21-16 ■ Ataxia-telangiectasia: bulbar conjunctiva. (From Jones K: Smith's Recognizable Patterns of Human Malformation. Saunders, Philadelphia, 2005, with permission.)

Cerebrotendinous Xanthomatosis

The dermatologic manifestations of this lipid storage disorder (OMIM 213700) are tuberous xanthomata and xanthelasma, similar to the characteristic deposits of cholesterol and cholestanol in multiple other tissues, particularly in the Achilles tendon, for which deposits the disorder is named. The progressive neurologic disorder begins in puberty with ataxia and progresses to involve the spinal cord and brainstem. These cardinal features correlate with focal lipid deposits, visible on either CT or MRI scans, in the cerebellar white matter and the cerebral peduncles as well as the brainstem and basal ganglia. Unlike in ataxia telangiectasia, a progressive dementia may develop as well as psychotic symptoms such as delusions and hallucinations. Systemic symptoms include cataracts, respiratory complaints, bony fragility, and myocardial infarction, even though plasma cholesterol levels are either normal or only modestly elevated.

This autosomal recessive disorder results from the lack of functional sterol 27-hydroxylase, an enzyme involved in the synthesis of bile acids, resulting from mutations in the *CYP27A1* gene on chromosome 2q35. This metabolic abnormality leads to decreased synthesis of bile acids and a compensatory increase in the activity of the rate-limiting enzyme in bile acid synthesis, cholesterol 7α-hydroxylase, and accumulation of 7α-hydroxylated bile acid precursors, including a precursor to cholestanol that readily crosses the blood–brain barrier. This complex biochemistry can be ameliorated by treatment with cholic acid, chenodeoxycholic acid, and statins, which reduce xanthomata and improve central neurologic symptoms, but not the axonal peripheral neuropathy which is part of this systemic disorder.

Classic Refsum Disease

This is a complex neurocutaneous disorder in which progressive ataxia is part of an invariable tetrad that also includes peripheral neuropathy, retinitis pigmentosa, and elevated protein in acellular cerebrospinal fluid (OMIM 266500). In most cases, there is also progressive hearing loss. The classic dermatologic abnormality of ichthyosis is less common, as are cardiac abnormalities and a skeletal abnormality, multiple epiphyseal dysplasia. Classic Refsum disease is to be distinguished from the genetically and clinically distinct infantile Refsum disease, which is one of a heterogeneous group of peroxisomal biogenesis disorders that include Zellweger syndrome and neonatal adrenoleukodystrophy.

Classic Refsum disease is a treatable autosomal recessive disorder. Affected individuals are homozygous for inactivating mutations in the gene encoding phytanoyl-CoA hydroxylase on chromosome 10p13. As a result, there is impaired degradation of phytanic acid, an unusual branched-chain fatty acid derived exclusively from dietary sources. Restriction of foods containing chlorophyll and phytols leads to reduction of blood levels of phytanic acid and some amelioration of clinical signs. Plasmapheresis may allow modest liberalization of the diet.

Hartnup Disease and Related Disorders

Unlike the previously described neurocutaneous ataxias, which are progressive when treatment is unavailable, Hartnup disease (OMIM 234500) is an intermittent ataxia, associated with a light-sensitive, pellagra-like skin rash and emotional instability. The characteristic rash is symmetric, hyperkeratotic, hyperpigmented, and desquamated in exposed areas.

It results from homozygosity for mutations that alter the activity of system B(0) neutral amino acid transporter 1, also referred to as solute carrier family 6 (neurotransmitter transporter), member 19 (SLC6A19), an amino acid transporter present in the intestinal brush border and renal cortical proximal tubules, but not in the skin or the nervous system. For this reason, signs and symptoms can be attributed to low plasma levels of neutral amino acids, principally tryptophan and methionine, resulting from aminoaciduria and selective intestinal malabsorption. The frequency of Hartnup disease is similar to that of phenylketonuria, that is, 1 in about 14,000 live births. Unlike phenylketonuria, however, Hartnup disease has no ill effects on the fetus because placental transport of amino acids is not affected. Indeed, despite this significant frequency, the full-blown classic disorder is now rarely seen in the United States because most diets supply sufficient levels of neutral amino acids to at least partially compensate for intestinal and renal losses.

A similar rash occurs in two other neurocutaneous disorders in which tryptophan metabolism is implicated. *Pellagra*, rarely seen in the developed world, results from dietary deficiency of a B vitamin, niacin, which can be taken directly in the diet or synthesized from dietary tryptophan, both of which are in short supply in a corn-based diet. This chronic wasting disease is characterized by a triad of dermatitis, dementia, and diarrhea.

Hydroxykynureninuria (OMIM 236800) is an autosomal recessive disorder resulting from deficiency of kynureninase, an enzyme apparently required for the synthesis of niacin from tryptophan. Its neurologic phenotype is intermediate between that of pellagra and Hartnup disease. In addition to the characteristic light-sensitive rash, there is a nonprogressive ataxic encephalopathy that can reversibly worsen under the stress of a viral infection, on occasion leading to coma and death.

MYELOPATHY

Transverse or compressive myelopathies may be rare presentations of a number of neurocutaneous syndromes. Two, in which myelopathy is a common presentation, are described here.

Rheumatoid Arthritis

Subcutaneous nodules at sites of trauma, such as extensor surfaces of forearms, posterior scalp, and ears are characteristic manifestations of rheumatoid arthritis. In addition, there may be painful papules of the finger pulp, bright red "liver palms," or a vivid washable yellow discoloration of the skin from inspissated sweat.

The most feared neurologic abnormality in rheumatoid arthritis is not from intrinsic inflammation of the nervous system but a potentially life-threatening compressive high cervical myelopathy resulting from localized pachymeningitis or arthritis with laxity of the atlantoaxial joint, present in about half of individuals with advanced rheumatoid arthritis. This can cause either horizontal atlantoaxial instability or vertical translation of the dens with a normal atlantoaxial interval. Repeated microtrauma to the craniocervical junction may give rise to a gradually progressive, high cervical myelopathy. However, moderately severe trauma from a fall or an otherwise minor motor vehicle accident can result in catastrophic, lethal, spinal cord compression.[13]

The high frequency of these potentially preventable complications requires screening with lateral radiographs of the cervical spine in the neutral position and in flexion to assess the atlantoaxial interval even in neurologically asymptomatic individuals in order to assess the potential for catastrophic subluxation. MRI of the craniocervical junction is useful for two purposes: (1) detection of an altered intraparenchymal signal indicating injury from milder repetitive compression due to minor subluxation of the atlantoaxial joint; and (2) for detection of an inflammatory pannus around the dens, which can further compromise the subarachnoid space. Neurosurgical intervention is warranted if there is a high degree of instability or evidence of myelopathy. Anatomy dictates the required intervention: a high degree of positional instability requires fusion; obliteration of the subarachnoid space without significant instability requires decompression.

Other neurologic complications of rheumatoid arthritis are discussed in detail in Chapter 50.

Sjögren Syndrome

Sjögren syndrome is characterized by autoimmune involvement of lacrimal and salivary glands, causing dry eyes and dry mouth (the sicca syndrome), but also by more widespread systemic and neurologic manifestations.[14] Cutaneous involvement, when present, is palpable purpura, a classic sign of cutaneous vasculitis. Both the central and the peripheral nervous systems are frequently also affected, as discussed in Chapter 50. The classic peripheral neurologic manifestation is a ganglionitis or a distal small-fiber axonal sensory neuropathy, but there may be multiple cranial neuropathies and mononeuritis multiplex as well. Although less frequent, the most common CNS presentation is a focal, transverse myelopathy with a T2 bright MRI lesion that spans several segments. This may mistakenly be attributed to multiple sclerosis, as may various other presentations of Sjögren syndrome including focal cerebral or brainstem lesions associated with perivenular inflammation, more often in the white matter than gray. Recognition of the sicca syndrome and cutaneous manifestations may therefore be critical in suggesting the correct diagnosis.

PERIPHERAL NEUROPATHY

Various entrapment neuropathies, mononeuropathies, plexopathies, distal symmetric, and cranial neuropathies with cutaneous manifestations are listed in Table 21-5. Three disorders in which peripheral nerve involvement is either the principal or only neurologic manifestation are described in this section.

Leprosy

Leprosy is also known as Hansen disease in honor of the Norwegian physician who discovered the causative organism, *Mycobacterium leprae*, in 1873. The disorder is discussed in detail in Chapter 41. Until the 1980s leprosy was perhaps the most common peripheral neuropathy and neurocutaneous disorder worldwide, affecting in excess of 10 million individuals and permanently disfiguring millions. A steady decline in its incidence has followed the introduction of multidrug therapy. The majority of cases are in the tropics, with about 50 percent of the cases in India, and high numbers in a periequatorial belt that includes Brazil, Madagascar, and Myanmar. About 250,000 new cases are diagnosed annually. Armadillos, the only other species to harbor the obligate intracellular bacillus, *M. leprae*, are still hunted for food in the American Southwest and can be a source of exposure to this infectious agent.

The neuropathy typically presents with characteristic skin lesions and a hypesthetic mononeuritis multiplex with palpably thickened nerves. The distribution of the mononeuritis is influenced by the organism's proclivity for endoneural invasion in the cool exposed face and extremities, as discussed in detail in Chapter 41. In addition to commonly affected superficial cutaneous nerves, there is frequent motor involvement in the distribution of the ulnar nerve and sensory involvement of the posterior tibial nerve.

Although all lepromatous neuropathy is a consequence of local mycobacterial invasion, the cutaneous manifestations depend on the strength of the host's immune response. A vigorous response leads to tuberculoid, or paucibacillary leprosy with

TABLE 21-5 ■ Peripheral Neuropathy with Cutaneous Manifestations

Disorder	Cutaneous Manifestations
AIDS	Seborrheic dermatitis, verruca vulgaris, molluscum contagiosum, Kaposi sarcoma
Alcoholism	Telangiectasias, malar rash, psoriasis and discoid eczema, exacerbation of rosacea, porphyria cutanea tarda, acne
Amyloidosis (primary)	Purpura in skin folds or flat surfaces or eyelids, papules, sometimes alopecia, rarely bullae on skin or oral mucosa
Angioedema, hereditary, type I (OMIM 106100)	Erythema marginatum
Arsenic poisoning	Dry scaly desquamation, linear hyperpigmentation of nails, Mees lines
Brachydactyly mental retardation syndrome (OMIM 600430)	Eczema
Cardiofaciocutaneous syndrome (OMIM 115150)	Severe atopic dermatitis, ichthyosis, hyperkeratosis (especially extensor surfaces), cavernous hemangiomas, keratosis pilaris, multiple palmar creases, multiple lentigines
Celiac disease (OMIM 212750)	Dermatitis herpetiformis, follicular keratosis
Cerebral dysgenesis, neuropathy, ichthyosis, and palmoplantar keratoderma syndrome (OMIM 609528)	Palmoplantar keratoderma, ichthyosis
Cerebrotendinous xanthomatosis (OMIM 213700)	Tuberous xanthoma, xanthelasma
Chediak–Higashi (OMIM 214500)	Partial albinism, silvery blond hair
Coenzyme Q10 deficiency, primary, 2 (OMIM 614651)	Hypopigmentation, malar flush, livedo reticularis
Coproporphyria, hereditary (OMIM 121300)	Photosensitivity
Cronkhite–Canada gastrointestinal hamartomatous polyposis (OMIM 175500)	Alopecia, skin hyperpigmentation, onychodystrophy
Diabetes mellitus	Necrobiosis lipoidica diabeticorum, poorly healing ulcers
Diphtheria (cutaneous)	Jungle sore
Fabry disease (OMIM 610651)	Angiokeratoma
Flynn–Aird disease (OMIM 136300)	Skin atrophy, hyperkeratosis, chronic ulceration
Fucosidosis (OMIM 230000)	Angiokeratoma; thin, dry skin; anhidrosis
Hemochromatosis (OMIM 235200)	Bronze pigmentation, telangiectasias
Histiocytic reticulosis	Purpura, jaundice, erythroderma
Hyperoxaluria, primary, type I (OMIM 259900)	Livedo reticularis, calcinosis cutis metastatica, acrocyanosis
Impaired long-chain fatty acid oxidation	Congenital ichthyosis, ichthyosiform erythroderma
Kanzaki disease (OMIM 609242)	Angiokeratoma corporis diffusum, hyperkeratosis, dry skin, diffuse maculopapular eruption, telangiectasia on lips and oral mucosa
Leprosy	Hypopigmentation and hyperpigmentation, leonine facies, erythema nodosum leprosum, Lucio phenomenon
Linear sebaceous nevi of Jadassohn (OMIM 163200, Schimmelpenning–Feuerstein–Mims syndrome)	Sebaceous and epithelial nevi, linear nevus sebaceous
Lyme disease	Target lesions
Neurocutaneous melanosis (OMIM 249400)	Large multiple pigmented skin nevi ($>$20 cm), no malignant melanoma other than CNS
Pellagra	Erythematous photosensitive rash, erythema, vesicles, glossitis, malar and supraorbital hyperpigmentation, rhagades

(Continued)

TABLE 21-5 ■ (Continued)

Disorder	Cutaneous Manifestations
Peripheral demyelinating neuropathy, central dysmyelination, Waardenburg syndrome, and Hirschsprung disease (OMIM 609136)	Hypopigmented skin patches
Phenylketonuria (OMIM 261600)	Pale pigmentation, dry skin, eczema, scleroderma
POEMS syndrome	Hyperpigmentation, thickening, verrucous angiomas, hirsutism, Raynaud phenomenon
Poikiloderma–spastic paraplegia	Poikiloderma: delicate, smooth, wasted skin
Refsum disease (classic) (OMIM 266500)	Ichthyosis
Sarcoidosis	Hypohidrosis, cicatricial alopecia; *acute*: erythema nodosum, vesicles, maculopapular rash; *chronic*: lupus pernio, plaques, scars, keloids
Sjögren syndrome	Purpura, Raynaud phenomenon, xerostomia, candidiasis
Spastic paraplegia 23 (OMIM 270750)	Patchy vitiligo, hyperpigmentation of exposed areas, lentigines
Stiff skin syndrome (OMIM 184900)	Thick, indurated skin over entire body
Systemic lupus erythematosus	Photosensitivity, malar rash, discoid lupus
Thallium intoxication	Hair loss
Trichorrhexis nodosa	Ichthyosis, flexural eczema, photosensitivity, short wooly hair
Vitamin B_{12} deficiency	Black nail pigmentation (nail bed and matrix), oral aphthae
Werner syndrome (pangeria) (OMIM 277700)	Scleroderma-like skin, graying hair and baldness, leg ulcers, progressive scalp alopecia, sparse body hair, telangiectasia, mottled pigmentation; loss of subcutaneous fat, subcutaneous calcification
Xeroderma pigmentosum (OMIM 610651)	Photosensitivity, early-onset skin cancer, atrophy, telangiectasia, actinic keratosis, angioma, keratoacanthomas

granuloma formation, anesthetic patches of skin adjacent to thickened peripheral nerves, and severe destruction of nerve. At the other end of the spectrum is lepromatous leprosy with widespread nodular cutaneous lesions (e.g., leonine facies) (Fig. 21-17) containing large quantities of *M. leprae*, leading to a more insidious destruction of nerves, in which there is an absence of a cell-mediated immune response. Most patients lie along a spectrum between these two extremes, depending in part on their complement of susceptibility genes, which have been mapped to a half-dozen gene loci, three of which have been associated with an identified gene (OMIM 610988, 613223, 248300).

Although the fully developed neurocutaneous syndrome is easily diagnosed in endemic areas even by individuals who are not medically trained, the long incubation period provides ample opportunity for transmission before the disease is evident. Furthermore, clinically evident nerve damage and disfigurement are irreversible. The recent development of antibody-based tests had given hope that presymptomatic leprosy could be diagnosed and treated, possibly as a final step to the goal of the World Health Organization of complete eradication of this neurocutaneous disorder. However, current versions of these tests still require improvement.

Systemic Sclerosis

This disorder is often commonly referred to as scleroderma, which is the name more properly applied to its characteristic cutaneous manifestation—a thickening of the skin—that can also occur as an isolated syndrome independent of the systemic and neurologic manifestations of systemic sclerosis. Another cutaneous feature of systemic sclerosis is a diffuse hyperpigmentation. Various peripheral neuropathies are by far the most common manifestations of systemic sclerosis, the most common being carpal tunnel syndrome, which occurs in about a quarter of patients, and cranial neuropathies, especially trigeminal neuralgia. Less commonly there are symmetric axonal neuropathies, often with autonomic involvement, as well as mononeuritis multiplex and plexopathies. In contrast to the frequent involvement of the peripheral nerves, the links between systemic sclerosis and pathology of the CNS are much more tenuous, apart from asymptomatic calcification of the basal ganglia, which occurs in about one-third of affected individuals.

Systemic Vasculitis

The classic neurocutaneous presentation of palpable purpura and mononeuritis multiplex occurs in several types of systemic vasculitis, a heterogeneous and partially overlapping group of neurocutaneous disorders that include classic polyarteritis nodosa, Churg–Strauss allergic angiitis and granulomatosis, and Wegener granulomatosis. All three of these disorders affect small and medium-sized arteries, the first two as prime examples of a larger class of systemic necrotizing vasculitis. Occlusion of small arteries results in mononeuritis, an abrupt, painful ischemic infarction of the segment of a peripheral nerve in which perfusion is compromised. These three disorders differ histopathologically and clinically. They are discussed in detail in Chapter 50. In order of frequency, classic polyarteritis nodosa affects kidneys, joints, peripheral nervous system, skin, gastrointestinal tract, and the CNS, but never the lungs. During the course of the disease, peripheral nerve involvement is seen in over half of cases, though rarely as one of the presenting signs. In less than a quarter of cases, the necrotizing vasculitis of polyarteritis nodosa extends into the CNS.

In contrast, the lungs are affected in Churg–Strauss syndrome, a granulomatous disorder closely associated with asthma, and in Wegener granulomatosis, a distinct disorder of granulomatous vasculitis of the upper and lower respiratory tract. In Wegener granulomatosis, renal involvement dominates the clinical picture in about 75 percent of patients, cutaneous manifestations occur in about 50 percent, and neurologic manifestations in about 25 percent. Palpable purpura, the signature lesion of cutaneous vasculitis (Fig. 21-18), may be prominent, as may vesicles, papules, ulcers, and subcutaneous nodules. Nervous system involvement is usually peripheral, with a mononeuritis multiplex similar to that of polyarteritis nodosa being a frequent feature, but with a much lower frequency of CNS vasculitis.

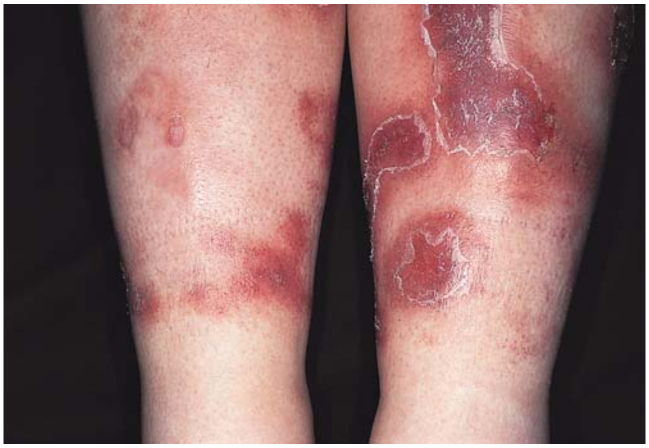

FIGURE 21-18 ■ Cutaneous small-vessel vasculitis was the first evidence of recurrence in this patient with Wegener granulomatosis. (From Callen J, Jorizzo J, Bolognia J, et al: Dermatological Signs of Internal Disease. Saunders, Philadelphia, 2009, with permission.)

Untreated, all three disorders are lethal. Treatment is based on corticosteroids and cyclophosphamide, except in the 20 percent of cases of polyarteritis nodosa with demonstrable blood levels of hepatitis B surface antigen, thought to be the inciting antigen for the pathophysiologic cascade initiated by deposition of immune complexes in the walls of blood vessels that attract the necrotizing leukocytic infiltrate. In such cases, there may be response to treatment with interferon-α and plasma exchange.

Different patterns of cutaneous and neurologic manifestations—sometimes including mononeuritis multiplex as a minor feature—occur in other disorders classified as vasculitis: notably Behçet disease and the vasculitis associated with certain connective tissue disorders, most notably systemic lupus erythematosus. Other vasculitic disorders, such as giant cell arteritis, with no cutaneous manifestations, or the primary cutaneous vasculitides, which by

definition have no neurologic or systemic manifestations, are not neurocutaneous syndromes and are not discussed here.

MYOPATHY

Dermatomyositis

Dermatomyositis is not "polymyositis with a rash" but a distinct vasculitis that can be diagnosed unequivocally by considering either the cutaneous or muscle pathology on its own.[15] Unlike polymyositis, it commonly affects children as well as adults. Photosensitivity either precedes or accompanies muscle weakness, facilitating diagnosis. This manifests as an erythematous rash over sun-exposed areas: the malar region, the "shawl" of the neck and shoulders, and the exposed anterior "V" of the chest as well as over the knuckles, malleoli, or other joints. Typically there is a distinctive heliotrope rash of the eyelids (Fig. 21-19). In about two-thirds of childhood cases, there is also subcutaneous calcification. These skin lesions may be the only clinically evident manifestation, especially when the muscle involvement is unusually mild. More typically, proximal limb-girdle weakness develops subacutely over weeks to months, often involving pharyngeal muscles and neck extensors, but with sparing of facial and extraocular muscles. The muscles may be tender. Muscle histology demonstrates a microangiopathy.

Dermatomyositis is associated with malignancy in about 15 percent of cases, more often in adults than in children. This is most often in the ovary, breast, or colon or a melanoma, but occasionally the lung or some other site is involved. Alternatively, it is occasionally seen in association with systemic sclerosis, with a rare Mendelian disorder (Barraquer–Simons syndrome, OMIM 608709) or as an isolated neurocutaneous syndrome.

ANKYLOSING SPONDYLITIS
  Diffuse Idiopathic Skeletal Hyperostosis
RELAPSING POLYCHONDRITIS

The brain, spinal cord, cranial nerves, and spinal roots share an intimate anatomic relationship to the spine and skull; as a result, disorders of the skeletal system may result in neurologic compromise. This broad group of conditions includes congenital malformations as well as degenerative, metabolic, traumatic, neoplastic, infectious, and inflammatory disorders of the bones and joints. The craniosynostoses (premature closure of the cranial sutures) are covered in major texts of pediatric neurology and are not addressed here. The neurologic complications of trauma and neoplastic involvement of bone are covered in other chapters. The neurologic complications of rheumatoid arthritis and some additional connective tissue disorders are discussed separately in Chapter 50.

DEGENERATIVE DISEASE OF THE SPINE

Degenerative disease of the spine includes changes to both the intervertebral discs and the vertebrae ("spondylosis") that in general become more common with age. The lifelong mechanical stress sustained by the highly mobile cervical spine and the somewhat less mobile, weight-bearing lumbar spine accounts for the preponderance of degeneration in these two regions. Spinal degeneration may be entirely asymptomatic or may cause local or referred pain, radiculopathy, or myelopathy. Degenerative spinal disease is commonly found on imaging of asymptomatic older adults.[1]

The intervertebral discs change in composition and structure with age. From the second decade onward, disc degeneration and its consequent clinical manifestations become more frequent. Concomitant degeneration of the bony elements of the spine also occurs, including "lipping" of the superior and inferior margins of the vertebral bodies, the formation of osteophytes, osteoarthritic changes of the facet joints (subluxation, osteophytosis, and cartilaginous changes), narrowing of the intervertebral disc spaces, hypertrophy of the ligamentum flavum, instability of adjacent vertebrae with spondylolisthesis (anteroposterior slippage of one vertebra on an adjacent one), and narrowing of the lateral recess and intervertebral foramina.

Encroachment of bone or disc may compromise the spinal roots or the spinal cord, resulting in radiculopathy or myelopathy, respectively. Inflammatory mechanisms resulting from exposure of the normally immunologically sequestrated nucleus pulposus, in addition to simple mechanical compression, contribute to the development of radicular symptoms and

signs. Although plain radiography of the spine may occasionally identify a vertebral fracture or other focal bony pathologic process, it is not an adequate screening investigation for patients with neurologic compromise. Spinal computed tomography (CT) provides detailed views of the bony components of the spine and, when paired with myelography, may demonstrate encroachment onto the thecal space. Spinal magnetic resonance imaging (MRI) is the modality of choice for demonstrating disc and other soft tissue anatomy; MRI can clearly show compression of the roots and spinal cord and does not expose the patient to ionizing radiation. Intramedullary signal abnormalities indicate significant spinal cord injury, but may not correspond closely with clinical severity.

Electromyography (EMG) provides additional, complementary information that helps to distinguish radiculopathy from more peripheral pathology, localize involvement to individual nerve roots, and suggest whether the underlying pathophysiology relates to axonal or demyelinating injury.

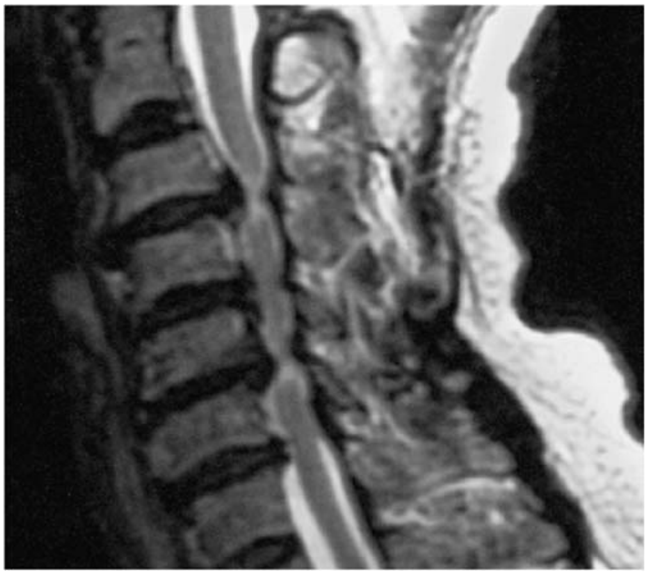

FIGURE 22-1 ■ Cervical spondylosis. Sagittal T2-weighted magnetic resonance imaging of the cervical spine. Multilevel spondylotic disease with spinal stenosis and signal changes in the spinal cord are indicative of myelopathic injury.

Cervical Spondylosis and Disc Disease

In addition to disc degeneration and vertebral spondylosis, the contribution of a congenitally narrow spinal canal, buckling of the ligamentum flavum with neck extension, formation of compressive spondylotic "bars," and ischemic factors have all been proposed as mechanisms leading to neural injury (Figs. 22-1 and 22-2).

Several aspects of the anatomy of this region are important to appreciate: eight pairs of cervical nerve roots are arranged such that a root exits *above* its respective vertebra after leaving its segmental origin in the spinal cord. A lateral disc herniation at the C5–C6 level, for example, will tend to compromise the C6 root. This is the most common level of cervical radicular involvement, followed in order by a herniation at C6–C7 (C7 root) and at C4–C5 (C5 root).

The clinical manifestations of cervical spondylosis can include midline pain over the spine, limited range of movement, referred pain to the ipsilateral neck and arm (often made worse with coughing, straining, or particular positions of the head), and sensory–motor deficits associated with radiculomyelopathy. An acute root injury may occasionally result from rapid movement of the neck with sudden disc herniation; more often, a subacute onset results from progressive foraminal stenosis secondary to spondylosis. Pain tends to be a prominent early symptom, and is often sharp, radiating to a particular dermatome in association with numbness and paresthesias; weakness occurs when motor roots are involved. Corresponding motor, sensory, and reflex changes are found on examination. Single-level disease is seen in 15 to 40 percent of patients, and multilevel disease occurs in 60 to 80 percent.

Cervical myelopathy tends to be a chronic, progressive process, but it may occasionally be abrupt in onset and catastrophic in severity. There are few data to indicate how often cervical spondylotic radiculopathy is eventually associated with myelopathy. Compression of the spinal cord is often heralded by difficulty in walking and may be followed by sensory loss in the lower limbs and the development of urinary frequency and nocturia. A Lhermitte sign may be present. "Numb, clumsy hands" is an unusual symptom complex resulting from upper cord compression.

The natural history of cervical radiculomyelopathy is poorly documented. Good recovery of function frequently follows root injury, especially with a purely demyelinating radiculopathy, from which full recovery within weeks may be expected. Even after partial axonal injury, considerable reinnervation occurs in time. The course of untreated cervical myelopathy varies considerably. Slowly progressive worsening is

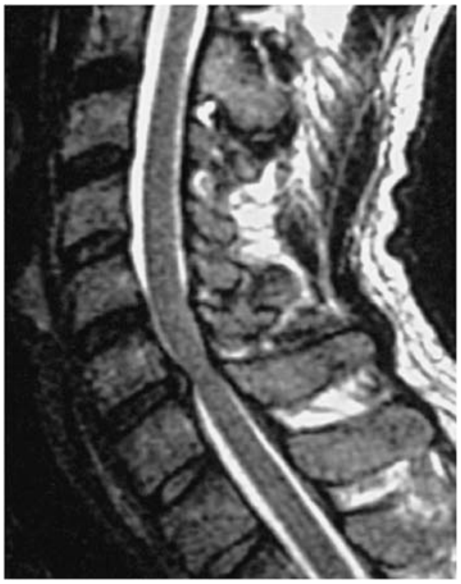

FIGURE 22-2 ■ Cervical disc disease. Sagittal T2-weighted MRI of the cervical spine. A herniated cervical disc is seen to compress the thecal sac at the C6–C7 level.

common, but the myelopathy may remain static for years, improve with conservative measures, or progress rapidly.

Treatment of radiculopathy varies widely, and there is no universally agreed standard of care. Surgery is frequently performed for a variety of indications, despite a lack of large-scale controlled trials comparing surgical and nonsurgical outcomes. A 2010 systematic review found only a single acceptable randomized study of surgery compared with conservative measures.[2] In view of the generally favorable prognosis for recovery of radiculopathy, it is reasonable to embark first on a trial of conservative treatment (a limited period of rest, short-term immobilization with a soft or hard collar, physical therapy, analgesics, anti-inflammatory agents, muscle relaxants) in all patients except those with documented axonal radiculopathy accompanied by progressive muscle weakness. A short course of high-dose oral corticosteroids may help with pain but is not routine. Cervical traction is probably best avoided. The role of local corticosteroid injection (typically fluoroscopically guided, and interlaminar, intralaminar, or transforaminal) is not clearly established; temporary symptomatic relief is often achieved, but the procedure probably has little influence on the ultimate outcome and is not free of complications. Injections may be diagnostically helpful where pain relief is clearly associated with injection at a specific level. The most commonly performed surgery is anterior cervical discectomy and fusion. A posterior approach may be employed if a lateral herniation is present. The role of disc replacement is as yet unclear. In general, surgery is indicated when clinical and electrodiagnostic findings of radiculopathy are congruent with radiologic abnormalities, and either a progressive motor deficit or unremitting pain persists despite an adequate trial of conservative therapy. Acute-onset myelopathy is routinely treated with high-dose intravenous corticosteroids; established myelopathy is usually regarded as a firm indication for discectomy and decompressive laminectomy, with or without fusion; clinical improvement or arrest of progression usually follows, but some 15 to 20 percent of patients continue to deteriorate despite surgery.

Lumbar Disc Disease

Around 80 percent of the adult population will have a functionally significant episode of low back pain over a lifetime; a subset of this group will have discogenic disease. Middle-aged men are most frequently affected. Disc herniation is seen less often in the elderly, probably as a consequence of a less mobile lifestyle and the gradual replacement of the disc material with fibrocartilage. Lumbar spine disease (Fig. 22-3) is frequently an asymptomatic finding on imaging, but may produce a range of symptoms including low back pain, locally referred pain, radiating radicular pain ("sciatica"), and a sensory–motor radicular neurologic deficit. The clinical onset may be spontaneous or associated with an episode of mechanical stress. A flexed posture or a transient increase in the pressure gradient across the dura (e.g., by coughing or sneezing) may exacerbate symptoms.

The site of disc pathology may be marked by local tenderness to palpation or percussion over the spinous processes. The patient may adopt a fixed posture, often tilted away from the affected side, and resist movement. A straight leg raise, with passive flexion of the hip while the leg is extended at the knee, may reproduce the patient's usual back or leg pain in lower lumbosacral radiculopathy. The pattern of neurologic deficit will allow identification of the affected root.

Most lumbar disc pathology involves the L4–L5 and L5–S1 interspaces. Disc abnormalities at L1–L2,

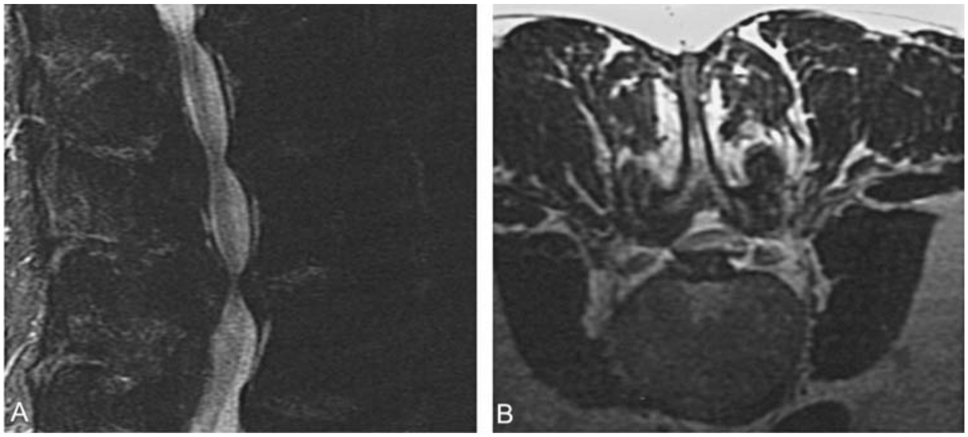

FIGURE 22-3 ■ Degenerative disease of the lumbar spine with spinal stenosis. Sagittal, *A*, and axial, *B*, T2-weighted MRI of the lumbar spine. Multilevel discogenic disease is apparent in the lumbar spine on the sagittal view. Disc material is seen compressing the anterior aspect of the thecal sac on the axial image.

L2–L3, and L3–L4 are rare, accounting for less than 5 percent of patients. Lumbar disc protrusions are most often posterolateral and affect either descending or exiting nerve roots; they typically cannot result in myelopathy because the spinal cord ends above the L1–L2 interspace. The roots are located posterolaterally at the intervertebral foramen and pass through this aperture in a superior position; therefore a disc protruding at the same level will tend to pass underneath the root exiting at the same interspace, often compressing the root of the segment immediately below. An L4–L5 disc, for example, will usually compromise the L5 root and leave the L4 root unaffected. There are exceptions to this rule—clinical assessment should always allow that a nerve root can be compromised at any point in its intraspinal course.

A large central disc may produce bilateral radicular signs or occasionally result in acute cauda equina syndrome characterized by flaccid paralysis, lower-limb areflexia, or urinary and fecal incontinence. Acute cauda equina syndrome is a surgical emergency and, even when managed promptly, carries a poor prognosis for neurologic recovery. Chronic lumbar canal stenosis may lead to neurogenic claudication (see later).

The differential diagnosis for these symptoms is wide. For patients who present with acute (duration of less than 3 months) low back pain, the emphasis of the initial assessment is on exclusion of serious underlying pathology. Neoplastic, infectious, and traumatic causes are important to identify and require specific treatment. Otherwise, conservative measures (limited bed rest, regular graded exercise, analgesic and anti-inflammatory medication, physical therapy, and the use of local corticosteroid injections in selected patients) without further investigation represent the most appropriate initial management. When there is no improvement, further investigation is indicated.

The natural history of uncomplicated lumbar disc disease is usually one of eventual disc resorption with improvement of symptoms. Despite this generally good prognosis, lumbar disc surgery represents the most common elective surgical procedure involving the nervous system. The traditional approach is resection of the intervertebral disc and fusion of the vertebrae above and below. Other approaches include intervertebral disc replacement and electrothermal and radiofrequency therapy, but their role is yet to be established. Surgery is indicated when a motor deficit (by clinical examination or EMG) is worsening despite conservative management. There is much debate regarding the efficacy of surgery for other patients, and few prospective data are available to help predict which patients are likely to be treated successfully.

LUMBAR SPINAL STENOSIS AND NEUROGENIC CLAUDICATION

Stenosis of the lumbar spinal canal (as well as stenosis of the lateral recess and neuroforamen) is frequently asymptomatic and found incidentally on imaging studies. Boden and colleagues found that 21 percent of asymptomatic adults older than 60 years had lumbar spinal stenosis on MRI.[1] Other patients may complain of low back pain and neurogenic claudication, classically described as discomfort and aching pain in the lower back, buttocks, and legs that is precipitated by walking and relieved by sitting. Patients may experience numbness, paresthesias, weakness, or a sense of heaviness in the legs, usually bilaterally and asymmetrically. Up to 11 percent of patients present with bladder and sexual dysfunction. Sitting for some time will usually relieve symptoms sufficiently to allow further walking. Relief of symptoms with flexion of the spine is the reason that it is often easier to walk up an incline than on a level surface, ride a bike, or lean on a grocery cart. Neurogenic claudication is usually of gradual onset and, once established, results in symptoms that may become disabling, but tends not to be associated with a progressive neurologic deficit, although single or multiple root deficits may occur. Abnormalities on clinical examination may become more apparent after exercise.

Pathogenesis is incompletely understood but is likely to include both mechanical compression and ischemia of the cauda equina leading to neurapraxia with transient conduction failure and clinical and electrophysiologic changes. The anatomic substrate is most commonly that of progressive, chronic, degenerative lumbar spine disease (disc protrusion, osteophytosis, and hypertrophy of the ligamentum flavum) on a background of a congenitally or developmentally narrow lumbar spinal canal, including conditions such as spina bifida and achondroplasia. Occasionally, disease of the spine or mass lesions are responsible.

Extension of the spine decreases, and flexion increases, the caliber of the spinal canal. Diagnosis requires recognition of the highly characteristic history together with radiologic evidence of lumbar spinal stenosis. There is no consensus on measurement: methods make use of anteroposterior diameter, cross-sectional area, and vertical extent of stenosis. There is also poor correlation between the degree of stenosis and clinical manifestations. Electrodiagnostic studies may show prolongation of minimum F-wave and H-reflex latencies, but are mainly useful to document associated radiculopathy. In contrast, vascular claudication typically causes burning pain in the calves when walking and is usually accompanied by evidence of circulatory insufficiency in the legs. A variety of other neurologic conditions may occasionally produce pseudoclaudication: these include multiple sclerosis and spinal cord arteriovenous malformation.

Many patients with lumbar spinal stenosis find that they can remain mobile within the specific constraints of their symptoms with conservative measures. Surgery aims to relieve symptoms and improve function and is appropriate where progressive disability or intractable pain is present. Of patients initially opting for conservative therapy, about 30 percent will eventually elect to have surgery. Surgery likely benefits some patients, but the literature provides few controlled data comparing it with conservative treatment. Further, benefit may not persist, and surgery at one level may lead to degeneration in adjacent vertebrae, leading to a progressive deficit. Decompressive laminectomy at one or several levels is typically performed with discectomy or simple foraminotomy, with or without fusion. Surgery is warranted if neurogenic claudication is progressive, significantly limits activities of daily living, or becomes intolerable. Surgery is usually elective, but may need to be expedited in the case of progressive weakness or cauda equina syndrome. Fusion with or without instrumentation is more frequently employed when there is associated spondylolisthesis. Interspinous decompression with placement of a spacer (e.g., X-STOP) between the spinous processes, preventing narrowing of the canal with extension, is a less-invasive technique that is sometimes employed.

OSTEOPOROSIS

Osteoporosis is a disorder characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and consequent increase in fracture risk. It is the most common bone disease. It results in 1.5 million fractures per year in the United States.[3] One-half of Caucasian women and around 20 percent of Caucasian men will experience an osteoporotic fracture. Despite this, only about a quarter of older woman who have an osteoporotic fracture are treated for osteoporosis in the 6 months following the fracture. Any neurologic disorder that impairs strength or balance leading to decreased mobility and an increased risk of falls is a risk factor for osteoporosis (Table 22-1). Patients with spinal cord injury are particularly prone to severe osteoporosis and nontraumatic fractures. Neurologic patients share common risk factors with

TABLE 22-1 ■ Neurologic Diseases Associated with Osteoporosis and Increased Fracture Risk

Alzheimer disease	Amyotrophic lateral sclerosis
Parkinson disease	Poliomyelitis
Spinal cord injury	Muscular dystrophy
Epilepsy and anticonvulsant use	Glycogen storage diseases
Stroke and anticoagulant use (heparin)	Gaucher disease
Multiple sclerosis	Menkes steely hair syndrome
	Riley–Day syndrome

elderly patients for osteoporosis, such as disuse and lack of exercise, being homebound, vitamin D deficiency, and poor diet. Parkinson disease is an independent risk factor. Tobacco and alcohol use are also risk factors for osteoporotic fractures.

There is growing interest in "neuroskeletal research" of the central nervous system (CNS) regulation of bone remodeling. Leptin is a peptide secreted by adipocytes that regulates appetite and energy metabolism by binding to a hypothalamic leptin receptor. Its effect on bone formation is through induction of the sympathetic nervous system. Osteoblasts in the bone marrow reside next to sympathetic neurons and express β_2-adrenergic receptors; catecholamines increase osteoblast proliferation and differentiation (bone formation) and increase bone resorption, with a resulting decrease in bone mass. There also is evidence of a circadian variation for bone remodeling.

The spine is the most frequent osteoporotic fracture site, accounting for approximately 1.4 million clinically detected fractures annually worldwide.[4] Low thoracic and high lumbar vertebral fractures are the most common. There is a 10-fold increased risk of a second vertebral fracture in these patients. About 25 percent of vertebral fractures occur from falls, but the majority are triggered by trivial activity such as bending, lifting a light object, or getting out of bed.

Most vertebral fractures are painless and only around 30 percent come to medical attention. Less than 10 percent result in hospital admission. Symptomatic patients usually present with acute low back pain localized to the site of the fracture, but sometimes diffuse and nonlocalizing. Radiating pain into the lower extremities is uncommon and usually does not correspond to a specific lumbar root pattern. Straining and local percussion typically increase the pain. The patient may not be able to bear weight initially, and symptoms often improve when lying down. There are typically no neurologic symptoms or signs.

Plain radiographs of the spine are the study of choice to document the presence of vertebral fracture. The most widely accepted radiologic definition of vertebral compression-fracture is a decrease of 15 to 25 percent in the anterior, central, or posterior height of a vertebral body compared with adjacent normal vertebrae or a population reference. The diagnosis can be confirmed by bone scan or CT when radiographs are equivocal.

The optimal treatment of acute osteoporotic vertebral fractures without neurologic compromise is uncertain. Prolonged bed rest may accelerate the underlying osteoporosis, so analgesics, local heat alternating with cold application, and mobilization with physical therapy and hydrotherapy are recommended. Rigid external support can prevent failed union of severe vertebral fractures when used in the first 6 months. Narcotics are occasionally required for pain, and calcitonin may provide relief in the acute phase. With persistent pain, an intercostal nerve block or epidural corticosteroid injection may be helpful. Vertebral augmentation can be done with vertebroplasty, a balloon implant (balloon kyphoplasty), or vertebral body stenting. Vertebroplasty is a technique that involves injection of polymethylmethacrylate into a fractured vertebral body. Compared to conservative treatment for acute painful fractures, it shows greater pain relief, functional recovery, and health-related quality of life.[4] Asymptomatic cement leaks are a potential side effect, and uncommon severe adverse events include radiculopathy due to cement leakage, new fractures of adjacent vertebrae, and osteomyelitis. Vertebral body stenting with an expandable metallic implant is another minimally invasive technique that may help preserve vertebral body height and prevent spinal deformity.

Preventive treatments for osteoporosis are essential to reduce the number of vertebral fractures in postmenopausal women and the elderly. Detailed recommendations for evidence-based osteoporosis prevention including exercise (balance, resistance, weight bearing, and muscle strengthening), fall prevention strategies, risk factor modulation, calcium and vitamin D supplementation, bisphosphonates, hormone replacement, selective estrogen-receptor modulators, desosumab, teriparatide, abaloparatide, romosozumab, and calcitonin are summarized elsewhere, including side effects and treatment holidays.[3]

The association between vertebral fractures and chronic back pain is unclear. In patients with osteoporosis and vertebral fractures, the presence and severity of back pain correlate with the number of collapsed thoracic vertebrae and the degree of kyphosis. Neurologic complications are uncommon and include myelopathy, cauda equina syndrome, and lumbosacral radiculopathy. Spinal CT or MRI reveals violation of the posterior cortex of the vertebral bodies (burst fracture) with retropulsion of bone into the spinal canal. The most common location is the thoracolumbar junction. Lower-extremity symptoms may develop from 10 days to 1.5 years after the onset of acute spine pain, owing to extension of vertebral fracture. The etiology is thought to be late collapse of the vertebral body due to disruption of the microcirculation and aseptic necrosis. Severe kyphosis may be a risk factor for progression of vertebral fracture and neurologic compromise.

The best operative approach for those with neurologic deficits is not known. Goals include improvement of the deficit, correction of the deformity, and stabilization of the spine. Clinical results are mixed, ranging from marked improvement to worsening of function with significant postoperative mortality. The approach used is often guided by the presence of intervertebral instability, the degree of kyphosis, and the occurrence of progressive neurologic deficits. Postoperative bracing may reduce the rate of instrumentation failure. Conservative management in some cases can result in significant recovery over months.

Occasionally, patients with vertebral fracture have purely radicular symptoms, with pain radiating into the lower extremity that worsens with change in position or on standing. There may be dermatomal sensory loss and weakness in muscles referable to that root. There may be a higher association of radiculopathy with inferior-type vertebral fractures. There can be substantial or complete resolution of symptoms following vertebroplasty.

OSTEOMALACIA

Osteomalacia is a metabolic bone disorder characterized by defective mineralization, which results in the accumulation of unmineralized matrix or osteoid in the skeleton. Normal bone mineralization requires adequate circulating levels of vitamin D metabolites, a normal supply of minerals, and optimal osteoblast function. The most common cause of osteomalacia is vitamin D deficiency. Other causes are listed in Table 22-2. Reduced cutaneous production of vitamin D is a concern in the elderly who are institutionalized or housebound, and in postmenopausal women. Increased time indoors, sunscreen, and the use of ultraviolet-protective glass and clothing contribute to hypovitaminosis D. Dark-skinned individuals require four to five times more sun exposure than light-skinned people. Dietary sources of vitamin D are limited (wild oily fish, egg yolk, codliver oil, and fortified food). Malabsorption results in decreased absorption of vitamin D, increased catabolism of vitamin D metabolites, and malabsorption of calcium or phosphate. Malabsorption from gastric bypass surgery for morbid obesity is

TABLE 22-2 ■ Causes of Osteomalacia

Vitamin D Deficiency
Reduced cutaneous production
Poor nutrition
Malabsorption
Abnormal Vitamin D Metabolism
Liver disease
Drugs (anticonvulsants)
Hereditary defective 25-hydroxycholecalciferol synthesis
Defective 1,25-dihydroxycholecalciferol synthesis
Renal failure
Vitamin D-dependent rickets type I (1α-hydroxylase deficiency)
Resistance to the Action of Vitamin D
Vitamin D-dependent rickets type II
Hypophosphatemia
Phosphate-binding antacids
X-linked hypophosphatemia
Oncogenic osteomalacia
Fanconi syndrome
Renal tubular acidosis
Bone Toxins
Bisphosphonates
Aluminum
Fluoride
Hypophosphatasia
Fibrogenesis Imperfecta Ossium

emerging as a leading cause of vitamin D deficiency in the United States.

The prevalence of low 25(OH)D levels ($<$20 ng/mL) is 36 percent in healthy young adults aged 18 to 29 years, 42 percent in black women aged 15 to 49 years, 41 percent in outpatients aged 49 to 83 years, and up to 57 percent in general medicine inpatients in the United States.[5] It is especially prevalent in nonelderly, ambulatory primary-care patients with persistent, nonspecific musculoskeletal pain refractory to standard pharmaceutical agents. Current recommendations in North America are that all adults supplement with vitamin D_3 600 IU/day and that those in at-risk groups or older than 70 years should take 800 IU/day. The global consensus is 400 IU daily for all infants until 12 months, 600 IU daily for women during pregnancy, and that all groups beyond 12 months receive 600 IU daily via diet or supplementation.[6] Food fortification is also recommended as a prevention measure.

The classic clinical features of osteomalacia include musculoskeletal pain, skeletal deformity, muscle weakness, and symptomatic hypocalcemia. The early symptoms are vague. Bone pain is invariably present, symmetric, and especially prominent in the spine, ribs, pelvis, and lower extremities. The pain is worse with muscle strain, weight bearing, or pressure, but persists with rest. Minimal pressure with the thumb or forefinger on the sternum, ribs, pelvic girdle, or anterior tibia can reproduce the pain on physical examination; it is postulated that collagen-rich osteoid deposited on the periosteal surface of the skeleton may become swollen, putting outward pressure on the periosteal covering that is innervated with nociceptors. These patients are often misdiagnosed as having fibromyalgia, chronic fatigue syndrome, or myositis, and treated inappropriately with nonsteroidal anti-inflammatory drugs (NSAIDs).

Proximal myopathy is common. The limb-girdle muscles are the most affected and result in a waddling gait, Gowers sign, or inability to walk. The proximal upper extremities and neck flexors are occasionally involved; distal weakness is rare, and bulbar and sphincter muscles are spared. Weakness is accompanied by myalgias and muscle atrophy, although the atrophy is often out of proportion to the degree of weakness. There is no known direct effect of vitamin D on muscle but the degree of weakness may be related in part to hypophosphatemia. Deep tendon reflexes are often brisk and the combination of weakness, atrophy, and hyperreflexia can be mistaken for amyotrophic lateral sclerosis. Vitamin D deficiency may contribute to age-related muscle weakness and falls, and vitamin D supplementation for elderly ambulatory and institutionalized individuals reduces the risk of falls.

Osteomalacia in childhood or nutritional rickets has a rising incidence globally, with short stature, bowing of the legs, and widening of the metaphyses, which leads to a "rickety rosary" appearance in the ribs. Muscle weakness results in hypotonia and motor delay. Other clinical features include swelling of the wrists and ankles, bone pain, restlessness, irritability and delayed tooth eruption. In older children and adolescents, rickets can manifest during periods of rapid growth. Rickets results in an increased risk of fracture.

Maternal vitamin D deficiency is passed on to the fetus and if severe can result in hypocalcemic complications in the newborn that include tetany, seizures, and dilated cardiomyopathy, with increased mortality. Premature closure of the sagittal cranial sutures may result in craniotabes and, if severe, hydrocephalus.

Vitamin D modulates the immune system by decreasing the proliferation of proinflammatory T lymphocytes and regulating the production of cytokines. There is an association between high vitamin D levels and a reduced risk of developing multiple sclerosis, but the impact of vitamin D levels on the severity and progression of multiple sclerosis remains unclear. Supplementation in this population with 1,000 IU/day is recommended to reach immune-modulating serum levels of vitamin D (30 ng/mL or 75 nmol/L). Vitamin D is also involved in brain development and adult brain function. Vitamin D receptors are present in almost all brain structures, in neuronal and glial cell types, and vitamin D functions as a neurosteroid. There is growing evidence that vitamin D deficiency increases the risk of Parkinson disease, cerebrovascular disease, epilepsy, and dementia, including Alzheimer disease.

Radiologic features of osteomalacia include cortical thinning of bone, cortical striations in the metacarpals and phalanges, and osteopenia. The most characteristic feature is the presence of Looser zones, which are lucent bands adjacent to the periosteum that may represent unhealed stress fractures and most commonly occur in the ribs, pubic rami, and outer borders of the scapulae. Biochemical abnormalities may be minimal and vary with the cause of osteomalacia. A classic triad is hypocalcemia, hypophosphatemia, and increased serum alkaline phosphatase. Serum 25(OH)D is the major circulating metabolite of vitamin D and reflects input from cutaneous synthesis and dietary intake. A minimum level of 20 ng/mL (50 nmol/L) is necessary to satisfy the body's vitamin D requirement, but a level of 30 to 50 ng/mL (75 to 125 nmol/L) is preferred. Despite clinical evidence of myopathy, the serum creatine kinase level is typically normal. Parathyroid hormone levels may be elevated. Hypocalcemia is usually present when osteomalacia is associated with renal failure, but the serum phosphate is normal or high because of reduced urinary excretion.

EMG may be normal in patients with weakness but most patients show small, short-duration, polyphasic motor unit action potentials in proximal muscles, without abnormal spontaneous activity. The findings on muscle biopsy are nonspecific and include type II atrophy.

Treatment of osteomalacia includes ultraviolet irradiation (UV-B wavelength of 290 to 315 nm) and vitamin D replacement. An oral dose of 50,000 IU/week of vitamin D_2 for 8 weeks, with monitoring of 25 OH) D and parathyroid hormone levels, should occur in those with vitamin D deficiency. In some cases, a second once-weekly 8-week course of 50,000 IU of vitamin D_2 may be necessary to boost 25(OH)D levels into the desired range of more than 30 to 50 ng/mL (75 to 125 nmol/L). For patients prone to developing vitamin D deficiency, after correction of any deficiency, the administration of 50,000 IU every 2 weeks will maintain a vitamin D-sufficient state. An alternative to vitamin D_2 is vitamin D_3 1000 IU/day. Calcium and magnesium supplements are also recommended concurrently. Complications of treatment are uncommon, but include hypercalcemia, renal dysfunction, and increased long bone and hip fractures as pain improves before bone mass and strength are restored. The bone pain, symptoms of hypocalcemia, and proximal weakness often resolve completely over weeks to months with treatment, but deformities persist despite remodeling of the bone. Global recommendations for the treatment of nutritional rickets is 2,000 IU per day for 3 months, together with oral calcium 500 mg daily.

Hypophosphatemic osteomalacia has different neurologic complications than other causes of osteomalacia. The most common form is an X-linked syndrome with hypophosphatemia, osteomalacia, short stature, and the eventual development of new bone at various body sites associated with mutations in the *PHEX* gene. The proximal myopathy seen with other forms of osteomalacia does not occur. Rarely, myelopathy develops as a result of intraspinal new bone formation. The mid- and low thoracic spine is the predominant site of involvement, but the cervical spine may also be affected. The onset of symptoms is acute or insidious with paresis, sensory loss, and, less frequently, bladder symptoms. Symptoms can be intermittent and involve multiple levels of the spinal cord, mimicking multiple sclerosis. A rare autosomal dominant form is associated with a mutation of the fibroblast growth factor 23 gene (*FGF23*). The clinical features are similar to the X-linked form but there is variable penetrance with variable age of onset and it may resolve later in life. An autosomal recessive form is defined by mutations in the dentin matrix protein 1 gene (*DMP1*).

CT of the spine shows enlargement of the facet joints, thickening of the laminae, and ossification within the spinal canal, resulting in severe central stenosis. Surgery is difficult due to thickening of the bone and adherence of the dura to the ligamentum flavum but can result in improvement or resolution of deficit. Treatment includes an oral neutral phosphate along with 1,25-dihydroxyvitamin D (calcitriol). Excess vitamin D replacement can cause hypercalcemia, leading to soft tissue calcification. Serum calcium levels should therefore be measured monthly. Diuretics such as amiloride or hydrochlorothiazide enhance calcium reabsorption and can reduce the risk of nephrocalcinosis.

OSTEOPETROSIS

Osteopetrosis refers to a rare group of sclerosing bone disorders characterized by a generalized increase of skeletal bone mass due to a defect in osteoclastic bone resorption.[7] At least 10 genes have been identified that result in a failure of osteoclast development or function (Table 22-3) and most forms result from late endosomal trafficking defects that prevent osteoclast ruffled-border formation. With more widespread genetic testing, new forms of osteopetrosis in single patients have been described with *TRAF6*, *LRRK1*, *MITF*, *CSF1R*, and *RELA* mutations. In osteopetrosis, the development of the marrow cavity is delayed or absent, and impaired bone modeling

TABLE 22-3 ■ Inheritance of Osteopetrosis

Disease	Inheritance	Gene	Protein
Malignant (infantile) form	AR	*TCIRG1*	Subunit of V-ATPase pump
	AR	*CLCN7*	Chloride channel
	AR	*OSTMI*	Osteopetrosis-associated transmembrane protein
	AR	*SNX10*	Sorting nexin-10 (protein cargo sorting)
	AR	*TNFSF11*	Receptor activator for nuclear factor κB ligand (osteoclast poor)
	AR	*TNFSF11A*	Receptor activator for nuclear factor κB (osteoclast poor)
Intermediate form	AR	*CLCN7*	Chloride channel
	AR	*PLEKHMI*	Pleckstrin homology domain containing family M, member I
Osteopetrosis with renal tubular acidosis	AR	*CAII*	Carbonic anhydrase II
Late-onset form	AD	*CLCN7*	Chloride channel
Asymptomatic (osteopoikilosis)	AD	*LEMD3*	LEM domain-containing 3
Osteopetrosis with ectodermal dysplasia and immune defect (OLEDAID)	X	*NEMO*	IκB kinase complex component
X-linked osteopetrosis	X	*NEMO*	NF-κB essential modulator
Leukocyte adhesion deficiency syndrome and osteopetrosis (LAD-III)	AR	*FERMT3*	Kindlin-3
	AR	*ColDAG-GEFI*	Calcium and diacylglycerol-regulated guanine nucleotide exchange factor I

AD, autosomal dominant; AR, autosomal recessive; X, X-linked.

during longitudinal growth results in a broad cylindrical shape at the ends of the long bones. These bones become brittle, with an increased susceptibility to fracture. Radiographic features are needed to make the diagnosis and include diffuse sclerosis, bone modeling defects at the metaphyses of long bones, "bone in bone" appearance of the vertebrae and phalanges, as well as focal sclerosis of the skull base, pelvis, and vertebral endplates. The most serious complications of the osteopetroses affect the nervous system and hematopoietic system. Cranial nerves, blood vessels, and the spinal cord are compressed by either gradual occlusion or lack of growth of skull foramina. The severity of osteopetrosis ranges from neonatal onset with life-threatening complications to asymptomatic.

Malignant osteopetrosis presents during infancy and is the most common form of childhood osteopetrosis. Inheritance is autosomal recessive and nearly 70 percent of mutations are in the osteoclast vacuolar proton pump and the H^+-Cl^- exchange transporter.[7] The course is severe, with a high mortality rate in early childhood without treatment. Its incidence is approximately 1 in 300,000 births. Neurologic involvement occurs frequently and includes hearing loss, optic atrophy with blindness, nystagmus, strabismus, trigeminal neuropathies, facial paralysis, dysarthria, hydrocephalus, intracranial hemorrhage, cognitive dysfunction, and tetanic convulsions. Hydrocephalus is due to obstruction of the venous outflow at the cranial foramina and to inadequate circulation of cerebrospinal fluid (CSF) as a consequence of thickening of the bones of the skull. Posterior fossa crowding and cerebellar tonsillar herniation may occur. Cranial nerve involvement relates to bony encroachment, and may necessitate decompression of the optic, facial, or vestibulocochlear nerves. Retinal degeneration has been described in some patients and is another cause of visual loss; the most frequent sign of early damage is a change in latency of the visual evoked potential. Baseline brain MRI with special attention to the optic foramina is recommended in these patients, followed by CT of the head if there is evidence of cranial nerve involvement.

Non-neurologic features include short stature, dental caries, and frequent fractures. The constricted bone marrow cavity cannot support adequate hematopoiesis, resulting in hepatosplenomegaly, thrombocytopenia, anemia, and infectious complications, particularly osteomyelitis. Hypocalcemia and rickets also occur. "Osteopetrorickets" occurs with the *TCIRG1* mutation due to low gastric acidity.

First-line treatment includes calcium and vitamin D supplementation to prevent tetanic seizures and treat secondary hyperparathyroidism. High-dose calcitriol is no longer recommended as evidence of clinical benefit is lacking. Interferon-γ1b, which reduces the number of infections and increases bone resorption and the size of bone marrow spaces, has early evidence of efficacy in malignant osteopetrosis. Bone marrow failure is treated with transfusions of red blood cells (if the anemia is symptomatic) and platelets. Allogenic hematopoietic cell transplantation is currently the only therapy capable of producing long-term benefit in children with autosomal recessive osteopetrosis with the exception of those with mutations of the *TNFRSR11* gene or if neurodegeneration is present (*OSTM1* and many *CLCN7* mutations). Early transplant (before 3 months) limits neurosensory defects and impaired bone growth and results in reconstitution of normal hematopoiesis and neutrophil function. Outcomes are improved with an HLA-identical donor. Significant risks include a high frequency of graft rejection, veno-occlusive disease, and severe pulmonary hypertension. Corticosteroids are recommended as second-line therapy in children when hematopoietic cell transplantation is not appropriate. Optic nerve decompression and optic sheath fenestration can improve visual function if performed early. There is some limited support for facial and acoustic nerve decompression to preserve facial strength and hearing, respectively.

Neuropathic autosomal-recessive osteopetrosis is a rare form with nontetanic seizures, developmental delay, hypotonia, retinal atrophy, and sensorineural deafness and is associated with the *OSTM1* mutation. There is primary neurodegeneration, and brain MRI abnormalities include delayed myelination, diffuse progressive cortical and subcortical atrophy, and bilateral atrial subependymal heterotopias.

Intermediate autosomal-recessive and autosomal-dominant osteopetroses (*CNCL7* mutation) have a less severe course and have few neurologic complications, with the uncommon exception of facial weakness and visual and hearing loss due to cranial nerve compression. Frequent fractures are the most common clinical feature.

Carbonic anhydrase II deficiency (marble brain disease) is an autosomal-recessive disorder resulting in osteopetrosis, renal tubular acidosis, and cerebral calcification. It presents in late infancy or early childhood with developmental delay, cognitive abnormalities, short stature, failure to thrive, a large cranial vault, weakness, cranial nerve compression, and a history of multiple fractures. Patients may have apathy, global hypotonia, or muscle weakness that is attributed to acidosis and diminished blood levels of potassium from renal tubular acidosis. Rarely, episodic hypokalemic weakness occurs. Many patients develop optic atrophy associated with reduced optic canal size on imaging. Less common cranial nerve deficits are facial palsy and deafness.

Metabolic abnormalities include a metabolic acidosis with a persistently positive urinary anion gap without renal failure. Anemia and splenomegaly may be present. Plain radiographs show increased density in the long bones, vertebral bodies, pelvis, and skull. Cranial CT or MRI shows thickened skulls with small or absent paranasal sinuses. Symmetric brain calcifications are present involving the basal ganglia, thalamus, gray–white junction (with a frontal lobe predilection), or some combinations of these sites. The amount of calcification progresses over time but does not correlate with the degree of cognitive abnormalities in these patients. The diagnosis can be made through an erythrocyte assay or by molecular probes for carbonic anhydrase II. Prenatal diagnosis requires direct carbonic anhydrase II gene sequencing. Patients are treated for acidosis with bicarbonate and Na/K citrate. Although the impact of treatment on the natural progression of the bone and neurologic features is unclear, there may be some effect in delaying the development of hearing loss and extramedullary hematopoiesis.

Infantile neuroaxonal dystrophy is a rare autosomal-recessive disorder due to a mutation of the *PLA2G6* gene, with widespread accumulation of neuroaxonal spheroids in the cortex, basal ganglia, brainstem, spinal cord, and peripheral nerves. It has been reported in association with osteopetrosis. It presents during the first 2 years of life with weakness, hypotonia, rigidity, pyramidal signs, cerebellar ataxia, diminished pain sensation, optic atrophy, and mental impairment, accompanied by hypocalcemia, hypomagnesemia, severe anemia, thrombocytopenia, hepatosplenomegaly, jaundice, and metabolic acidosis. Peripheral nerve signs such as diminished muscle stretch reflexes may be present, and the combination of central and peripheral signs is a clue to the diagnosis. Neuroimaging shows agenesis of the corpus callosum, ventriculomegaly, and cerebellar atrophy with hyperintensity on T2-weighted images. Electrodiagnostic findings are consistent with a distal axonal sensorimotor neuropathy. This form of osteopetrosis is fatal within the first few years of life.

PAGET DISEASE OF BONE

Paget disease is a focal disorder of bone turnover in which there is excessive bone resorption coupled with abnormal new bone formation, resulting in architecturally disorganized and mechanically weak bone. It has a predilection for the axial skeleton and involves the cervical spine in 15 percent, thoracic spine in 44 percent, lumbar spine in 54 percent, and skull in 42 percent of cases.[8] The prevalence increases with age, and the disorder is found primarily in Caucasians, although in recent years its incidence and severity have decreased.[9] There is a family history in 15 percent of patient with an autosomal-dominant pattern of inheritance. The etiology is incompletely understood but probably relates to a combination of genetic susceptibility and environmental factors, although the only disease-causing gene identified to date is sequestosome 1 (*SQSTM1*), found in one-half of affected families and 9 percent of sporadic cases. Patients with *SQSTM1* mutations have earlier onset and more severe disease.

Most patients with Paget disease are asymptomatic. The most common presentation in symptomatic patients is local bone pain coupled with overlying skin warmth due to increased bone microvasculature. The pain is continuous and worse at rest and at night. There may be obvious deformity of the bones, and skeletal complications include osteoarthritis, fractures, and sarcomatous changes.

Plain radiographs may show lytic lesions early in the disease; as the disease progresses, a chaotic, crisscross pattern with thickened cortical and trabecular bone is seen, sometimes accompanied by pseudofractures. The most sensitive metabolic marker of Paget disease is total serum alkaline phosphatase, which is elevated in almost all untreated patients. Procollagen-1N-propeptide is a good marker of bone turnover in Paget disease.

Treatment depends on the location and activity of the disease.[9] Asymptomatic patients usually do not require treatment, and pain is the only symptom for which there is proven benefit from treatment. Bisphosphonates (e.g., alendronate, tiludronate, risedronate, pamidronate, and zoledronic acid) produce a marked and prolonged inhibition of osteoclast function and are currently the first-line therapy. These agents reduce or normalize serum total alkaline phosphatase levels. Zolendronic acid may be superior to risedronate for treating symptoms, and patients with milder disease may only require a single intravenous treatment. It is important to correct vitamin D deficiency prior to intravenous bisphosphonate treatment to prevent hypocalcemia. Calcitonin or possibly the osteoclast inhibitor denusumab can be used in patients in whom bisphosphonates are contraindicated. Analgesics, anti-inflammatory drugs, and antineuropathic drugs may be helpful for bone pain.

Neurologic involvement is rare and occurs as a result of the close anatomic relationship of bone with the brain, spinal cord, cauda equina, spinal roots, and cranial nerves.[8] Compression from expanding bones or fracture is the most common cause of neurologic dysfunction. Less common causes include ossification of extradural structures, osteosarcoma, and epidural hematoma. Ischemia of the nervous system may occur occasionally due to compression of vascular structures or a vascular steal phenomenon; measurement of skeletal blood flow demonstrates that the affected bone receives up to 18 percent of cardiac output compared with 5 percent in normal bone.[8]

Other neurologic complications of cranial disease include headache, epilepsy, dementia, brainstem and cerebellar dysfunction, and cranial neuropathies. Headache is severe, frequently occipital, and worsened by coughing, sneezing, or straining. Dementia may result from direct compression of the cerebral hemispheres or from hydrocephalus. Epilepsy may occur from direct compression of the cerebral cortex.

In advanced cranial disease, there is softening of the skull base that can result in an anatomic lowering of the skull onto the upper cervical vertebrae (i.e., basilar invagination), leading to obstructive hydrocephalus and compression of the cerebellum, lower cranial nerves, corticospinal tract, and upper cervical nerves. The severity ranges from asymptomatic to tonsillar herniation and death. The typical presentation is that of slowly progressive ataxia, vertigo, tinnitus, dysphagia, dysarthria, and occipital headache. Vertebrobasilar insufficiency as well as obstructed venous return may lead to cerebrovascular compromise. An unusual picture resembling amyotrophic lateral sclerosis sometimes occurs in association with cervical cord involvement.

Any of the cranial nerves may be affected with Paget disease, but the olfactory and auditory nerves are involved most commonly. Hearing loss occurs in one-third of patients. It may be neuronal, conductive, or of mixed type. The cochlea is the most common site of involvement. The optic nerve may be affected at the optic foramen by compression of the vasa nervorum; patients present with diminished vision or blindness, retinal hemorrhages, choroiditis, optic atrophy, papilledema, and angioid streaks. The nerves controlling eye movements are vulnerable as they pass through the superior orbital fissure, leading to diplopia and abnormal pupillary responses. Exophthalmos from direct impingement of the extraocular muscles themselves occurs rarely. Trigeminal nerve involvement can lead to facial numbness and trigeminal neuralgia. Involvement of the facial nerve may result in hemifacial spasm or facial paresis.

Osteosarcoma of the skull occurs in less than 1 percent of patients with Paget disease.[8] It usually presents as a partially fluctuant and locally painful skull mass with rapid neurologic deterioration in the setting of long-standing disease. The prognosis is poor despite radiation therapy and surgery. Epidural hematomas can cause acute compression of the spinal cord or brain and are related to the increased blood flow to bone and increased risk of pathologic fractures. The prognosis in these cases is also poor, owing to excessive bleeding during surgery.

The spine is the second most common site of involvement in Paget disease and, prior to effective treatment with bisphosphonates, resulted in symptoms of spinal stenosis in 26 percent of patients.[8] Mechanisms of neurologic compromise include: (1) direct compression of the spinal cord, cauda equina, or nerve roots by enlarged vertebrae (most commonly) or expansion of facet joints; (2) pathologic fractures or subluxation; (3) ossification of extradural structures; (4) diversion of the local blood supply to highly vascular bones; and (5) pressure on vessels as they pass through the intervertebral foramina. Sarcomas or epidural hematomas are rare. The onset of continuous severe spinal pain and rapid neurologic deterioration should raise concern of osteosarcoma.

Back pain often occurs in patients with involvement of the spine. Osteoarthritis is prevalent in this elderly population and can be difficult to distinguish from Paget disease as the cause of pain. Other changes in the spine include thickening of the pedicles and laminae, flattening of the vertebral bodies, and encroachment of the spinal canal by osteophytes. Involved vertebrae are increased in width and reduced in height. The most commonly involved levels are the upper and lower cervical, low thoracic, and midlumbar regions. Of those with involvement of the spine demonstrated on plain radiographs, two-thirds will have evidence of spinal stenosis by CT and half of those patients will have clinical evidence of myelopathy or a cauda equina syndrome. There is no association between the number of vertebrae involved and presence of symptoms.

Low back pain may respond to treatment with bisphosphonates. Pain that does not respond after 3 months should be treated with NSAIDs. Improvement or reversal of symptoms of spinal stenosis has been demonstrated with mithramycin, etidronate, pamidronate, and clodronate. Prompt surgical decompression is appropriate for patients who do not respond to pharmacologic treatment. Preoperative assessment of bone vascularity by radionuclide bone blood flow can help direct perioperative medical therapy and prevent massive bleeding.

Extradural ossification of the ligamentum flavum and epidural fat can result in compression of the spinal cord or nerve roots and may require surgical decompression. Myelopathy and cauda equina syndrome can occur without evidence of compression on neuroimaging and can respond dramatically to medical therapy (calcitonin or bisphosphonates), suggesting that ischemia due to a vascular steal phenomenon is responsible.

Serum alkaline phosphatase concentrations and urine hydroxyproline are usually increased in patients with neurologic complications, but alkaline phosphatase levels are normal in one-third of those with spinal stenosis. Plain radiographs and radionuclide scans should be obtained to localize disease activity and identify pathologic fractures. Cranial CT or brain MRI and CT myelography or MRI of the spine are necessary to demonstrate compression of neural structures and to exclude other causes of symptoms (Fig. 22-4). Sarcomatous transformation is best assessed with MRI. Patients with neurologic complications should have serum alkaline phosphatase and urinary hydroxyproline level determinations every 6 months. Clinical monitoring of neurologic function in symptomatic patients and repeat radiographs of the skull and weight-bearing long bones are recommended every 6 to 12 months in those with osteolytic lesions.

Medical and surgical management of neurologic complications depends on location, basis, and clinical course. Asymptomatic disease that affects the skull or spine should be treated with bisphosphonates. Patients with neurologic compromise respond to etidronate and intravenous pamidronate. Calcitonin is no longer recommended as the bisphosphonates are

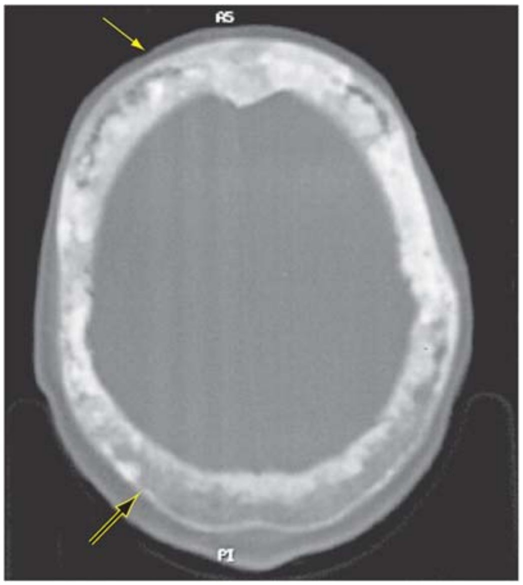

FIGURE 22-4 ■ Paget disease of bone. Axial CT scan of the head with bone windows. The closed arrow shows thickened osteosclerotic bone anteriorly. The open arrow shows thickened hypodense osteolytic bone posteriorly.

more effective with fewer treatment failures.[8] Rapidly progressive neurologic deterioration should be treated with intravenous bisphosphonates before surgery to minimize intraoperative bone hemorrhage.

Obstructive hydrocephalus usually requires the placement of a ventricular shunt. Hydrocephalic dementia with memory loss, gait disturbance, and urinary incontinence may improve with shunting and bisphosphonate therapy.

Bisphosphonate treatment probably results in stabilization of hearing loss. Trigeminal neuralgia and hemifacial spasm are treated with carbamazepine. Hemifacial spasm may also respond to alendronate or botulinum toxin injection. Facial nerve paresis sometimes responds to surgical decompression, and there are older reports of benefit with suboccipital craniectomy and upper cervical laminectomy for patients with lower cranial neuropathies.

Surgical treatment of spinal disease is difficult because involvement is usually at multiple levels, highly vascular bone leads to perioperative bleeding, and patients are typically in an older age group. Some degree of benefit may occur but there is a significant reoperation and mortality rate. Relapses may occur after either bisphosphonate treatment or surgical treatment, and benefit may then follow by repeating or changing therapy.

Inclusion-Body Myopathy, Paget Disease, and Frontotemporal Dementia

Inclusion-body myopathy, Paget disease of bone, and frontotemporal dementia (IBMPFD) is a rare autosomal-dominant disorder caused by missense mutations in the valosin-containing protein (*VCP*) gene.[10] There is variable penetrance of weakness (90%), osteolytic bone lesions (51%), and frontotemporal dementia (32%). The onset of the disorder is in the third and fourth decades, and over half of patients present with weakness. Clinical patterns described include: (1) proximal lower extremity weakness; (2) scapulohumeral weakness with scapular winging; (3) axial weakness with head drop and lumbar lordosis; (4) distal weakness; or (5) a mixture of these patterns. Facial or tongue weakness can occur. The weakness is slowly progressive and is often asymmetric. Other neurologic features include sensorineural hearing loss and sensorimotor axonal neuropathy. A disorder resembling amyotrophic lateral sclerosis in some respects, with upper motor neuron findings, parkinsonism, and myotonia, is described in some families.[10] Patients die of respiratory insufficiency, cardiac failure, or complications from end-stage dementia in the fourth to sixth decades.

Laboratory findings include a serum creatine kinase level that is normal or mildly elevated. Total serum alkaline phosphatase may be elevated if pagetic involvement of bone is present. Standard motor and sensory nerve conduction studies are normal, but EMG shows myopathic units and, sometimes, abnormal spontaneous activity. Patients with an amyotrophic lateral sclerosis-like phenotype may have neurogenic changes by EMG. Neuropsychologic testing is helpful to assess for dementia.

Muscle biopsy shows variation in fiber size and endomysial fibrosis. Subsarcolemmal or sarcoplasmic rimmed vacuoles are present in 40 percent of patients. Electron microscopy shows ubiquitin-positive and tubulofilamentous inclusions similar to sporadic inclusion-body myopathy. A common finding is VCP and TAR DNA-binding protein 43 (TDP-43) inclusions that can co-localize with ubiquitin-positive inclusions. CNS pathology includes atrophy and neuronal loss in the frontal and temporal lobes with ubiquitin-positive inclusions that are positive for TDP-43 in 55 percent of patients.[10]

VCP DNA sequencing is available to make the diagnosis but, interestingly, *VCP* mutations are also described in 2 percent of patients with familial amyotrophic lateral sclerosis. The exact pathogenesis of *VCP* mutations is not completely understood but may relate to impairment of protein degradation. There is no current treatment for the myopathy and dementia in these patients other than supportive measures. Symptomatic Paget disease is treated with bisphosphonates. Other genetic mutations can cause multisystem proteinopathies with Paget disease of bone as one feature. These include *HNRNPA2B1*, *HNRNPA1*, and *SQSTM1*.

VERTEBRAL OSTEOMYELITIS

Infection of the spine by a variety of pathogenic organisms is primarily a disease of older adults; men are affected twice as commonly as women, and recent observations suggest an increasing incidence. Bacteria most commonly reach the spine by hematogenous spread from a distant source, but may also originate from a focus of contiguous infection or be introduced by direct penetrating trauma, surgery, epidural injections, or, rarely, lumbar puncture. Risk factors include degenerative spine disease, intravenous drug use, endocarditis, diabetes, corticosteroid use, immunocompromise, and prior spine surgery.

The lumbar spine is most commonly affected, followed by the cervical spine. With hematogenous spread, septic emboli lodge in the metaphyseal subchondral area of the vertebra, often causing bone infarction. Infection within the vertebral body then tends to spread sequentially to involve the adjacent (avascular) intervertebral disc followed by the next adjacent vertebra (spondylodiscitis). This propensity to traverse disc spaces distinguishes osteomyelitis clinically and radiographically from neoplasia, which tends to remain confined. Abscesses may form when infection extends beyond the cortex of the vertebra. An epidural abscess may cause both radicular injury and spinal cord compression. Extraspinal abscesses may track to a variety of sites (e.g., paraspinal, retroperitoneal, psoas muscle). Chronic osteomyelitis is characterized pathologically by necrosis of bone, a predominantly mononuclear infiltrate, fibrosis, and a paucity of organisms. A sinus tract may develop occasionally between the affected bone and skin.

Osteomyelitis resulting from blood-borne bacterial seeding is almost always the result of infection by a single organism. Diabetes and chronic alcoholism are common risk factors. More than half are due to *Staphylococcus aureus* (meticillin-susceptible isolates account for the majority) and are often associated with vascular catheters and other invasive medical procedures. Causative organisms also include *Escherichia coli* and other enteric gram-negative bacteria, *Brucella*, and fungi (e.g., *Candida*). *Pseudomonas* and staphylococcal infections are associated with intravenous drug use. Streptococci and enterococci are frequently associated with endocarditis. Tuberculous infection is addressed elsewhere in this chapter. Polymicrobial ("mixed") cultures are associated with trauma and spread of contiguous infection.

Back pain, often with local tenderness, is the most frequent presenting feature. Pain is often not relieved by rest; it persists at night and may radiate to the abdomen, pelvis, or lower limbs. The spine may be held rigidly, with paraspinal muscle spasm. In many patients, back pain is preceded by a subacute prodrome of constitutional symptoms—fever, fatigue, lethargy, anorexia—for several weeks. By the time of initial presentation, however, the patient may be afebrile with few other signs of systemic infection. Neurologic deficit occurs in only one-half of the patients and constitutes the major complication. Vertebral collapse may cause spinal cord compression. Encroachment on sensory and motor roots gives rise to pain and segmental sensorimotor loss. Cauda equina syndrome may result from compression of multiple lumbosacral roots. Epidural abscess formation with compression of the spinal cord may develop acutely or subacutely over several weeks and requires immediate surgical decompression.

A high index of clinical suspicion is required for the timely diagnosis of osteomyelitis. Identification is crucial, because effective antibiotic therapy may prevent necrosis of bone and permanent skeletal abnormality. Plain radiography is frequently normal in the first 2 to 4 weeks since lytic lesions are not apparent until significant bone loss has occurred. By contrast, MRI abnormalities (Fig. 22-5)—commonly hypodensities within the vertebral body and contrast enhancement of the body and disc—can be seen in early disease, representing edema; other findings include spondylodiscitis, erosion of bone, and intra- and extravertebral collections. Radionuclide scans are highly sensitive but the findings are nonspecific; this technique is particularly useful when MRI is contraindicated.

Blood cultures are positive in around 30 percent of cases. Material from the focus of infection may be obtained by needle aspiration or open biopsy, and is generally needed to confirm the diagnosis. Biopsy may be avoided if blood cultures are positive for an appropriate organism, and there is confidence

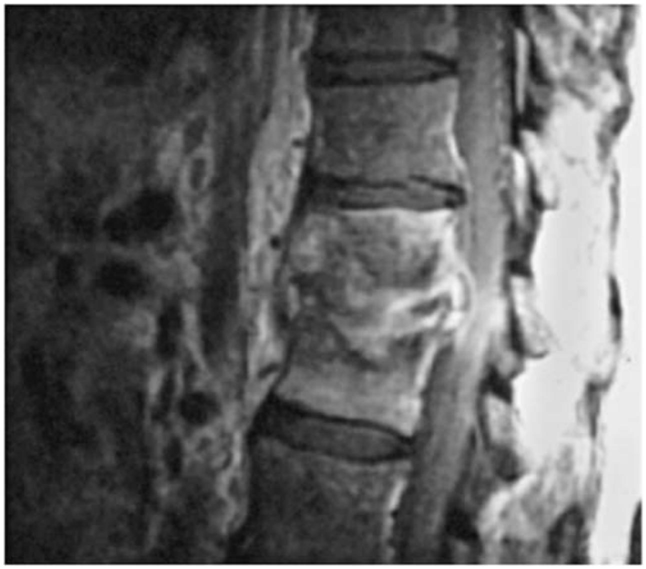

FIGURE 22-5 ■ Osteomyelitis. Sagittal T1-weighted MRI of the lower thoracic spine, with contrast. A septic focus is seen to involve the intervertebral disc and the two adjacent vertebral bodies. An epidural abscess compresses the thecal sac.

regarding the diagnosis. Specimens for microbiologic culture and antibiotic sensitivity should be obtained before the institution of antibiotic therapy, although one study found that antibiotics administered prior to biopsy did not reduce culture yield.[11] The concurrent presence of endocarditis should always be considered, particularly in the setting of underlying valvular disease and gram-positive cultures. A second biopsy may be needed if the first is negative. Brucellosis and tuberculosis serology may be helpful.

High-dose intravenous antibiotics are used for treatment although there are no randomized, controlled trials to evaluate specific regimens or duration of therapy. Choice of agent is determined by tissue or blood culture and sensitivity testing. Treatment for 6 to 12 weeks with antibiotics may be needed. Empiric treatment (usually a penicillinase-resistant penicillin or vancomycin, plus a third-generation cephalosporin) may be necessary before microbiology results return or when cultures are negative. Intravenous antibiotics should be continued for an extended period of weeks to months before switching to an oral preparation once a favorable response has been achieved. Close monitoring in the first few weeks is essential to identify complications such as cord compression and abscess formation. If there is no improvement clinically (pain, fever), or settling of the erythrocyte sedimentation rate and C-reactive protein level within 3 to 4 weeks, biopsy may need to be repeated. Imaging abnormalities tend to persist despite clinical measures of improvement and are not necessary to follow routinely. In contrast, the erythrocyte sedimentation rate and C-reactive protein level are frequently elevated and may be useful to follow weekly to gauge response to therapy. Bed rest with external immobilization with a back brace is generally enforced until back pain has receded. With appropriate antibiotic therapy, recovery is the rule; surgery is required in 10 to 20 percent of cases, usually for drainage of large abscesses, decompression in cases of progressive neurologic deficit, particularly cord compression, fixation for spinal instability, and debridement in severe, unresponsive infection. Prognosis is worse in older patients and when there is a delay in diagnosis. A systematic review found an overall mortality of 6 percent, with residual deficit seen in 32 percent of patients.[12] Osteomyelitis resulting from trauma or contiguous infection requires broad-spectrum antibiotic therapy due to its polymicrobial nature and, frequently, surgical debridement. The management of chronic osteomyelitis is difficult and controversial, usually involving complete surgical removal of the nidus of infection along with long-term antibiotic therapy.

Tuberculous Osteomyelitis

First reported in detail by Sir Percivall Pott in the late eighteenth century, tuberculous involvement of bone and joint tissue accounts for 10 to 35 percent of cases of extrapulmonary tuberculosis worldwide, with the spine (Pott disease) being the most common site of skeletal involvement. Immigrants from endemic areas to developed countries have higher rates of extrapulmonary tuberculosis. Tuberculous infection of the spine may occur by hematogenous seeding at the time of primary infection (typically children in endemic areas) or as a result of reactivation of a focus of latent infection with hematogenous or lymphatic spread to the spine, frequently years after the initial pulmonary infection (typically adults in nonendemic areas). Usually, a vertebral body in the lower thoracic or upper lumbar spine is affected, followed by spread to adjacent vertebrae. Involvement of the intervening disc occurs later than in bacterial osteomyelitis and may give rise to a radiologic appearance of relative disc-sparing. Destruction of cancellous bone renders the involved vertebral body liable to compression fractures and vertebral body collapse. In advanced cases, both kyphosis and scoliosis can produce a striking gibbus deformity which may be associated with (thoracic) myelopathy. Paravertebral collections may form at various sites including within the psoas muscle. Occasionally, contiguous spread is seen from a primary focus in the lung apex to the atlanto-axial joint.

Back pain is common and patients may adopt a stiff-backed posture, walking with careful, short steps to avoid jarring the spine. Constitutional symptoms (lethargy, night sweats, weight loss) and systemic signs (anemia, low-grade fever) are frequent but may not be prominent. Neurologic deficits are present in fewer than one-half of patients. The possibility of tuberculous infection of the spine is usually an obvious consideration in patients with known pulmonary tuberculosis (particularly when treatment was incomplete), or in immunosuppressed patients. In the majority of patients, however, there is no history of tuberculosis, and a high index of clinical suspicion and appropriate (radiologic) investigations are needed for recognition; in many series, diagnosis was delayed for 12 to 18 months after presentation.

There may be few clues to the diagnosis on routine tests: erythrocyte sedimentation rate and C-reactive protein may not be elevated, and the peripheral white count may be normal or elevated only slightly. Chest radiography is normal in half the cases, and sputum is usually negative for acid-fast bacilli. CT or MRI may show involvement of the anterior aspect of a vertebral body, later with involvement of several contiguous vertebral bodies with heterogeneous enhancement and the presence of epidural and subdural abscesses. The intervening discs may not show involvement, unlike the case with pyogenic infections. The differential diagnosis may include degenerative disease, compression fractures, bacterial and fungal osteomyelitis, and metastatic disease.

Attempts to confirm the tuberculous nature of such lesions usually begin with a purified protein derivative (PPD) skin test, which has poor sensitivity. Biopsy (needle aspiration or open biopsy) demonstrates the characteristic caseating granulomatous histology with Langhans giant cells and acid-fast bacilli; culture may be positive.

Treatment is with prolonged antituberculous drugs similar to the approach used for pulmonary tuberculosis. The duration of therapy is unclear and is judged according to clinical response. In general, 6 to 9 months of initial treatment with a regimen of first-line drugs including rifampin is sufficient in uncomplicated disease; a longer 9- to 12-month course with or without surgical debridement may be needed in advanced disease or where the drug regimen does not include rifampin. Drug-resistant infection may require prolonged therapy for 18 to 24 months. In patients infected with human immunodeficiency virus, spinal tuberculosis may worsen following institution of antiretroviral therapy as a result of immune reconstitution inflammatory syndrome. Response to treatment may take weeks to months by clinical and laboratory measures, but radiologic changes tend to persist, suggesting that imaging need not be repeated in patients who are improving. Surgical debridement and stabilization of the spine is sometimes required in addition to drug therapy for those patients with spinal instability or severe disease, but should not be performed routinely. Spinal cord compression is a medical emergency necessitating immediate surgical decompression.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is an HLA-B27-associated chronic inflammatory disease of joints with predilection for the sacroiliac joints and spine and with ossification of associated ligaments (enthesopathy). HLA-B27 is present in 74 to 89 percent of patients with the disorder.[13] Clinical manifestations typically begin in late adolescence or early adulthood. The most common symptoms are pain and stiffness of the low back and pelvis. Pain can be severe and is often referred along the iliac crest to the greater trochanteric region or down the dorsal thigh. It sometimes alternates from side to side and may be accentuated by cough, sneeze, or a twisting motion of the back. Features that help to differentiate it from mechanical low back pain include the onset of back discomfort before the age of 45, an insidious onset, persistence for at least 3 months, associated morning stiffness, improvement with exercise, and failure to improve with rest. Within a few months of onset, as symptoms become persistent, the pain becomes bilateral and prominent at night, and is relieved by getting up and walking around. Pain in the chest occurs in 40 percent.[13]

The findings on physical examination include flattening of the lumbar spine and loss of the lumbar

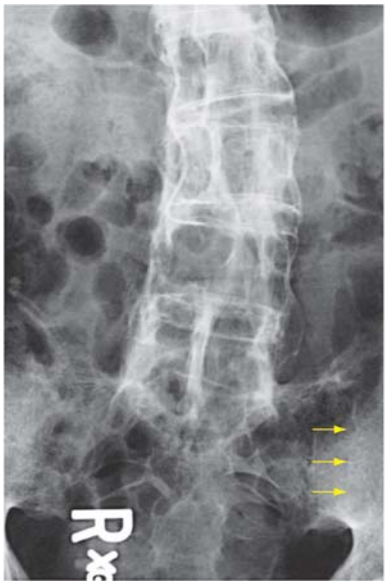

FIGURE 22-6 ■ Ankylosing spondylitis. Plain radiograph of lumbosacral spine. The characteristic "bamboo spine" with fusion of the intervertebral ligaments is evident. The arrows show fusion of the sacroiliac joint.

lordosis. There is limited motion of the axial skeleton, especially with hyperextension and lateral bending. Percussion over the sacroiliac joints elicits pain. Radiographs or MRI of the sacroiliac joints are used to make the diagnosis in conjunction with the clinical features and laboratory investigations, including C-reactive protein, erythrocyte sedimentation rate, and HLA-B27 (Fig. 22-6).

Therapies for ankylosing spondylitis that have evidence-based beneficial effects include physical therapy, NSAIDs, and tumor necrosis factor alpha (TNF-α) inhibitors. It is unclear whether these therapies alter the course of the illness, particularly the loss of spinal mobility, with the possible exception of the TNF-α inhibitors. Intensive physical therapy and exercise are important to maintain mobility, posture, and range of motion. Braces, splints, and corsets should be avoided. NSAIDs are the first line of therapy for pain and stiffness. For patients who cannot tolerate continuous NSAIDs or who do not have adequate control, TNF-α inhibitors are recommended. Younger age, milder disease, short disease duration, elevated nonspecific markers of inflammation, and HLA-B27 positivity are associated with better response to TNF-α inhibitors. Interleukin-17 inhibitors are a promising new approach to treatment. A detailed description of treatments for ankylosing spondylitis is provided elsewhere.[13]

Neurologic complications are uncommon. They include radiculopathy from foraminal stenosis or inflammation and myelopathy resulting from fracture-dislocation, atlanto-axial subluxation, pseudoarthritis, ossified intraspinal ligaments, or granulation tissue. Cauda equina syndrome is a late complication attributed to arachnoiditis. Sciatic nerve compression can occur secondary to inflammation of the attachment of the piriformis muscle to the sacroiliac joint, mimicking sciatica from root compression (pseudosciatica).

The risk of spine fractures in patients with ankylosing spondylitis is 10 percent. The spine is brittle and thus prone to fracture, and osteoporosis in these patients is another important risk factor. Fracture risk worsens with age and is more common in men. The fracture often goes entirely through the vertebral body and/or calcified disc and ossified ligaments, resulting in increased instability and a high risk of neurologic compromise. The most common fracture location is in the low cervical spine and in the majority of cases results from low-energy trauma. Secondary neurologic compromise can also occur, with deterioration sometimes occurring more than 3 months after the initial fracture. Delayed diagnosis is common, due to physician misdiagnosis or patient delay in seeking care. Sudden neck or back pain in these patients should prompt a CT and possibly an MRI of the spine to search for fracture.

Surgical intervention is complicated but appears to have a greater chance of improvement or stabilization of neurologic function and a lower mortality than nonoperative treatment, although selection bias is a factor.[14] There is a high failure rate for nonoperative treatment. Bracing must be customized and risks impairing pulmonary function. Traction is not recommended. If possible, a combined anterior and posterior surgical approach is recommended for cervical fractures. For craniovertebral junction fractures, posterior segmental stabilization after reduction is the usual approach. For thoracic and lumbar spine fractures, posterior stabilizing surgery is recommended. Surgical complications occur frequently, including postoperative wound infections, deep vein thrombosis, pneumonia, and respiratory insufficiency. Fatal but rare complications of surgery include aortic dissection, aortic pseudoaneurysm, and tracheal rupture.

Spinal stenosis with cord compression is rare. Patients may develop "radicular" pain without neurologic symptoms or signs, and this usually resolves spontaneously. The cervical spine may be involved, resulting in atlanto-axial subluxation in some patients. Atlanto-occipital subluxation with vertebral artery occlusion and brainstem transient ischemic attack or infarction may also occur. Studies of the natural history of ankylosing spondylitis have demonstrated that cerebrovascular disease is a common cause of mortality in patients younger than 60 years of age, often without clear etiology; prophylactic antiplatelet therapy may be indicated.

Cauda equina syndrome occurs in rare patients, predominantly male, on average 32 years after the onset of disease. In most patients, there are no inflammatory markers in the blood. The typical presentation includes insidious onset and progression of bowel and bladder symptoms, sensory loss (often asymmetric) in an L5–S4 distribution, pain radiating into the lower limbs or the rectal area, and minimal weakness in muscles innervated by the L5–S2 segments. Bladder symptoms include decreased awareness of bladder sensation, decreased ability to empty the bladder, hesitancy, decreased force of urinary stream, urgency, and frequency. Radiography of the lumbar spine may show erosions of the lamina. Spinal MRI shows dorsal dural diverticula associated with a widened thecal sac and scalloped erosions of the laminae and spinous processes. Nerve roots appear to deviate toward the diverticula and may be displaced posteriorly; they appear to be adherent to the arachnoid membrane and to each other, suggesting arachnoiditis. There is no associated gadolinium enhancement. Spinal CT typically demonstrates asymmetric, multilevel erosions that selectively involve the pedicles, laminae, and spinous processes of the lumbosacral spine. Infrequently, erosion of the posterior portion of the vertebral body is found, or involvement is unilateral or confined to one level. Myelography is technically difficult and can be complicated by epidural hematoma in patients with ankylosing spondylitis. CSF is normal or shows a slightly elevated protein concentration, although rarely a lymphocytic pleocytosis occurs. EMG shows denervation changes, often asymmetric, in the L2–S1 distribution.

The pathologic findings depend on the timing of surgery or autopsy relative to the onset of neurologic symptoms. Early pathologic findings include inflammation of the spinal ligaments, dura, and arachnoid. Over time, there is fibrosis and chronic arachnoiditis embedding atrophic nerve roots, with small sacral roots splayed and adherent to the dura. A CSF resorption defect has been documented and may contribute to thecal sac enlargement. Compression of the nerve roots by diverticula sometimes occurs. The disease may be patchy, with some roots appearing normal.

NSAIDs result in improvement of back pain in cauda equina syndrome, but without improvement of neurologic deficits. There can be partial improvement with infliximab. Patients may have improvement of neurologic function or halting of progression with either lumboperitoneal shunting or laminectomy, but neurologic deficits persist despite surgical intervention in most patients. The clinical course is slowly progressive, although patients rarely lose the ability to walk. Any patient with longstanding ankylosing spondylitis who develops sphincter dysfunction should receive a careful neurologic assessment.

There is an unclear association between ankylosing spondylitis and multiple sclerosis. There is an increased incidence of autoimmune neurologic disorders including multiple sclerosis and demyelinating neuropathy in rheumatologic patients, including those with ankylosing spondylitis, treated with TNF-α inhibitors. There may be more CNS side effects with etanercept therapy, and peripheral nervous system side effects with infliximab. The incidence of these complications in patients with ankylosing spondylitis treated with TNF-α inhibitors is unknown. It is recommended in these cases that the TNF-α inhibitor be discontinued; some, but not all, patients improve after discontinuation. The use of TNF-α inhibitors in patients with a prior history of multiple sclerosis or a CNS demyelinating disorder is best avoided. Demyelinating neuropathy should be treated with corticosteroids or intravenous immunoglobulin.

Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis is a noninflammatory arthropathy with ossification of spinal longitudinal ligaments and entheses resulting in decreased mobility and ankylosis. The etiology is unknown but there is an association with male gender, obesity, adult-onset diabetes mellitus, pulmonary hypertension, and advanced age. Diagnosis is made by the presence of ossification of the anterior longitudinal ligament over four consecutive levels on spine radiographs. The most common areas of involvement are T7 to T11. Common clinical symptoms are pain and stiffness in the spine. Serious complications from cervical spine involvement include dysphagia, sleep apnea, difficult endotracheal intubation, and spinal canal stenosis with myelopathy.

There is an increased incidence of traumatic vertebral fracture in these patients, and they are more likely to have multiple fractures. A unique feature is fracture through the vertebral body. The cervical spine is the most common site involved. Low-energy impact commonly precedes fracture but high-energy impact is recognized in about a quarter of patients. Hyperextension is the most frequent cause. There is delay in diagnosis of the fracture in more than half of patients and almost one-half have a neurologic deficit on presentation. Secondary neurologic deterioration may occur and is sometimes due to inadequate immobilization, inconsiderate transfers, or the application of a hard collar with a pre-existing kyphotic deformity. About half of these patients are treated with surgical posterior fixation, and the rest are managed conservatively, often with a collar or bracing for thoracic fractures. Neurologic improvement is unlikely regardless of treatment and there is substantial morbidity and mortality in both operated and unoperated cases. Pneumonia, respiratory failure, and pseudoarthosis are described most frequently.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is an uncommon, immune-mediated multisystem disorder characterized by recurrent episodes of inflammation and eventual destruction of cartilaginous tissues. The prevalence of the disorder is 3.5 per 1 million persons, with an age range from 16 to 84 years, with peak onset in the fifth decade.[15] There is an equal prevalence in men and women, and it has been described in all races. It can affect all types of cartilage, including the ears and nose (most commonly), peripheral joints, fibrocartilage at axial sites, and the tracheobronchial tree. The eye, heart, blood vessels, and inner ear are rich in proteoglycans and can also be affected. There is a genetic association with HLA-DR4 and negative association with HLA-DR6. More than 30 percent of patients with relapsing polychondritis have an associated hematologic or rheumatologic disorder (especially a vasculitis associated with antineutrophil cytoplasmic antibodies). Antibodies to types II, IX, and XI collagen can be present, and immune-complex deposition is found in cartilage.

The clinical presentation involves the acute or subacute onset of ear pain, tenderness and swelling of the external auditory meatus, erythema, and a clear serous discharge from the ear (Fig. 22-7). Ear involvement is often the initial presenting symptom and ultimately occurs in almost all patients. The noncartilaginous lobule is spared. Repeated bouts of inflammation result in a floppy ear. Nasal pain, hoarseness, and difficulty in talking are also common. Nasal crusting, rhinorrhea, and epistaxis can occur, and repeated inflammation of the nasal cartilage results in a saddle nose deformity. Systemic symptoms include fever, lethargy, and weight loss. The course is typically relapsing, but over the course of the illness, progressive disability occurs in most patients. Inflammation of the trachea and larynx occurs in 50 percent of patients and may be fatal. A detailed description of the cardiovascular, joint, respiratory, and dermatologic complications is provided elsewhere.[15]

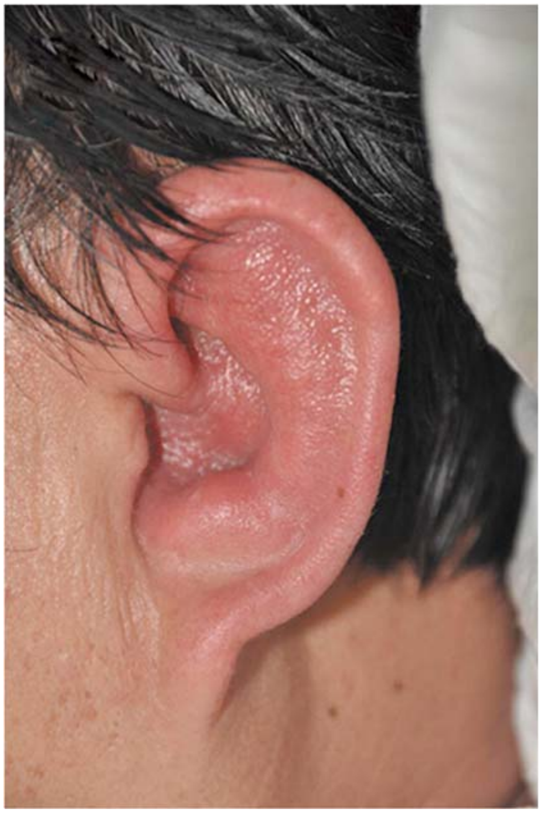

FIGURE 22-7 ■ Relapsing polychondritis, illustrating marked auricular swelling and redness. (From Wang ZJ, Pu CQ, Wang ZJ, et al: Meningoencephalitis or meningitis in relapsing polychondritis: four case reports and a literature review. J Clin Neurosci 18:1608, 2011, with permission.)

Vertigo, conductive or sensorineural hearing loss, and tinnitus are common and can be the presenting symptom. The sensorineural hearing loss is attributed to vasculitis of the vestibular or cochlear branch of the internal auditory artery. The abrupt onset of hearing loss, sometimes accompanied by vertigo, nausea, vomiting, and imbalance, can mimic a posterior circulation stroke. Ocular involvement occurs in 65 percent of patients including recurrent conjunctivitis, episcleritis, scleritis, iritis, or keratoconjuctivitis sicca. Rarely, chorioretinitis, retinal vasculitis, exophthalmos due to orbital pseudotumor, uveitis, and optic neuritis are seen. Extraocular palsies occur either due to direct extension of pseudotumor-like inflammation of the orbit or from vasculitic ischemia to cranial nerves III, VI, or IV.

Vasculitis occurs in up to half of patients with relapsing polychondritis and affects the skin, internal organs, or CNS. It can affect the large arteries, resembling Takayasu arteritis, or small- to medium-sized vessels. The prognosis in patients with systemic vasculitis is poor, with a 5-year survival rate of 45 percent.

Neurologic involvement is infrequent but may be the presenting feature. It may manifest with cranial neuropathies, cerebral vasculitis, mononeuritis multiplex, sensorimotor distal symmetric neuropathy, aseptic meningitis, meningoencephalitis with limbic encephalopathy, rhombencephalitis, myelitis, acute spinal cord infarction due to aortic disease, or thromboembolic strokes secondary to vasculitis, sometimes with associated anticardiolipin antibodies. Cerebral aneurysms occur in rare instances.

Cranial nerve abnormalities are the most frequent, with involvement of II, VI, VII, and VIII being most common. Involvement of III, IV, and XII has also been described. Vasculitic infarction is the presumed etiology. CNS involvement can be due to vasculitis or meningoencephalitis; patients present with an acute headache accompanied by encephalopathy, personality change, hallucinations, seizures, and focal or multifocal deficits such as hemiparesis, ataxia, or the clinical features of a lateral medullary syndrome. An acute limbic encephalitis can present with fever, delirium, visual and auditory hallucinations, agitation, disinhibition, cognitive decline, and seizures. There may be an association with antiglutamate receptor ε2 antibodies. CSF may show a pleocytosis and elevated protein concentration. Parkinsonism, apathy, psychosis, and dementia may also develop. Papilledema or meningeal signs can occur. Aseptic meningitis presents with headache, meningeal signs, and fever; in these cases, CSF results most often show a lymphocytic pleocytosis, but a polymorphonuclear leukocyte predominance sometimes occurs. Total protein level can be elevated markedly and there are cases with a decreased CSF glucose mimicking infection. Oligoclonal bands are sometimes present. MRI may show patchy thickening of the dura mater with gadolinium enhancement. With meningoencephalitis, T2 and FLAIR hyperintensity and enhancement are also seen in the gray and white matter in a patchy distribution. Recurrent encephalitis can result in atrophy of affected areas.

With CNS vasculitis, the erythrocyte sedimentation rate is usually elevated (> 100 mm/hour), and mild systemic leukocytosis may be present. The CSF is normal or shows a pleocytosis. The electroencephalogram can be normal, slow, or show focal areas of epileptiform activity. Cranial CT often shows cerebral and cerebellar atrophy or focal areas of hypodensity, but it can be normal. MRI is suggestive of cerebral vasculitis, with increased T2 signal in the periventricular white matter and centrum semiovale, focal lesions in the gray matter, and wedge-shaped cortical infarcts. Focal occlusion of vessels can be seen on MR angiography. In cases of limbic encephalitis, the MRI shows increased T2 signal in one or both medial temporal lobes. A clue to the diagnosis of relapsing polychondritis in some patients with neurologic presentations is increased signal on diffusion-weighted imaging of the external ears (Fig. 22-8). Brain biopsy in these cases shows marked gliosis, perivascular cuffing, and destruction of the vascular well.

The diagnosis of relapsing polychondritis is based on clinical criteria (Table 22-4), supportive laboratory parameters, imaging, and biopsy of involved cartilaginous tissues, including the ear. Evaluation of organ involvement on physical examination is critical, including the ear, nose, and throat. Nonspecific laboratory findings include an elevated erythrocyte sedimentation rate and C-reactive protein level, anemia, leukocytosis, and thrombocytosis. Esoinophilia may be present. Serum creatinine and urinalysis should be checked to assess for renal involvement. A serologic screen for associated rheumatologic disorders should occur. Type II collagen antibodies may be present. The airway and lungs should be evaluated by radiography, pulmonary function tests, and high-resolution CT scans, specifically dynamic expiratory CT. Echocardiogram to evaluate the heart valves is also recommended. PET-CT is a newer technique to determine the distribution of lesions in relapsing polychondritis and help target tissue biopsy. MRI of the joints and ear can also be helpful for early diagnosis. Early pathology of affected cartilaginous tissue shows a pleomorphic inflammatory infiltrate.

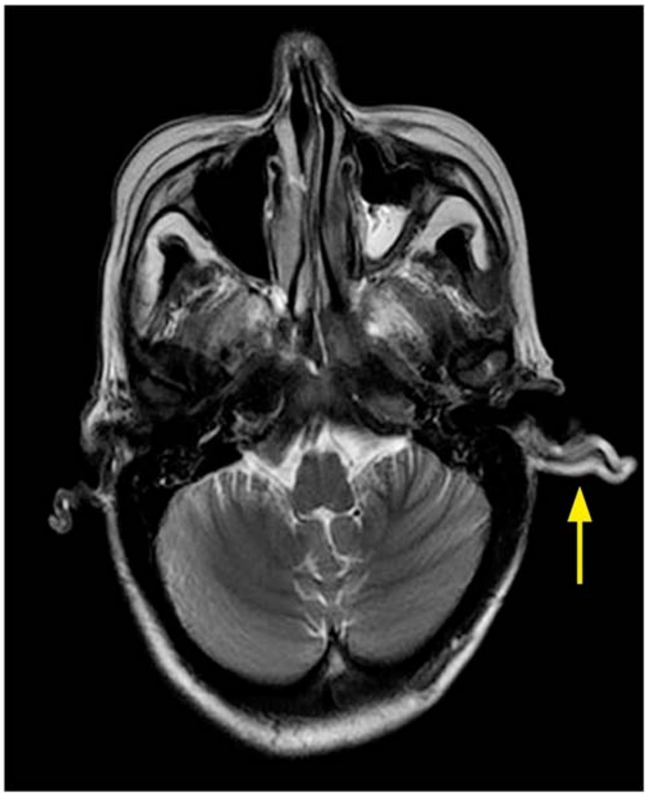

FIGURE 22-8 ■ Relapsing polychondritis. T2-weighted MRI showing abnormal signal in the left auricle. (From Wang ZJ, Pu CQ, Wang ZJ, et al: Meningoencephalitis or meningitis in relapsing polychondritis: four case reports and a literature review. J Clin Neurosci 18:1608, 2011, with permission.)

TABLE 22-4 ■ **Diagnostic Criteria for Relapsing Polychondritis***

Bilateral auricular chondritis
Nonerosive seronegative inflammatory arthritis
Nasal chondritis
Ocular inflammation
Respiratory tract chondritis
Audiovestibular damage

*A minimum of three criteria must be met to establish the diagnosis.

T lymphocytes are mainly CD4-positive. There is inconstant deposition of Ig and C3 at the junction between the perichondrium and cartilage. With time, inflammatory infiltrates invade the cartilage and there is progressive destruction of the cartilage with replacement by collagen.

The differential diagnosis includes Wegener granulomatosis. Distinguishing clinical features include involvement of the mucosa and lung parenchyma and the presence of positive cytoplasmic antineutrophil cytoplasmic antibodies, which are not seen in uncomplicated relapsing polychondritis.

Treatment is empiric as there are no standardized therapeutic guidelines. Mild inflammation of joints, ear, or nose can be managed with NSAIDs, dapsone, or colchicine. If there is significant laryngotracheal, bronchial, cardiovascular, renal, or neurologic involvement, a more aggressive course is recommended. Rapid response is obtained with high-dose oral or intravenous corticosteroids. Relapses occur if corticosteroids are reduced too rapidly. Corticosteroid-sparing agents may be necessary, including cyclophosphamide, azathioprine, cyclosporine, and methotrexate. TNF-α inhibitors are of particular interest since there is a massive expression of TNF-α in affected cartilaginous tissue in patients with relapsing polychondritis. There are mixed results for treatment with biologic agents, with best outcomes with infliximab, followed by etanercept and rituximab. Similarly there are limited data concerning the efficacy of adalimumab, toclizumab, abatacept, leflunomide, mycophenylate mofetil, and intravenous immunoglobulin in refractory cases or when there is loss of efficacy of first-line agents. Certolizumab and rituximab are not recommended. Elevated serum IL-6 levels may predict response to tocilizumab.

Treatment of CNS vasculitis, limbic encephalitis, meningoencephalitis, and aseptic meningitis includes high-dose corticosteroids, often with additional corticosteroid-sparing agents during the course of the illness. Limbic encephalitis can respond dramatically to infliximab. Aseptic meningitis in relapsing polychondritis responds to corticosteroids in most cases.

NEUROLOGIC MANIFESTATIONS OF OTOLOGIC DISEASE

Complications of Middle Ear Pathology

Intracranial complications occur in 0.25 to 0.5 percent of all cases of otitis media. The mortality rate of intracranial complications has decreased dramatically over the last century, from approximately 90 percent in the preantibiotic era to 10 percent now. However, significant morbidity still exists despite this improvement in survival. Diagnosis of an intracranial complication of otitis media relies heavily on an accurate history and a high index of suspicion. Important elements include determining whether the patient has acute or chronic otitis media, a prior history of otologic disease or surgery, a history of head trauma or temporal bone fracture, previous antibiotic treatment, and symptoms suggesting intracranial involvement such as headache, lethargy, visual changes, fever, and nausea or vomiting.[1]

The differential diagnosis for a patient with otitis media and symptoms and signs of intracranial involvement is long, and potential complications are numerous, including extradural abscesses or granulation tissue, dural venous sinus thrombosis, petrous apicitis (Gradenigo syndrome; Fig. 23-1), intraparenchymal brain abscesses, subdural abscesses, otitic hydrocephalus, and meningitis (most commonly purulent).[1]

The microbiology of the intracranial complications of otitis media varies with the duration of otitis as well as the type of complication. Complications of acute otitis media usually are secondary to *Streptococcus pneumoniae* or *Haemophilus influenzae*. Chronic otitis media frequently leads to complications with gram-negative bacteria, such as *Pseudomonas aeruginosa*, or anaerobes.[1] The most common organisms implicated in otitic meningitis include *S. pneumoniae*, *H. influenzae*, *Proteus* species, *P. aeruginosa*, and *Staphylococcus aureus*. Brain abscesses are typically polymicrobial.

If an intracranial complication is suspected on the basis of the history or physical findings, further evaluation should include computerized tomography (CT) of the temporal bones to evaluate for bony erosion, congenital malformation, or fracture; contrast-enhanced magnetic resonance imaging (MRI) or CT of the head to evaluate for enhancement of the meninges, dural sinus thrombosis (Fig. 23-2), or brain

abscess; and a lumbar puncture if no mass effect is visualized on imaging.[1] The cerebrospinal fluid (CSF) will typically show increased protein and decreased glucose concentrations along with organisms on Gram stain in bacterial meningitis; those patients given antibiotics in the days or weeks preceding the spinal tap may have more normal-appearing CSF chemistries and a negative Gram stain, but should be treated with antibiotics until cultures are negative, given the possibility of a partially treated bacterial meningitis. In otitic hydrocephalus, the opening pressure will be increased, but the other studies will be normal.

Treatment of the intracranial complications of otitis media includes medical stabilization and usually requires inpatient admission. Broad-spectrum intravenous antibiotics should be initiated empirically. Surgical consultation with an otolaryngologist or neurosurgeon should be obtained to assess for drainage of the primary source and address intracranial complications that warrant such procedures (such as intracranial abscess). Complications due to acute otitis media may be treated with a second- or third-generation cephalosporin to target the usual three pathogens: *H. influenzae*, *Moraxella catarrhalis*, and *S. pneumoniae*. Gram-negative and anaerobic coverage should be added for complications of chronic otitis media. Corticosteroids such as dexamethasone should be administered concurrently with intravenous antibiotics for otogenic meningitis in order to reduce the chance of sensorineural hearing loss and, in meningitis caused by *S. pneumoniae*, to reduce mortality.[1]

Labyrinthine Disorders

Meniere disease and benign paroxysmal positional vertigo are two of the most common labyrinthine disorders that cause vertigo and dysequilibrium. The pathologic correlate of Meniere disease is endolymphatic hydrops, which is usually idiopathic but may occur following inner ear trauma or infection. Patients with Meniere disease typically experience episodes of unilateral tinnitus, unilateral hearing loss, unilateral ear fullness, and vertigo lasting for minutes to hours. They do not typically experience neurologic symptoms that cannot be attributable directly to the inner ear.[2] However, some patients experience visual changes, especially blurred vision, during attacks of Meniere disease, and headaches may occur. Other patients become anxious during attacks and may experience numbness and paresthesias. The first attack of Meniere disease often prompts an evaluation in an emergency department, leading to brain imaging to exclude cerebellar hemorrhage or infarction. First-line treatment of Meniere disease consists of sodium restriction and a diuretic, typically a combination of hydrochlorothiazide and triamterene. Nonablative procedures, such as intratympanic steroid infusion, and ablative procedures, such as intratympanic gentamicin or labyrinthectomy, are options for patients who do not respond to conservative management.[3]

Benign paroxysmal positional vertigo is caused by free-floating otolithic debris in the posterior semicircular canal. As with Meniere disease, benign paroxysmal positional vertigo may follow inner ear trauma or infections but usually is idiopathic. Patients typically have positionally induced vertigo when rolling over in bed or looking up.[4] The vertigo typically lasts for less than 1 minute but more generalized symptoms of dizziness and dysequilibrium may persist for several hours. Neurologic symptoms other than vertigo and transitory visual difficulties are generally absent, although patients may have difficulty in walking due to their vertigo. On physical examination, the findings on Dix–Hallpike maneuvers, illustrated in Fig. 23-3, are diagnostic. Treatment consists of a particle repositioning maneuver (Fig. 23-4), which is highly successful and can be taught to the patient for use in future attacks. Despite the “benign” nature of benign paroxysmal positional vertigo, the initial episode often leads to emergency medical care. Since several nonbenign conditions, such as posterior fossa tumors, may present with positional dizziness, a thorough neurologic evaluation of all patients with positional vertigo is warranted.

Eighth Nerve Lesions

Eighth nerve lesions leading to neurologic manifestations include auditory neuropathy and vestibular neuronitis. Auditory neuropathy is a disorder of dysfunction or dyssynchrony of the inner hair cells or cochlear nerve, leading to hearing loss and impaired speech discrimination with intact outer hair cell function.[5] Risk factors for auditory neuropathy include prematurity, hyperbilirubinemia, and exposure to ototoxic medications, although genetic factors have also been implicated. This type of hearing loss can be associated with other neurologic diseases and may be seen in up to 11 percent of children with sensorineural hearing loss.

Vestibular neuronitis is an idiopathic inflammation of the vestibular portion of the eighth cranial nerve leading to acute symptoms of vertigo, nystagmus, nausea, and vomiting. Acute symptoms persist for several days and are often preceded by viral illness. In some patients, mild symptoms can last for weeks or months. Unilateral reduction in vestibular response is seen on caloric testing or vestibular evoked myogenic potentials. Possible etiologies include viral infection, immunologic causes, or vascular occlusion. The superior or inferior vestibular nerve, or both, may be involved.

Cerebellopontine Angle Disorders

Cerebellopontine angle masses may cause hearing loss, tinnitus, and vertigo. The most common type of mass found in this location is a vestibular schwannoma, commonly referred to as an acoustic neuroma. Symptoms are typically of insidious onset, but sudden hearing loss or vertigo may occur. Additionally, facial numbness may be seen with large tumors due to compression of the trigeminal nerve. Facial nerve dysfunction from vestibular schwannoma is uncommon. Without treatment, lower cranial nerve involvement and brainstem compression may eventually occur (Fig. 23-5). MRI of the internal auditory canal is the typical modality used to identify these lesions. Acoustic neuromas are treated with surgical excision or stereotactic radiation; small tumors may be observed for evidence of growth. Other masses occurring in the cerebellopontine angle include meningiomas, epidermoid tumors, and metastases, which may cause similar symptoms, although the time scale of symptomatology is typically more rapid with metastatic lesions in this area.

Superior Semicircular Canal Dehiscence Syndrome

Superior semicircular canal dehiscence syndrome was first recognized in 1998 as a cause of vertigo.[6] The

FIGURE 23-3 ■ Dix–Hallpike Maneuver. The Dix–Hallpike test of a patient with benign paroxysmal positional vertigo affecting the right ear. *A*, The examiner stands at the patient's right side and rotates the patient's head 45 degrees to the right to align the right posterior semicircular canal with the sagittal plane of the body. *B*, The examiner moves the patient, whose eyes are open, from the seated to the supine right-ear-down position and then extends the patient's neck so that the chin is pointed slightly upward. The latency, duration, and direction of nystagmus, if present, and the latency and duration of vertigo, if present, should be noted. The arrows in the inset depict the direction of nystagmus in patients with typical benign paroxysmal positional vertigo. The presumed location in the labyrinth of the free-floating debris thought to cause the disorder is also shown. (From Furman JM, Cass SPC: Benign paroxysmal positional vertigo. N Engl J Med 341:1590, 1999, with permission.)

disorder is caused by a defect in the bone over the superior semicircular canal, which renders the canal sound sensitive. Symptoms of superior semicircular canal dehiscence syndrome include vertigo induced by sound or pressure (such as during a Valsalva maneuver), hearing loss, and autophony. Systemic neurologic symptoms are absent. Noncontrast CT scan of the temporal bone demonstrates the absence of bone over the superior semicircular canal. Treatment consists of surgically plugging the superior canal in patients with bothersome vestibular symptoms (Fig. 23-6).

Central Vestibular Disorders

The most common central vestibular disorders include vestibular migraine, vascular disease affecting

FIGURE 23-4 ■ Particle repositioning maneuver for the bedside treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of the debris within the labyrinth during the maneuver is shown in each panel. The maneuver is a three-step procedure. First, a Dix–Hallpike test is performed with the patient's head rotated 45 degrees toward the right ear and the neck slightly extended with the chin pointed slightly upward. This position results in the patient's head hanging to the right, *A*. Once the vertigo and nystagmus provoked by the Dix–Hallpike test cease, the patient's head is rotated about the rostral-caudal body axis until the left ear is down, *B*. Then the head and body are further rotated until the head is face down, *C*. The vertex of the head is kept tilted downward throughout the rotation. The maneuver usually provokes brief vertigo. The patient should be kept in the final, face-down position for about 10 to 15 sec. With the head kept turned toward the left shoulder, the patient is brought into the seated position, *D*. Once the patient is upright, the head is tilted so that the chin is pointed slightly downward. (From Furman JM, Cass SPC: Benign paroxysmal positional vertigo. N Engl J Med 341:1590, 1999, with permission.)

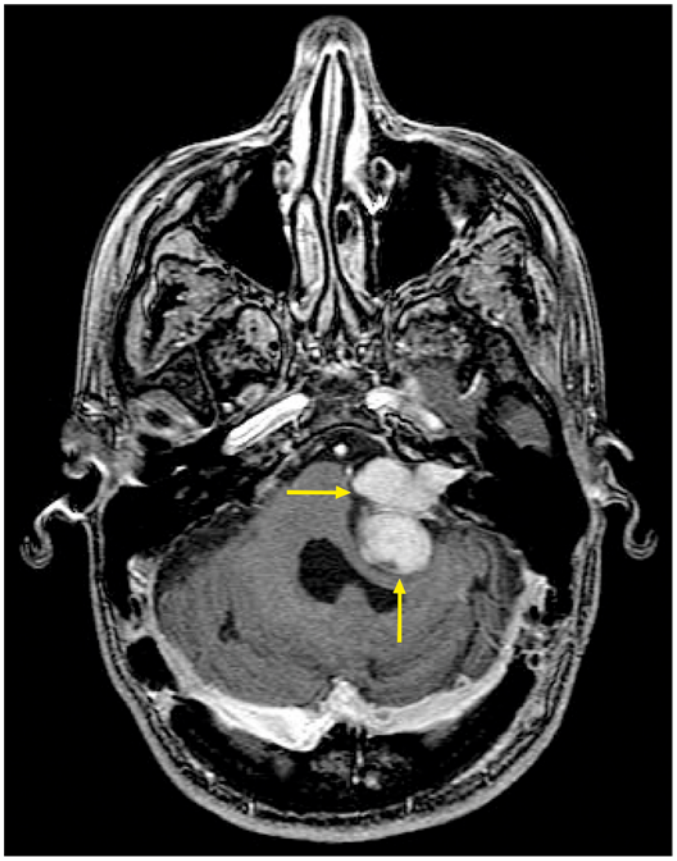

FIGURE 23-5 ■ Magnetic resonance imaging (MRI) of a large acoustic neuroma with brainstem compression. Axial contrast-enhanced T1-weighted MRI reveals a large, lobulated, enhancing mass (*arrows*) filling the left cerebellopontine angle, with compression of the pons and thinning of the brachium pontis. The patient was known to have neurofibromatosis type 2, and this lesion is most likely a schwannoma of the eighth cranial nerve. (Courtesy of Barton F. Branstetter, MD, University of Pittsburgh.)

the brainstem and cerebellar vestibular pathways, cerebellar degeneration, and Chiari malformation. Vestibular migraine, which can be considered a migraine variant, affects women more often than men, particularly women in their childbearing years. As with migraine headache, it is a diagnosis of exclusion, since there are no pathognomonic tests for this condition. Diagnostic criteria consist of a combination of the International Headache Society criteria for migraine headache and criteria developed specifically for vestibular migraine.[7] Establishing a diagnosis of vestibular migraine requires a temporal association between dizziness and either migraine headache or typical migrainous symptoms and the absence of another diagnosis that can account for the dizziness. The pathophysiology is uncertain but is likely to be related to serotonin effects on central vestibular structures. Treatment is similar to the treatment for migraine headache and includes both decreasing triggers for migraine and use of pharmacotherapy. For patients with frequent (greater than one per week) episodes of vestibular migraine, prophylactic medications are indicated to reduce the frequency and severity of attacks and include antidepressants, β-blockers, anticonvulsants, and calcium-channel blockers. Some patients may benefit from triptans for acute attacks.

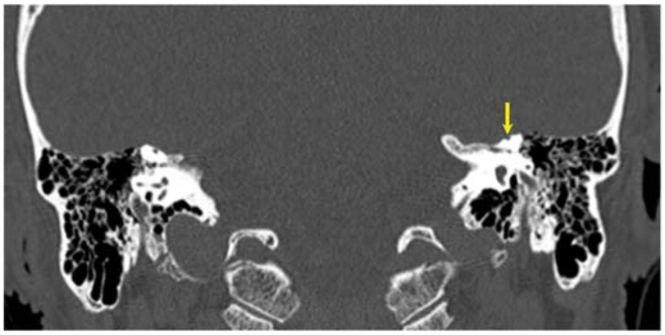

FIGURE 23-6 ■ Coronal CT scan through the level of the temporal bone demonstrating superior canal dehiscence. Arrow points to the left superior semicircular canal dehiscence. The membranous superior semicircular canal (seen in cross section) is in contact with the overlying contents of the middle cranial fossa. Compare this with the right side, where a very thin plate of bone is separating the superior semicircular canal from the middle cranial fossa. (Courtesy of Andrew A. McCall, MD, University of Pittsburgh.)

Central vestibular structures in the brainstem and cerebellum are supplied by the posterior inferior cerebellar artery and the anterior inferior cerebellar artery. Infarction of the lateral medulla in the territory of the posterior inferior cerebellar artery leads to a Wallenberg syndrome, wherein one of two vestibular nuclear complexes is damaged, leading to central vestibular imbalance. Accompanying symptoms are caused by involvement of the ascending spinothalamic tract and descending sympathetic tracts. Patients with Wallenberg syndrome may experience lateropulsion (i.e., a sense of being pushed or pulled to one side). Infarction in the territory of the anterior inferior cerebellar artery leads to a similar syndrome but may also include the presence of unilateral hearing loss resulting from cochlear ischemia because the internal auditory artery arises from the anterior inferior cerebellar artery.

Another condition to be considered in patients with acute vertigo and accompanying neurologic disturbances referable to the brainstem and cerebellum is that of cerebellar hemorrhage or infarction with concomitant brainstem compression. This condition represents a neurosurgical emergency. Brain imaging provides definitive diagnostic information.

Vertebrobasilar insufficiency may present with various neurologic symptoms including vertigo and changes in hearing as well as symptoms referable to posterior fossa structures, such as changes in vision, sensation, strength, or level of consciousness. Symptoms typically last for minutes. Isolated vertigo is rarely a result of vertebrobasilar insufficiency. Diagnostic imaging such as MR or CT angiography is helpful in establishing a diagnosis of vertebrobasilar insufficiency in the context of appropriate symptoms. Treatment with antiplatelet agents and management of risk factors for cardiovascular disease are warranted for most cases; endovascular treatment with angioplasty, stenting, or both, is rarely employed.

Cerebellar degeneration can be associated with dizziness and dysequilibrium. Some types of cerebellar degeneration (particularly spinocerebellar ataxia type 6) can also be associated with episodic features including episodic vertigo and dysequilibrium. In association with such symptoms, patients with cerebellar degeneration often demonstrate limb ataxia and sometimes long-tract signs. Chiari malformations sometimes present with "dizziness" and dysequilibrium. Physical examination may disclose downbeating nystagmus (i.e., vertical nystagmus with a downward fast component), which may reflect a central vestibular imbalance. Additionally, patients with a Chiari malformation often have nonvestibular symptoms such as dysphagia and long-tract signs. A diagnosis of a Chiari malformation can be confirmed by sagittal MRI (Fig. 23-7). Treatment is surgical and involves suboccipital craniotomy.

Central Auditory Processing Disorder

Central auditory processing disorder, as its name implies, is characterized by defects in higher-level processing of auditory information in the setting of normal hearing as measured by conventional audiometry. This disorder leads to difficulty in understanding oral communication, particularly when there is background noise, and can be associated with attention deficit–hyperactivity disorder, learning disabilities, head trauma, and other neurologic disorders. Psychoacoustic testing often identifies specific deficits that correlate with patients' symptoms.[8] Treatment consists of improving the signal-to-noise ratio by reduction of background noise or use of FM systems, as well as auditory training.[9]

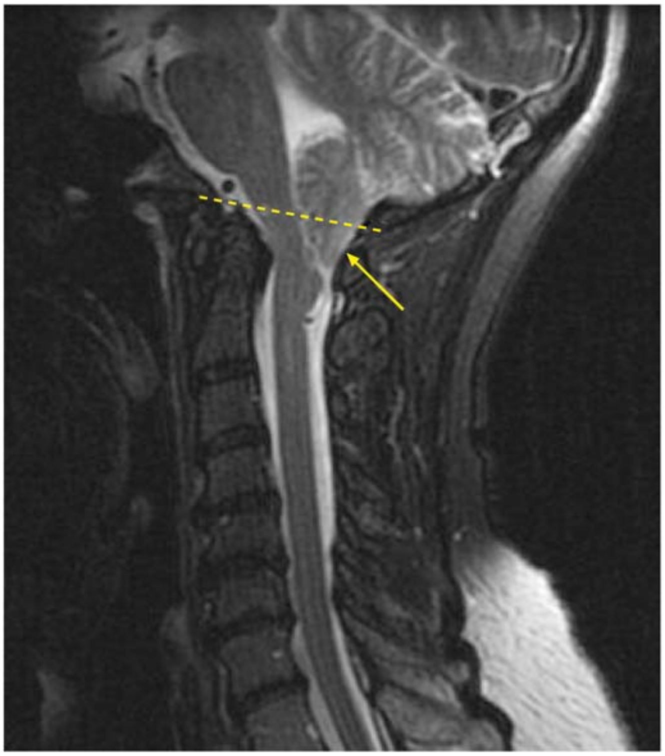

FIGURE 23-7 ■ Chiari malformation. Sagittal T2-weighted MRI through the cranio-cervical junction shows the cerebellar tonsils (*solid arrow*) extending far below the foramen magnum (*dashed line*). The medulla is compressed. (Courtesy of Barton F. Branstetter, MD, University of Pittsburgh.)

OTONEUROLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE

Infection

Many infections can cause otoneurologic symptoms and signs. Viral infection, in particular herpes simplex virus, has been implicated in Bell palsy. Fig. 23-8 shows herpes simplex virus type 1 particles seen by electron microscopy in the geniculate ganglion of

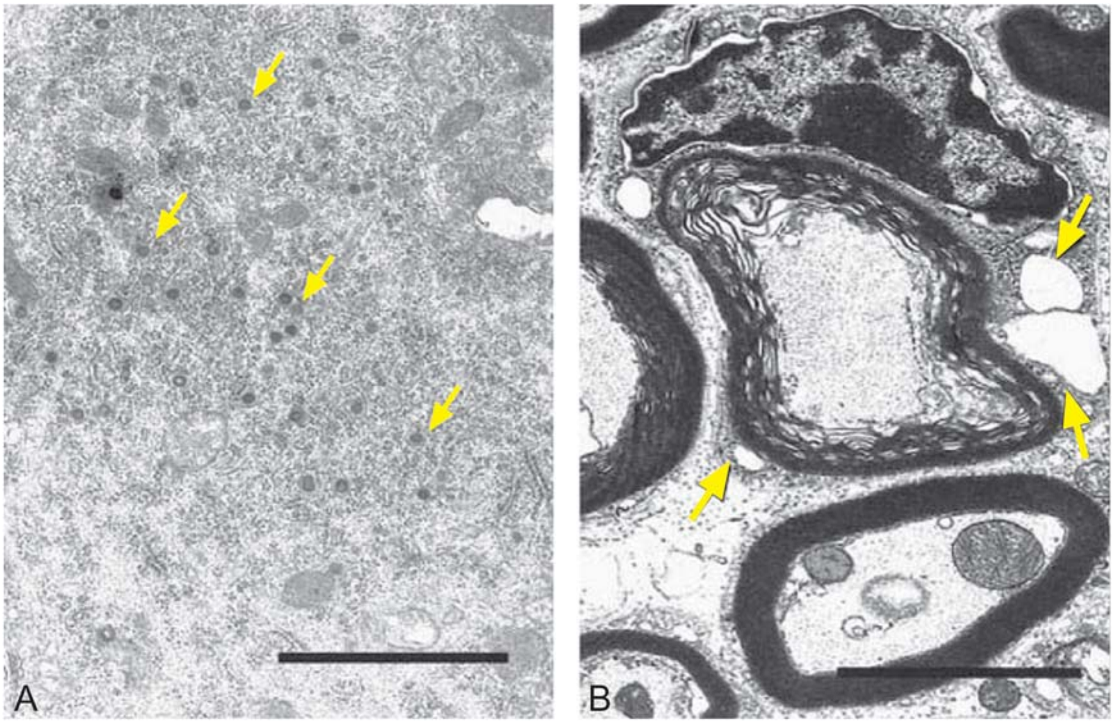

FIGURE 23-8 ■ Herpes simplex virus (HSV) in a mouse model of Bell palsy. *A*, The intratemporal portion of the facial nerve from the paralyzed side showing a neuron in the geniculate ganglion. Replicating HSV-1 viruses in the rough endoplasmic reticulum of a neuron in the geniculate ganglion are indicated by the arrows. *B*, The geniculate portion of the facial motor nerve. Arrows indicate vacuolar changes in the cytoplasm of a Schwann cell which resulted in demyelination. Scale bars: *A*, 1 μm; *B*, 5 μm. (From Takahashi H, Hitsumoto Y, Honda N, et al: Mouse model of Bell's palsy induced by reactivation of herpes simplex virus type 1. J Neuropathol Exp Neurol 60:621, 2001, with permission.)

mice with experimentally induced Bell palsy. Corticosteroids are used for treatment. Viral infection is also thought to play a role in idiopathic sudden sensorineural hearing loss and vestibular neuronitis. Mumps, measles, and congenital rubella infection may cause significant hearing loss.

Another member of the herpes virus family, varicella-zoster virus, causes herpes zoster oticus, often referred to as Ramsay Hunt syndrome. This syndrome, from reactivation of varicella-zoster virus in the geniculate ganglion, is characterized by facial weakness associated with vesicular lesions in the external auditory canal and auricle. The symptoms are typically preceded by otalgia. Sensorineural hearing loss and vertigo are sometimes present. Investigators have postulated that the reactivation of varicella-zoster virus may occur in the vestibular and spiral ganglia as well. Ramsay Hunt syndrome may involve other cranial nerves; polymerase chain reaction has localized viral material to the CSF in some cases. MRI typically reveals enhancement of the geniculate ganglion on the affected side. Treatment is with antiviral agents and corticosteroids. The facial palsy associated with Ramsay Hunt syndrome has a poorer prognosis than that of Bell palsy.[10]

Otosyphilis was first described in 1887 by Politzer. Following the introduction of penicillin, it became rare. However, with the emergence of human immunodeficiency virus (HIV) infection, syphilis has experienced a resurgence in the United States and Western Europe. Otoneurologic manifestations may occur in secondary, tertiary, or congenital syphilis. Sensorineural hearing loss and hydropic symptoms of episodic tinnitus and vertigo may occur. Treatment is with penicillin G and corticosteroids.

Lyme disease may cause sudden sensorineural hearing loss or facial palsy. Vertigo is uncommon but has been reported. The mainstay of treatment is antibiotics, most typically doxycycline.

Tuberculosis may affect the ear. As with syphilis, tuberculosis has become increasingly common in patients with HIV infection. Tuberculous otitis media remains rare. The classic description of mycobacterial otitis media is of chronic otorrhea and multiple perforations of the tympanic membrane. Polyps and granulation tissue may also be seen. Treatment is primarily medical, with surgery reserved for complications.

HIV infection and immunodeficiency may cause otologic symptoms. Otitis externa may be caused by common pathogens such as *P. aeruginosa*; however, opportunistic infections such as *Pneumocystis* species may also be responsible in these populations. There are also reports of malignant otitis externa (i.e., skull base osteomyelitis secondary to otitis externa) in individuals with HIV infection, although some authors note that the incidence of malignant otitis externa is not increased in the HIV-infected population as a whole. Children with HIV infection often suffer from chronic otitis media. Serous otitis media may result from eustachian tube obstruction secondary to adenoid hypertrophy. Sensorineural hearing loss occurs in 21 to 49 percent of HIV-positive patients and is thought to be multifactorial. Possible causes include secondary infection, central nervous system (CNS) involvement, and ototoxicity. Finally, facial palsy is more common in HIV-positive patients.

Immune-Mediated and Connective Tissue Disease

There are a number of autoimmune and connective tissue disorders that cause otoneurologic symptoms, ranging from otitis media to hearing loss or vertigo.

Granulomatosis with polyangiitis (GPA; previously Wegener granulomatosis) is characterized by vasculitis of medium-sized and small vessels, as well as by necrotizing granulomas of the upper and lower respiratory tract. Up to 70 percent of patients with this disorder experience otologic symptoms. The most common otoneurologic manifestation of GPA is serous otitis media. The middle ear space can be affected by granulomas, leading to a clinical picture resembling chronic suppurative otitis media (Fig. 23-9). Facial palsy may also result, from either vasculitis or direct involvement of the facial nerve by the granulomatous process. Sensorineural hearing loss occurs in 8 percent of patients and is sometimes rapidly progressive. Vertigo is uncommon. GPA is diagnosed by the presence of cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA) and by the combination of necrotizing granulomas and vasculitis seen on histopathology. Treatment is with high-dose corticosteroids and immunosuppressive agents.

Sarcoidosis is an immune-mediated disease of unknown etiology characterized by hilar adenopathy, pulmonary infiltrates, peripheral lymphadenopathy, and cutaneous and splenic involvement that can involve the CNS. The characteristic histopathologic finding is of noncaseating granulomas, although they are nonspecific. The most common otoneurologic manifestation of sarcoidosis is facial palsy, which may be unilateral or bilateral and can be associated with parotiditis, fever, and uveitis (uveoparotid fever or Heerfordt disease). Multiple cranial nerve palsies are common in neurosarcoidosis, occurring in approximately 5 percent of patients with sarcoidosis due to involvement of the meninges of the skull base. Hearing loss and vertigo are less common symptoms. The presentation of hearing loss is variable, ranging from mild to severe, and may be unilateral or bilateral. Vestibular testing may be abnormal. Auditory and vestibular symptoms are thought to reflect involvement of the eighth cranial nerve by neurosarcoidosis rather than a direct effect on the inner ear end organs. Contrast-enhanced MRI may show enhancement of the basal leptomeninges; intracranial mass lesions can also be seen.

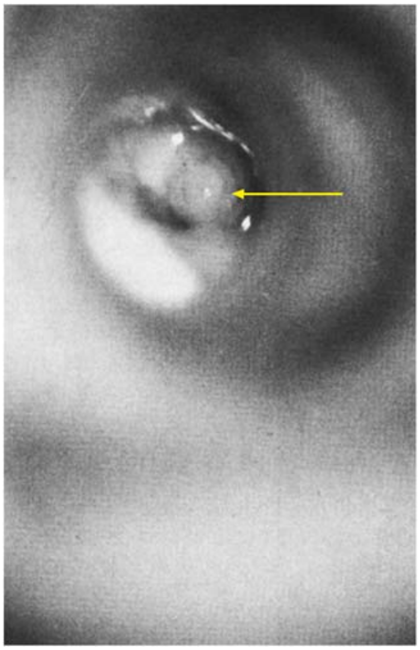

FIGURE 23-9 ■ Chronic otitis media in granulomatosis with polyangiitis. Granulomatous swelling of the posterior part of the left eardrum viewed through an otomicroscope (*arrow*). The large white area inferior and to the left of the eardrum is the anterior wall of the external ear canal. (From Rasmussen N: Ear, nose and throat manifestations in c-ANCA positive vasculitides. Ann Med Interne 143:401–404 1992.)

Systemic lupus erythematosus may cause sensorineural hearing loss that is unilateral or bilateral in 8 to 31 percent of patients and can be rapidly progressive.[11] The hearing loss appears to be associated with elevated anticardiolipin antibodies but not with ANA titer and frequently improves with treatment.[11] Vestibular symptoms are less common.

Other immune-mediated diseases causing otologic symptoms include polyarteritis nodosa, Cogan syndrome, Behçet syndrome, relapsing polychondritis, Sjögren syndrome, and Churg–Strauss syndrome. Polyarteritis nodosa, a small-vessel vasculitis, may cause sudden sensorineural hearing loss. Cogan syndrome is characterized by sudden or rapidly progressive sensorineural hearing loss, vestibular dysfunction, and interstitial keratitis, mimicking syphilis, or Meniere disease. Symptoms often respond to treatment with corticosteroids. Behçet syndrome may cause hearing loss, tinnitus, and vertigo. Relapsing polychondritis typically involves the cartilage of the external ear and nose; however, as the disease progresses, hearing loss and vertigo sometimes develop. The disorder is discussed further in Chapter 22. High-frequency hearing loss may also be seen in 25 percent of patients with Sjögren syndrome. Churg–Strauss syndrome causes hearing loss in rare instances.[11]

Autoimmune hearing loss also may occur in the absence of systemic illness. It is characterized by fluctuating or rapidly progressive bilateral sensorineural hearing loss that is responsive to immunosuppressive therapy.

Neurocutaneous Syndromes

The most common neurocutaneous syndrome causing otoneurologic symptoms is neurofibromatosis type II (NF2), which is discussed in detail in Chapter 21. This disease is characterized by bilateral vestibular schwannomas, eventually causing bilateral deafness and vestibular dysfunction. Other features of neurofibromatosis type II can include meningiomas, ependymomas, gliomas, and juvenile posterior subcapsular lens opacities.[12] Otologic manifestations consist of progressive hearing loss that may be unilateral or bilateral, tinnitus, vestibular dysfunction, and facial weakness. Genetic testing is available to detect mutations in the neurofibromin 2 (*merlin*) tumor suppressor gene.[12] Auditory rehabilitation of affected patients is complex owing to the presence of bilateral acoustic neuroma; auditory brainstem implants have been used in this population with fair results.

Metabolic and Endocrine Disorders

Certain metabolic or endocrine disorders are known to contribute to hearing loss. Diabetes mellitus has been linked to hearing loss, perhaps secondary to microangiopathy and neuropathy. A small subset of diabetic patients has been found to have a mitochondrial mutation causing both hearing loss and diabetes, termed maternally inherited diabetes and deafness (MIDD).[13] The same mitochondrial mutation responsible for MIDD can also result in mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS). Diabetic patients frequently suffer from "dizziness" and imbalance, and peripheral neuropathy, autonomic dysfunction, and peripheral vestibular deficits all probably play a role in etiology.

Renal failure in the absence of diabetes is also associated with high-frequency hearing loss. Alport syndrome is characterized by congenital hearing loss and renal failure. Neonatal jaundice may cause sensorineural hearing loss. Hyperlipidemia has also been associated with fluctuating hearing loss and vestibular dysfunction.

An association between thyroid disease and otologic symptoms exists. Vertigo and hearing loss have been described in the setting of hypothyroidism. Pendred syndrome is characterized by congenital hearing loss, reduced vestibular responses, and goiter. In a study of 42 kindreds, resistance to thyroid hormone was found to be associated with hearing loss in 21 percent of individuals.

Certain mucopolysaccharidoses are associated with hearing loss, and many forms predispose to otitis media. The Hurler and Hunter forms (MPS I and II) cause sensorineural hearing loss. The mechanism of loss is unclear and may involve deposition of glycosaminoglycans in the cochlea.

Diseases of Bone

Several disorders of bone, discussed in Chapter 22, lead to otoneurologic manifestations, most notably hearing loss. These include osteogenesis imperfecta, Paget disease, fibrous dysplasia, and osteopetrosis.

Osteogenesis imperfecta is usually an autosomal-dominant disease caused mainly by mutations in the *COL1A1* or *COL1A2* genes, which code for type 1 collagen. The disorder is characterized by fragility of bones, hearing loss, and blue sclera. Eight major types are currently described; hearing loss is most

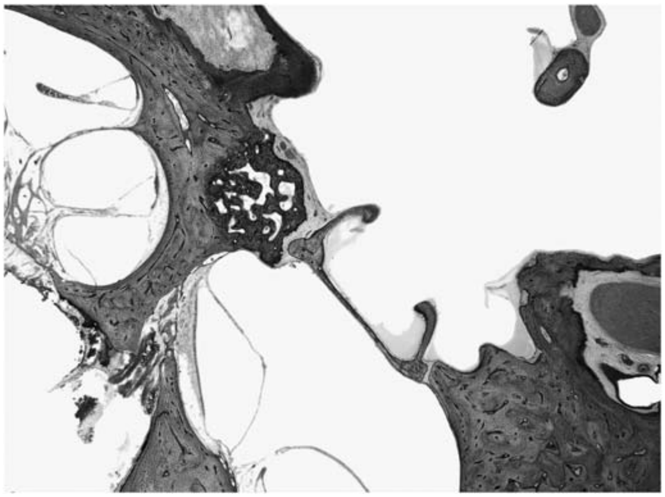

FIGURE 23-10 ■ Osteogenesis imperfecta of the temporal bone. Histologic section of the right temporal bone from a patient with osteogenesis imperfecta, showing an otosclerotic lesion anterior to the oval window. (From Santos F, McCall A, Chein W, et al: Otopathology in osteogenesis imperfecta. Otol Neurotol 33:1562, 2012, with permission.)

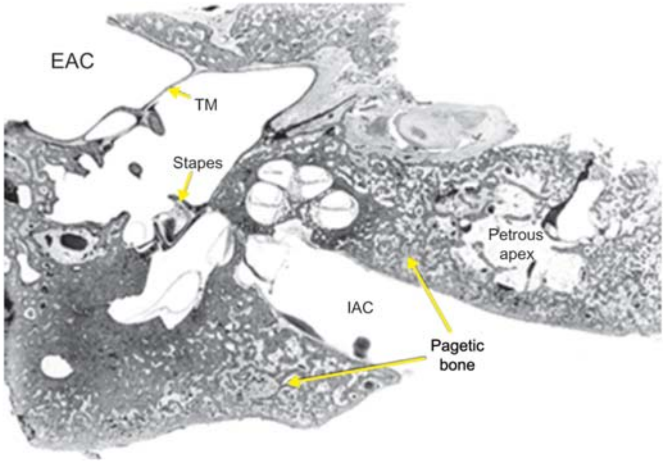

FIGURE 23-11 ■ Paget disease of the temporal bone. Histologic section through the left temporal bone showing pagetic bone surrounding the internal auditory canal. (From Bahmad F Jr, Merchant SN: Paget disease of the temporal bone. Otol Neurotol 28:1157, 2007, with permission.)

common in types IA and IB. Hearing loss occurs in 23 to 58 percent of patients with osteogenesis imperfecta and typically presents in the second or third decade.[14] Histologic examination of temporal bones from individuals with type I osteogenesis imperfecta demonstrates otosclerosis-like lesions (Fig. 23-10). The hearing loss typically begins as a conductive loss and progresses to become mixed or largely sensorineural in nature; both ears are eventually affected. Hearing loss may be treated with amplification or stapedectomy. Tinnitus and vertigo are also common in osteogenesis imperfecta, particularly in those patients with sensorineural hearing loss. Vertigo is typically mild, triggered by head movements or position change, and brief in duration. Abnormalities are frequently seen on electronystagmography but do not necessarily correlate with subjective vertigo.

Paget disease is caused by increased bone absorption and repair, leading to an overall increase in the amount of bone. There are monostotic and polyostotic forms. Hearing loss is common in Paget disease and is usually mixed conductive and sensorineural. Conductive hearing loss may be caused by ossicular fixation or obliteration of the oval or round window. Bony changes in the cochlea may also contribute. Involvement of the petrous portion of the temporal bone may alter the shape of the internal auditory canal, potentially impairing the function of the eighth cranial nerve. Histologically, Paget disease is characterized by disordered lamellar bone (Fig. 23-11). CT may reveal demineralization of the temporal bone. Treatment is with bisphosphonates and calcitonin, which may prevent further hearing loss.

Fibrous dysplasia, like Paget disease, also has monostotic and polyostotic forms. In its polyostotic form it can also be associated with café-au-lait spots on the skin and endocrinopathies in a syndrome designated McCune–Albright syndrome. McCune–Albright syndrome is nonfamilial but usually caused by mutations in the *GNAS* gene, which codes for a second messenger G protein. The disease is characterized by expansile bony lesions (Fig. 23-12). Involvement of the temporal bone can cause narrowing of the external auditory canal, resulting in conductive hearing loss. A lesser percentage of patients will manifest sensorineural hearing loss, labyrinthitis, dizziness, or facial weakness.[15] Treatment is with bisphosphonates or surgical resection. Irradiation increases the risk of malignant transformation and is not indicated.

Osteopetrosis is characterized by decreased osteoclastic activity, leading to constriction of various skull base foramina. Hearing loss, vertigo, and facial palsy or spasm may develop secondary to compression. Eustachian tube dysfunction and middle ear effusions may be seen. Treatment is with vitamin D (calcitriol), prednisone, and interferon-gamma.

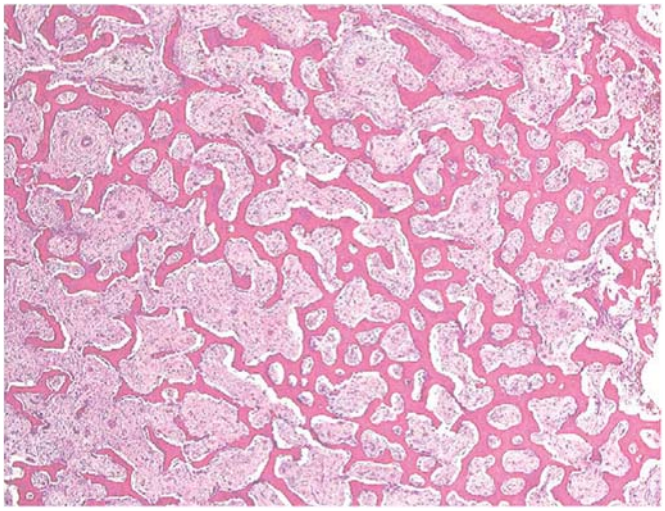

FIGURE 23-12 ■ Histology of fibrous dysplasia. Note the irregular shapes of woven bone. (From Speight PM, Carlos R: Maxillofacial fibro-osseous lesions. Curr Diagn Pathol 12:1, 2006, with permission.)

Drug-Induced Disorders

There are numerous medications that exert ototoxic effects on the cochlea and labyrinth. The most commonly encountered ototoxic medications are chemotherapeutic agents, antibiotics, and loop diuretics. Cochlear ototoxicity is typically heralded by tinnitus or a sense of fullness in the ear; however, high-frequency hearing loss may also occur without the patient's knowledge. Hearing loss due to certain drugs, most notably salicylates and furosemide, can be reversible, whereas toxicity secondary to cisplatin and aminoglycosides is most often permanent. Vertigo and disequilibrium may result from vestibular toxicity; bobbing oscillopsia is a common symptom.[16] Conditions contributing to a higher risk for ototoxicity include renal insufficiency, hepatic insufficiency, elevated serum levels of medication, pre-existing hearing loss or vestibular dysfunction, use of multiple ototoxic medications or a previous history of ototoxic medication use, treatment for more than 14 days, prior exposure to noise, hypovolemia, bacteremia, fever, and age over 65 years.[16]

Ototoxicity leads to distinct histologic changes within the cochlea and labyrinth, and the histologic manifestations are typically either hair cell loss (Fig. 23-13) or changes in the stria vascularis.

Aminoglycoside antibiotics have been known to be ototoxic since the parenteral use of streptomycin for tuberculosis in the early twentieth century. Symptomatic hearing loss occurs in 2 to 14 percent of patients treated with aminoglycosides; however, high-frequency (10 to 20 kHz) audiometry reveals the incidence of hearing loss to be as high as 62 percent. Certain aminoglycosides, such as streptomycin and gentamicin, preferentially lead to vestibular toxicity but also cause cochlear toxicity. It is unclear whether elevated serum levels of antibiotic correlate with increased risk of toxicity. The pathogenesis is thought to involve generation of free radicals leading to apoptosis of hair cells. There is evidence that certain mitochondrial mutations cause increased susceptibility to the ototoxic effects of aminoglycosides. Other anti-infective agents reported to cause ototoxicity less frequently include vancomycin, macrolides, fluoroquinolones, tetracycline, antivirals, amphotericin, flucytosine, and antimalarials.

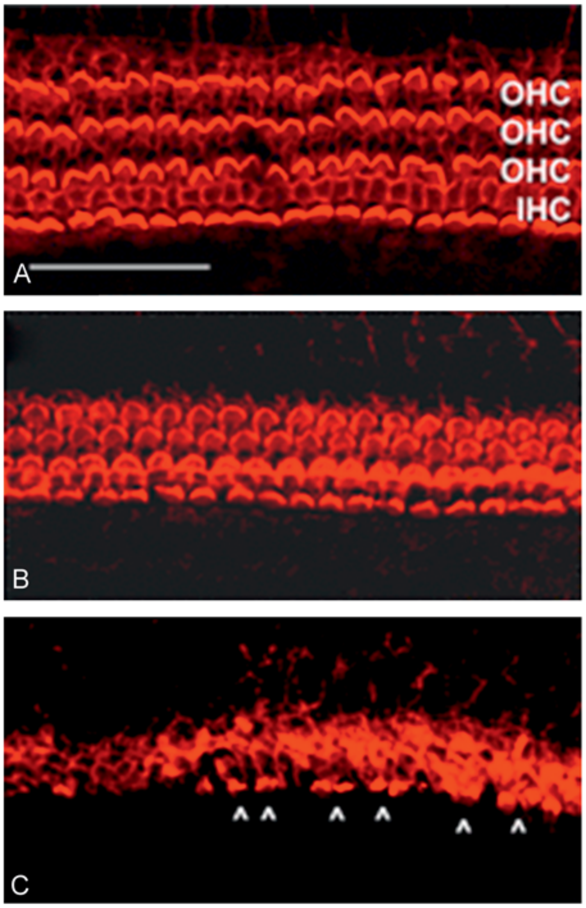

FIGURE 23-13 ■ Hair cell loss from gentamicin ototoxicity. *A* and *B* demonstrate a normal complement of inner (IHC) and outer hair cells (OHC) of the cochlea. *C* shows severe loss of outer hair cells and many inner hair cells after exposure to gentamicin (mouse cochlea). (From Matt T, Ng CL, Lang K, et al: Dissociation of antibacterial activity and aminoglycoside ototoxicity in the 4-monosubstituted 2-deoxystreptamine apramycin. Proc Natl Acad Sci USA 109:10988, 2012, with permission.)

Cisplatin is the chemotherapy agent most frequently associated with ototoxicity, with an incidence of 20 to 65 percent. Hearing loss initially manifests in the high frequencies and progressively worsens with continued administration. Tinnitus is a common presenting complaint. Ototoxicity appears related to the cumulative dose. Histologic findings in cisplatin ototoxicity include damage to the stria vascularis and hair cell loss. Ongoing studies are evaluating agents that may protect against cisplatin-induced ototoxicity. Owing to the high incidence of ototoxicity with aminoglycosides and cisplatin, patient monitoring with high-frequency audiometry and careful attention to symptoms is recommended for early diagnosis and management. Other ototoxic chemotherapeutic agents include carboplatin, oxiliplatin, vinca alkaloids, bexarotene, and taxanes.

Loop diuretics can cause hearing loss, tinnitus, and occasionally vertigo, perhaps because disturbances in the sodium and potassium concentrations in endolymph cause edema of the stria vascularis. Hearing loss is typically reversible and is usually seen with parenteral rather than oral administration of the offending medication. Bumetanide may be less ototoxic than furosemide or ethacrynic acid.

Salicylates can cause tinnitus and reversible hearing loss, although some cases of permanent hearing impairment have been reported following overdoses.

Environmental Disorders

Numerous types of environmental injury can result in otoneurologic symptoms. Noise exposure is well known to cause hearing loss. The typical audiometric configuration is a sensorineural hearing loss with a notched pattern around 4000 Hz. Both occupational and recreational exposure can cause significant loss. Some individuals appear more likely than others to sustain noise-induced loss. The best treatment of noise-induced hearing loss is prevention. Hearing protection with earplugs or earmuffs can decrease exposure to sound. Maximum allowable amount and duration of noise exposure are available through the Occupational Health and Safety Administration (OSHA). The National Institute of Occupational Safety and Health (NIOSH) also has guidelines on the amount and duration of exposure that are safe, but the levels differ between the two agencies.

Barotrauma may cause otologic injury through multiple mechanisms. The most common injury is perforation of the tympanic membrane. Barotrauma may also lead to conductive hearing loss from fracture or dislocation of the ossicles. Rarely, facial nerve paresis can result. Inner ear barotrauma can manifest as a perilymphatic fistula, manifest by hearing loss, vertigo, nausea, and vomiting following exposure to increased atmospheric pressure. Inner ear decompression sickness causes similar symptoms, usually manifesting itself after surfacing from a dive. The prognosis for recovery is good for inner ear barotrauma, but progressive damage to the cochlear and vestibular organs often occurs following inner ear decompression sickness.

Lightning strikes have also been documented to have otoneurologic sequelae. Lightning may produce injury either through a direct strike or over telephone lines. Hearing loss, tinnitus, tympanic membrane perforation, facial palsy, and vertigo have been reported. Hearing loss is nonprogressive and may have a mixed conductive and sensorineural pattern.

Blast injuries to the ear may lead to tympanic membrane rupture and resulting conductive hearing loss. Sensorineural hearing loss is also common and appears to occur via a different mechanism from noise-induced hearing loss, as the audiometric pattern lacks a notch at 4000 Hz. Tinnitus can result from blast injury and may be particularly noticeable in that disorder because of its sudden onset.[17] Balance disorders can also manifest following blast and mild traumatic brain injury.

Severe thermal injury to the ear may result from slag burns from welding. Often nonhealing perforations of the tympanic membrane are seen. Facial paralysis, sensorineural hearing loss, and vertigo have also been reported.

Nutritional Disease

Wernicke encephalopathy, which results from hypovitaminosis B_1 (thiamine), manifests with ataxia, abnormal eye movements, and mental status change. Vestibular laboratory testing of patients with Wernicke encephalopathy typically indicates bilaterally reduced vestibular responses and abnormal central vestibular processing. Treatment is by replacement of thiamine, which usually corrects the abnormal eye movements and ataxia. Vestibular function remains abnormal.

Neoplastic Disease

The temporal bone is affected by primary malignancies as well as metastatic disease. Primary tumors may

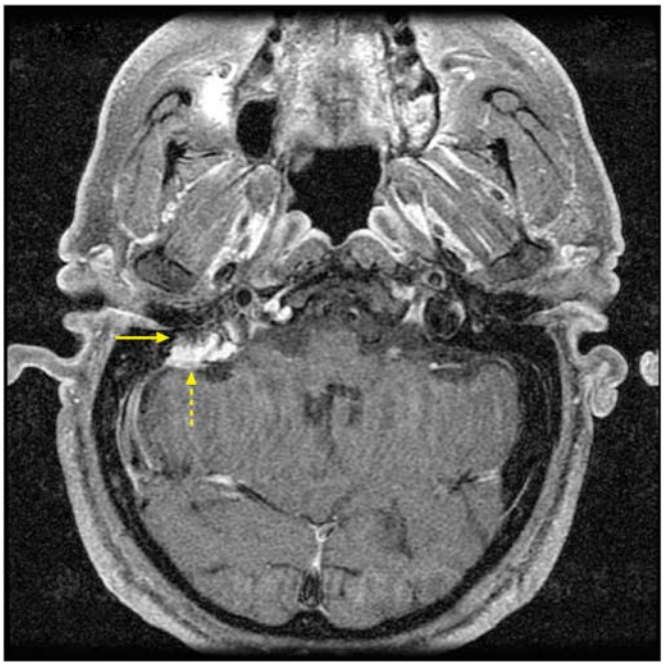

FIGURE 23-14 ■ MRI of endolymphatic sac tumor. Axial contrast-enhanced T1-weighted MRI demonstrates an irregular, enhancing mass along the posterior border of the petrous apex, at the expected location of the endolymphatic sac (*dashed arrow*). The mass erodes into the underlying temporal bone (*solid arrow*). (Courtesy of Barton F. Branstetter, MD, University of Pittsburgh.)

originate in the external ear, middle ear and mastoid, or inner ear structures. Squamous cell carcinoma and basal cell carcinoma can arise from the auricle and external auditory canal or they may spread from adjacent sites. Pain is a common complaint, although hearing loss and facial weakness may also occur.[18] Rhabdomyosarcoma may originate in the temporal bone in children. Endolymphatic sac tumors occur both sporadically and associated with von Hippel–Lindau disease (Fig. 23-14). Symptoms arise from local extension of the tumor and may include pain, hearing loss, and, less commonly, vertigo. Cancers of the breast, kidney, lung, stomach, thyroid gland, and prostate all may metastasize to the temporal bone.[18]

NEURO-OTOLOGIC MANIFESTATIONS OF AGING

Dysequilibrium of Aging

Dysequilibrium of aging refers to a loss of balance in association with advanced age in individuals who have no other known etiology for their balance disturbance. Patients with dysequilibrium of aging are generally in their seventies and demonstrate white matter disease on MRI including periventricular and subcortical white matter disease (Fig. 23-15) that may relate to microvascular ischemic changes. Treatment consists of managing risk factors for cerebrovascular disease and balance therapy. Vestibular-suppressant medications should be discontinued.

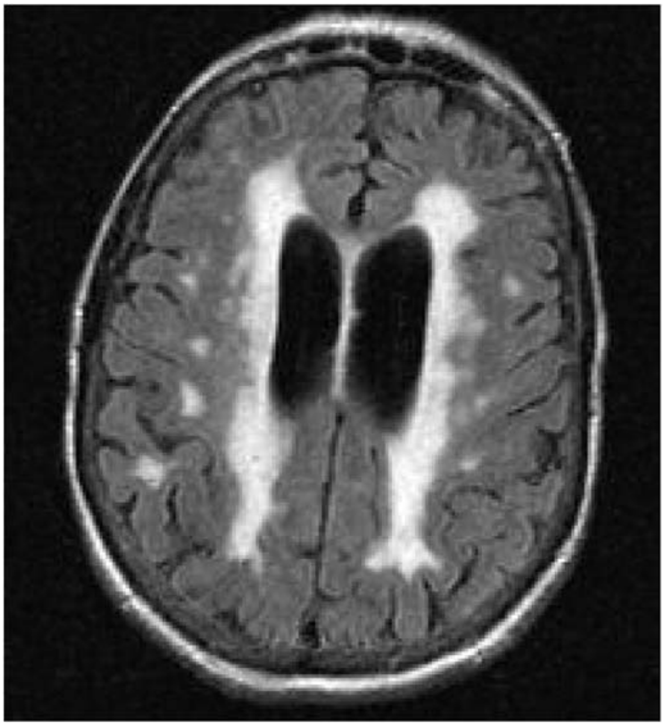

FIGURE 23-15 ■ MRI of a patient with microvascular disease seen in disequilibrium of aging. Axial fluid-attenuated inversion recovery sequence through the bodies of the lateral ventricles shows extensive, confluent areas of abnormal signal in a periventricular and subcortical distribution, consistent with white matter microvascular disease. The ventricles are slightly enlarged from associated central volume loss. (Courtesy of Barton F. Branstetter, MD, University of Pittsburgh.)

Presbycusis

Sensorineural hearing loss related to aging is termed presbycusis. Approximately one-third of persons between the ages of 60 and 70, and up to half of those between 70 and 80, have hearing loss.[10] Four subtypes of presbycusis have been described, relating to different audiometric patterns. The most common type is called sensory presbycusis, manifesting as a

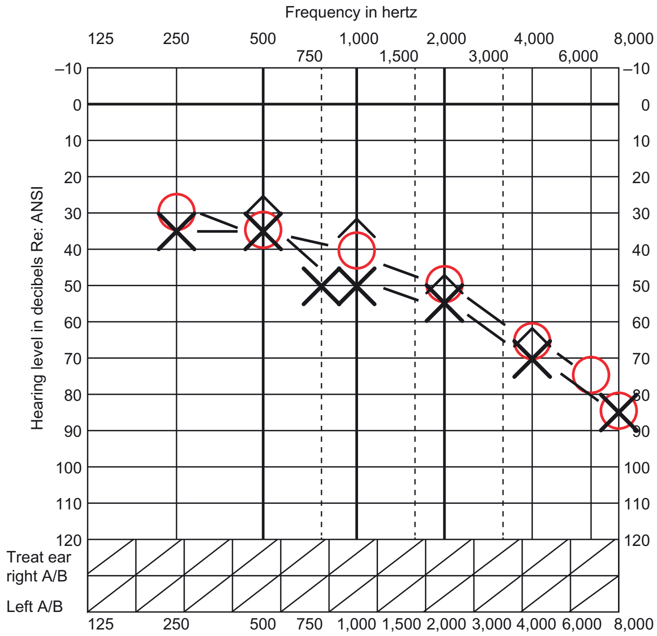

FIGURE 23-16 ■ Audiogram of presbycusis. This audiogram shows sensorineural hearing loss in a downsloping pattern, typical of presbycusis.

symmetric high-frequency sensorineural hearing loss that progressively worsens with age (Fig. 23-16). Primary synaptic degeneration is believed to play a role in the early stages of age-related hearing loss where no deficits are seen on audiometry, but patients experience hearing-in-noise deficits.[19] Both genetic and environmental factors play a role in etiology. Patients typically complain of difficulty understanding speech, especially in the presence of background noise. They may also suffer from tinnitus.

Perhaps more than any other realm of neurology, neuro-ophthalmologic disorders require a systematic approach that emphasizes precise localization guided by the patient's history followed by confirmation with specific examination maneuvers. To this end, the neurologist should be familiar with specialized techniques concerning fundus examination, eye movements and alignment, and pupillary assessment in order to examine patients properly and guide their evaluation.

AFFERENT VISUAL DISTURBANCES

Afferent neuro-ophthalmologic disorders may be limited to the eye (e.g., optic neuropathy), may be secondary to a primary neurologic disorder (e.g., papilledema from an intracranial tumor), or may be related to a systemic medical disorder (e.g., giant-cell arteritis). The neuro-ophthalmologic examination provides a window to the diagnosis and natural history of the variety of medical conditions that present with afferent disturbances (Table 24-1).

Optic Neuropathy

The optic nerve is approximately 50 mm in length and is anatomically separated into intraocular, intraorbital, intracanalicular, and intracranial portions. Damage to the optic nerve can occur anywhere along its course, and optic neuropathy may result from ischemic, demyelinating, compressive, genetic, infiltrative, nutritional, traumatic, or toxic causes (Table 24-2).

The term "optic neuritis" should not be used to describe any type of optic neuropathy, but should be

TABLE 24-1 ■ Selected Manifestations of Neuro-Ophthalmologic Disease Across the Spectrum of Organ Systems

Organ System	Disease State	Example of Neuro-Ophthalmologic Manifestation
Psychiatry	Conversion disorder	Functional blindness
Hematology	Sickle cell disease	Retrobulbar ischemic optic neuropathy
Cardiovascular	Endocarditis	Embolic retinal artery occlusion
Pulmonary	Pulmonary hypertension	Papilledema
Renal	Chronic renal failure	Intracranial hypertension
Gastrointestinal	Pancreatitis	Purtscher syndrome
Genitourinary	Ovarian cancer	Paraneoplastic syndromes with cerebellar degeneration (e.g., with anti-Yo antibodies)
Endocrine	Graves disease	Compressive optic neuropathy due to increased orbital fat content and enlarged extraocular muscles
Obstetric	Eclampsia	Cerebral blindness from posterior reversible encephalopathy syndrome (PRES)

TABLE 24-2 ■ Classification of Optic Neuropathy

Category	Prototypic Examples	Comment
Inflammatory/demyelinating	Optic neuritis	Usually associated with multiple sclerosis or neuromyelitis optica
Paraneoplastic	CRMP5, an autoantibody directed against collapsin response mediator protein	Reported with small cell lung cancer, lymphoma, nasopharyngeal carcinoma, and neuroblastoma
Infectious	Tuberculosis, cryptococcosis, human herpesvirus 6 infection, *Bartonella* infection	These infections causing optic neuropathy should prompt evaluation for infection with human immunodeficiency virus
Ischemic	Ischemic optic neuropathy (arteritic and nonarteritic), retinal artery occlusion (central or branch)	Funduscopy may show occlusive material (Hollenhorst plaque) in retinal artery occlusions
Compressive	Optic nerve sheath meningioma, Graves ophthalmopathy	Proptosis (exophthalmos) often present
Infiltrative	Sarcoidosis, metastasis, lymphoma	Orbit MRI often shows persistent enhancement of the optic nerve
Traumatic	Direct (penetrating) trauma, indirect trauma (often frontal or midfacial), or chiasmal	Injury due to compression, avulsion, or shear injury. No evidence-based guidelines regarding optimal treatment
Nutritional	Deficiency of vitamin B_1, B_2, B_{12}, or folate	Slowly progressive, symmetric optic neuropathy. Does not present acutely
Toxic	Ethambutol, carbon monoxide, methanol, tobacco-alcohol amblyopia, amiodarone	Typically bilateral and symmetric. May improve with removal of offending agent
Hereditary	Leber, Kjer (dominant optic atrophy) optic neuropathies	Leber hereditary optic neuropathy is transmitted via maternally inherited mitochondrial mutation

reserved to denote the inflammatory, demyelinating optic neuropathy that is either idiopathic or related to demyelinating disease such as multiple sclerosis (MS) or neuromyelitis optica (NMO). Inflammatory or infectious optic neuropathies from other known etiologies are best described in specific terms (e.g., sarcoid or syphilitic optic neuropathy).

Optic neuropathy may be classified anatomically as bulbar/anterior (usually associated with acute disc edema) or retrobulbar (i.e., posterior to the globe without disc swelling) (Fig. 24-1). Any cause of optic neuropathy that results in loss of axons will eventually produce optic atrophy, appearing on funduscopic examination as visible nerve fiber layer loss and disc pallor (Fig. 24-2). Optical coherence tomography is a noninvasive means of quantifying retinal nerve fiber layer atrophy or elevation and is more sensitive to detect axonal loss of the optic nerve. The presence of a relative afferent pupillary defect on the swinging flashlight test can be an important clue to the presence of optic nerve dysfunction, although this finding can also occur with significant asymmetric retinal

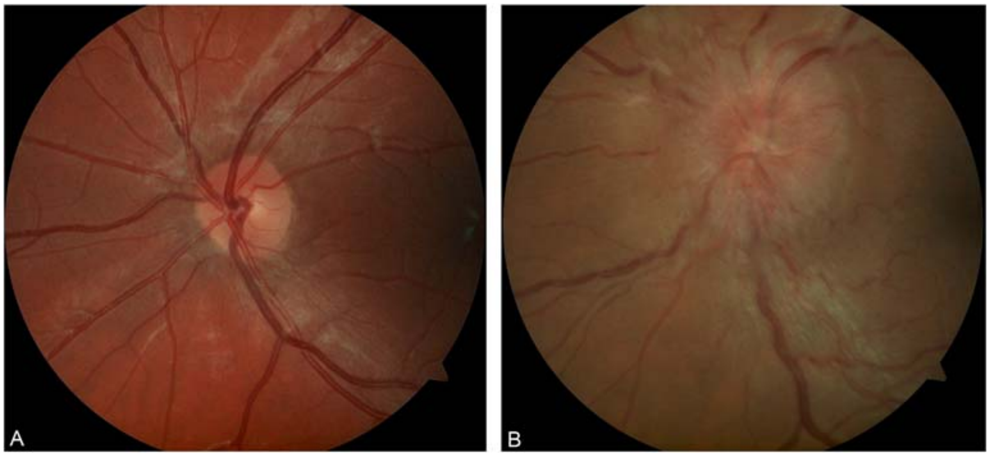

FIGURE 24-1 ■ *A*, Normal optic nerve. Note clearly visible vessels coursing over the disc edge, small central disc depression of the physiologic cup, and visible nerve fiber layer, especially in the superior and inferior arcades. *B*, Disc edema. Note obscurations of vessels coursing over the disc and swollen peripapillary nerve fiber layer causing disc elevation.

dysfunction. Bilateral symmetric optic nerve dysfunction does not produce a relative afferent pupillary defect as there is no difference in light transmission in the optic nerve of each eye, although both pupils will react sluggishly.

INFLAMMATORY DEMYELINATING OPTIC NEURITIS

Optic neuritis may be idiopathic or associated with demyelinating disease, most commonly MS. The clinical course is characterized by a relatively sudden onset of typically unilateral visual loss. The condition worsens to a nadir over several days, and then recovery begins, typically within several weeks, independent of corticosteroid treatment (although intravenous corticosteroids given in a 3-day course followed by a 2-week oral prednisone course and taper is a frequently used therapy).[1] Visual acuity at nadir ranges from 20/20 to no light perception. Pain occurs in more than 90 percent of cases, and often worsens with eye movement. Although centrocecal scotomas are classically associated with demyelinating optic neuritis, other types of field defects (e.g., central, altitudinal, diffuse, paracentral, and arcuate) frequently occur.

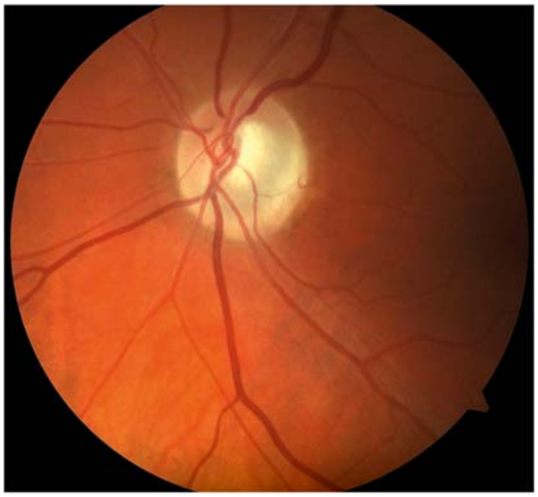

FIGURE 24-2 ■ Optic atrophy. Note disc pallor and lack of visible nerve fiber layer striations.

Demyelinating optic neuritis is retrobulbar in two-thirds of instances and the optic disc appears normal in the acute phase; the remainder of cases display mild disc edema acutely (“papillitis”). Magnetic resonance imaging (MRI) demonstrates contrast enhancement of the optic nerve in at least 90 percent of cases of demyelinating optic neuritis within the first several weeks, especially when fat-suppressed orbital sequences are obtained (Fig. 24-3).[2] Between 3 and 6 months after optic neuritis, optic atrophy becomes visible if there is nerve fiber loss, and visual evoked potentials may document delayed latencies. Not all cases of optic neuritis result in such optic atrophy.

While the overall prognosis of visual recovery from optic neuritis is good, it is common for many patients to have residual deficits ranging from mildly reduced contrast sensitivity to more significantly reduced acuity. The Optic Neuritis Treatment Trial followed patients with optic neuritis longitudinally and found that 72 percent of subjects had recovered visual acuity to at least 20/20, and 85 percent had acuity of at least 20/25 at 15 years after onset. If the initial visual acuity was limited to counting fingers or worse, there was a decreased chance of 20/20 (49%) or 20/25 (63%) visual recovery at 15 years. There was only a weak correlation between the severity of visual loss at baseline and recovery of vision in patients with an initial visual acuity between 20/20 and 20/200.

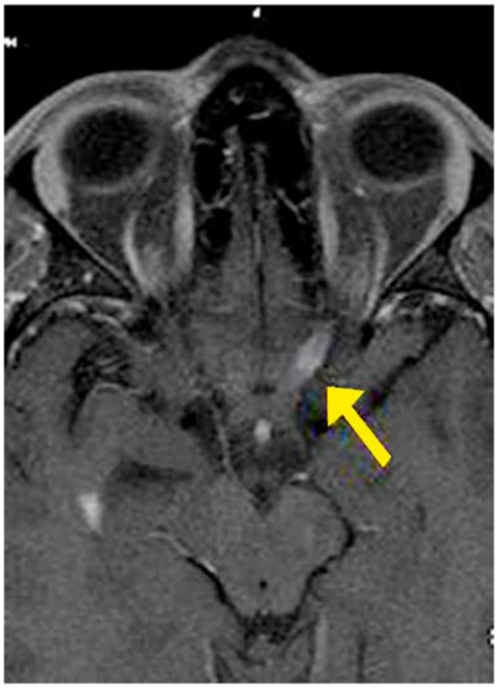

FIGURE 24-3 ■ Axial T1-weighted magnetic resonance imaging demonstrating gadolinium enhancement of the left retrobulbar portion of the optic nerve *(arrow)*.

The baseline brain MRI predicts the risk of developing MS in the decades following optic neuritis, and accordingly is an important test following a first attack of optic neuritis. The number of T2-weighted hyperintensities at least 3 mm in size on baseline MRI reflects the likelihood that a patient with optic neuritis will develop clinically definite MS as defined by a second subsequent relapse. A normal baseline MRI is associated with a 25 percent chance of developing MS in 15 years. The presence of just one lesion increases the 15-year cumulative probability of MS to 60 percent, while three or more lesions on the baseline brain MRI increase the likelihood to approximately 80 percent.[3] Optic nerve enhancement itself is not counted as a lesion. The overall risk of developing MS within 15 years after optic neuritis is 50 percent, independent of MRI findings, a figure that can be used to counsel those patients who cannot obtain an MRI. The majority of patients developing MS do so within the first 5 years. MRI characteristics also predict future disability in patients with optic neuritis. Spinal cord and infratentorial lesions are associated with a higher future disability.

NEUROMYELITIS OPTICA

NMO is an antibody-mediated inflammatory disease of the central nervous system (CNS) with a predilection for the optic nerves, spinal cord, and certain brain regions. While NMO was previously considered a variant of MS, it is now known to have distinct clinical, pathologic, and immunologic features. AQP4-IgG, a pathogenic antibody against aquaporin-4 (AQP4), has been shown to have high specificity to delineate NMO from presentations consistent with MS. More recently, a subset of patients with an NMO phenotype has been found to have autoantibodies targeting myelin oligodendrocyte glycoprotein.

Optic neuritis from NMO is often bilateral and frequently results in severe vision loss.[4] MRI features of NMO include involvement of greater than half the length of the optic nerve and involvement of the chiasm (Fig. 24-4). NMO-related optic neuritis is associated with greater retinal nerve fiber layer loss than MS, which can be measured by optical coherence tomography (Fig. 24-5).

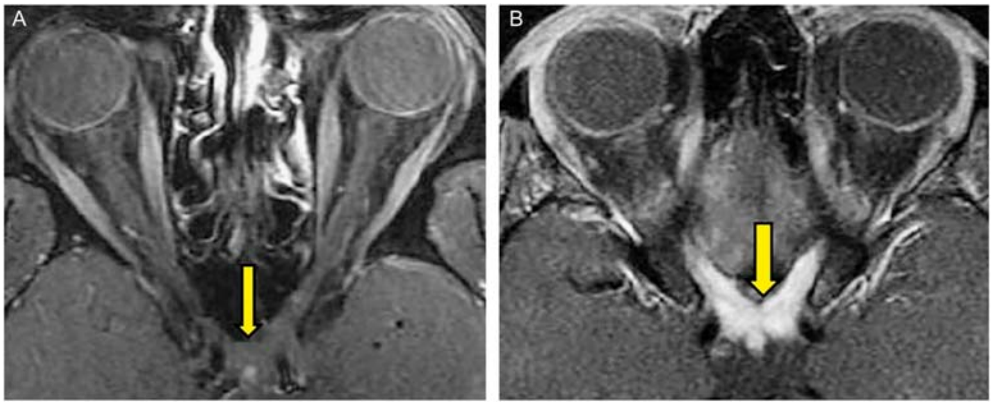

FIGURE 24-4 ■ Axial T1-weighted gadolinium-enhanced brain MRI at the level of the optic chiasm. *A*, Normal optic chiasm *(arrow)* does not enhance. *B*, An acute attack of neuromyelitis optica resulting in abnormal enhancement of the optic chiasm *(arrow)*.

FIGURE 24-5 ■ Optical coherence tomography demonstrating severe optic atrophy. Note sector *(green arrow)* and quadrant *(black arrow)* maps depicting dramatic nerve fiber layer (RNFL) loss in all quadrants. The average RNFL values of 34.1 μm (OD) and 27.02 μm (OS) indicate extreme optic atrophy (normal average RNFL ~104 μm).

Early treatment of NMO-associated optic neuritis with high-dose corticosteroids is associated with better visual outcomes and preservation of retinal nerve fiber layer. In cases where corticosteroids are ineffective or only transiently helpful, plasma exchange can be utilized; the effectiveness may depend on how early treatment is initiated.[5] Consequently, it is imperative to attempt to distinguish MS from NMO in the acute stage; bilaterality, severe visual acuity loss at onset, and recurrent visual decline following corticosteroid treatment are factors suggestive of NMO.

ISCHEMIC OPTIC NEUROPATHY

Ischemic optic neuropathy presents with acute visual loss due to impaired circulation to the optic disc or

TABLE 24-3 ■ Neuro-Ophthalmologic Disorders due to Ischemic Disease

Category	Funduscopic Features	Systemic Associations
Nonarteritic anterior ischemic optic neuropathy (NAION)	Generalized or sectoral disc edema, flame-shaped peripapillary hemorrhages, disc-at-risk in opposite eye	Diabetes, nocturnal hypotension, antihypertensive medications, sleep apnea
Nonarteritic posterior ischemic optic neuropathy	Normal in acute stage. May result in disc atrophy chronically	Severe systemic hypotension or anemia, sepsis
Arteritic ischemic optic neuropathy	Papilledema, evidence of choroidal ischemia, infarction in distribution of cilio-retinal artery, if present	Giant-cell arteritis, polymyalgia rheumatica, thrombocytosis, inflammatory aortitis
Diabetic papillopathy	Similar in appearance to NAION, but severity of fundus appearance may be out of proportion to relative sparing of visual function	Diabetes mellitus, diabetic retinopathy
Central retinal artery occlusion	Normal optic disc, but with generalized retinal edema with cherry-red macular spot	Carotid atherosclerosis, hypertension, tobacco use, hyperhomocysteinemia
Branch retinal artery occlusion	Normal optic disc with focal area of retinal edema, sometimes associated with a visible occlusive plaque	Carotid atherosclerosis, hypertension, tobacco use

retrobulbar optic nerve. It may be divided into arteritic (e.g., giant-cell arteritis) and nonarteritic varieties (Table 24-3). Nonarteritic anterior ischemic optic neuropathy (NAION) is always associated with disc edema acutely; the pathophysiologic mechanism of cell death is presumed to be mainly ischemia from impaired perfusion supplied by the network of short posterior ciliary arteries. Individuals with a crowded optic disc (small cup-to-disc ratio) are predisposed to developing NAION. It is believed that an episode of hypoperfusion to the optic disc can invoke a cycle whereby local ischemia gives rise to swelling of the crowded optic disc, which further compromises the circulation and leads to further swelling.

NAION typically presents with sudden, painless, unilateral vision loss, often with an altitudinal visual field defect (Fig. 24-6). Acutely disc edema may be focal or diffuse. Because the affected optic disc is swollen, the characteristic risk factor of a crowded optic disc is best observed in the opposite eye in the acute phase. Treatment for NAION is limited—systemic high-dose corticosteroids, intravitreal bevacizumab, and optic nerve decompression surgery are not effective. The risk to the opposite eye is approximately 15 percent over the next several years, and efforts should be made to address vascular risk factors such as hypertension, hyperlipidemia, and tobacco abuse. In addition, it is important to take measures to avoid nocturnal hypotension and treat obstructive sleep apnea if it is present.

Giant-cell arteritis (arteritic anterior ischemic optic neuropathy) is a neuro-ophthalmic emergency which may cause ischemia to the eye and optic nerve, leading to permanent visual loss. In addition, it can affect extraocular muscles and present with diplopia. Systemic symptoms such as jaw claudication, headache, scalp tenderness, fever, anorexia, weight loss, or polymyalgia rheumatica can be important clues to the diagnosis. Laboratory abnormalities include elevation of the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) as well as thrombocytosis; a normal ESR may be present in up to one-third of patients, but ESR and CRP together have a combined sensitivity of 99 percent.[6] Immediate treatment with corticosteroids is indicated when giant-cell arteritis is suspected and should be initiated even before biopsy, as histopathologic findings will persist for some time following corticosteroid exposure. For patients with difficulty weaning the dose of corticosteroids, tocilizumab has emerged as an effective

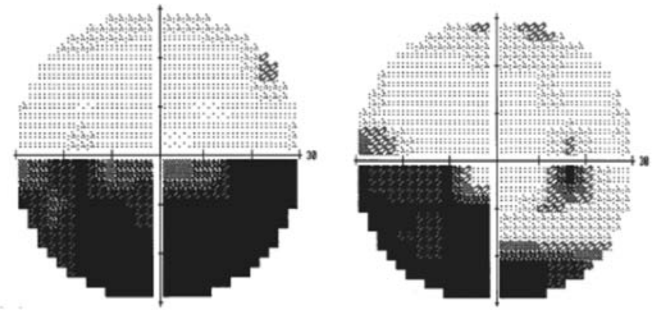

FIGURE 24-6 ■ Bilateral visual field defects in sequential nonarteritic anterior ischemic optic neuropathy. The right eye demonstrates an inferior arcuate defect with "nasal step" while the left eye reveals a denser inferior field defect.

immunotherapy targeting the IL6 receptor.[7] Temporal artery biopsy often demonstrates characteristic giant cells, noninfectious granulomas, inflammatory infiltrates, and interruption of the internal elastic lamina, although the phenomenon of skip lesions accounts for some biopsy-negative cases.

Posterior ischemic optic neuropathy is extremely rare and usually follows profound hypotension as a complication of surgery (especially prolonged spinal surgeries in the prone position), an episode of severe anemia, or as a result of giant-cell arteritis. Because the responsible lesion occurs distal to the lamina cribrosa of the optic nerve, the disc is not swollen (thus "posterior").

COMPRESSIVE OPTIC NEUROPATHY

Compressive optic neuropathies are usually painless (unless other cranial nerves are affected) and subacutely progressive (Table 24-4). When the lesion is intraorbital, associated features may include proptosis and optic disc swelling. Diplopia may be present, owing to restricted extraocular muscles or ocular motor nerve involvement. In contrast, retro-orbital lesions such as pituitary macroadenoma or intracranial meningioma cause visual loss and progressive optic disc pallor, but not optic disc edema. MRI including fat-saturated postgadolinium images is often the diagnostic tool of choice and coronal sequences are particularly helpful to delineate the relevant anatomy (Fig. 24-7).

TABLE 24-4 ■ Compressive Optic Neuropathy Locations and Etiology

Orbit	Sellar Region
Optic nerve sheath meningioma	Pituitary adenoma
Orbital metastases	Craniopharyngioma
Graves ophthalmopathy	Meningioma
Idiopathic orbital inflammatory pseudotumor	Internal carotid aneurysm
Primary bone lesions (e.g., fibrous dysplasia, Paget disease)	Histiocytosis
Orbital fracture or hemorrhage	

GENETIC OPTIC NEUROPATHY

While several inherited optic neuropathies have a chronic, insidious presentation, the main inherited optic neuropathy with an acute presentation is Leber hereditary optic neuropathy (LHON). LHON is a maternally inherited mitochondrial optic neuropathy that is phenotypically expressed most commonly in younger males. LHON typically produces bilateral, sequential, painless optic neuropathy with severe central scotomas causing profoundly reduced acuity. Acutely, the disc may appear erythematous with telangiectactic vessels, but no true disc edema is present. Genetic testing is commercially available for the three mitochondrial mutations that cause over 90 percent of cases. There is currently no proven

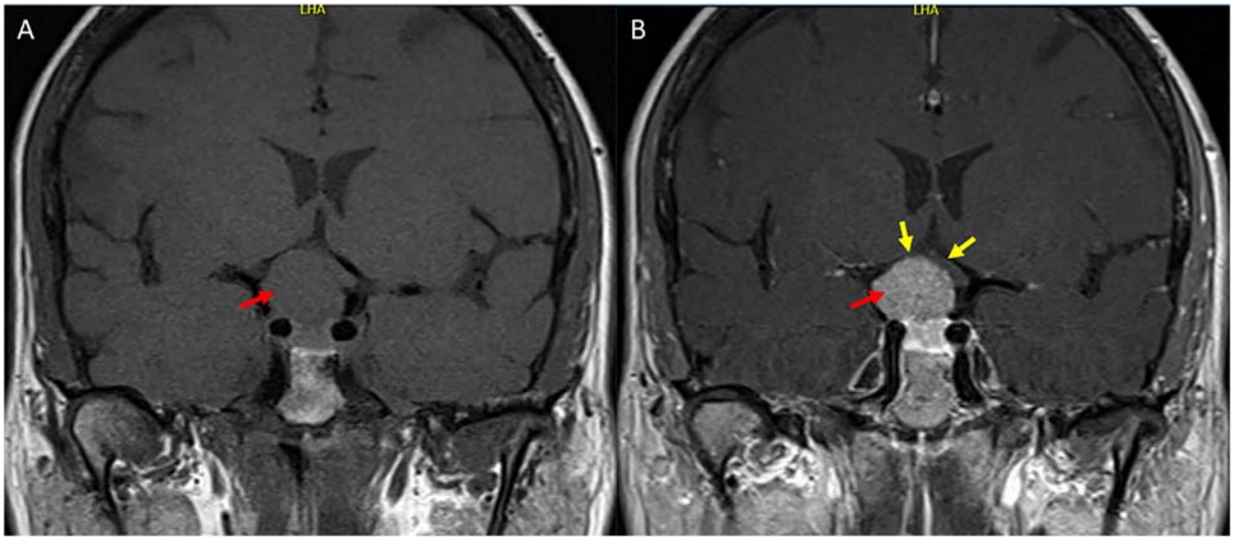

FIGURE 24-7 ■ Compressive optic neuropathy due to meningioma. Coronal T1-weighted MRI without (*A*) and with (*B*) gadolinium contrast shows a homogeneously enhancing lesion *(red arrows)* in the region of the pituitary sella compressing the optic nerves *(yellow arrows)* and chiasm inferiorly.

therapy; idebenone did not meet its primary endpoint of recovery of visual acuity in a randomized clinical trial but showed some promise when secondary endpoints were examined.[8] Gene therapy delivered by intravitreal injection is currently being evaluated in clinical trials.

PAPILLEDEMA

The term papilledema is meant to specifically refer to optic disc edema caused by elevated intracranial pressure (ICP), in contrast to the broader term optic disc edema, which also encompasses causes such as local ischemic, infiltrative, and inflammatory causes of optic neuropathy. Papilledema is nearly always bilateral, but can be asymmetric. It can range in appearance from mild to severe, described by using the Frisén scale (Fig. 24-8; Table 24-5). Peripapillary hemorrhages can be seen acutely but generally resolve once papilledema becomes chronic. Patients with papilledema often report other symptoms of elevated ICP, including headache, diplopia related to abducens neuropathy, and transient visual obscurations. In contrast to the significant central visual loss that can accompany other intrinsic causes of optic disc edema, the visual loss caused by papilledema often spares the central visual field. Visual loss caused by papilledema often starts with an enlarging blind spot and progresses to arcuate nerve fiber layer defects that may advance toward central visual loss when particularly severe. The most common causes of papilledema are listed in Table 24-6.

TABLE 24-5 ■ Frisén Scale for Rating Papilledema

Frisen Grade	Funduscopic Features
0	Normal except for mild blurring of the nasal and temporal disc
1	C-shaped peripapillary gray halo sparing temporal quadrant
2	360-degree gray peripapillary halo, nasal elevation
3	Obscuration of ≥1 major vessel segment at disc border, 360-degree elevation
4	Total obscuration of a major vessel on the disc
5	Partial obscuration of all vessels on the disc

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH), or pseudotumor cerebri, is most characteristically a syndrome of obese females of childbearing age. Pediatric IIH is distinct in that the predisposition for obesity and female sex does not apply. The clinical characteristics of IIH include headache, pulsatile tinnitus, transient visual obscurations, and diplopia related to abducens nerve palsy.[9] Patients with IIH may have variable Frisén grades of optic disc edema. The pathophysiology of IIH is not fully understood, but vitamin A metabolism, endocrine-secreting adipose tissue, and cerebral venous dysregulation are all proposed possibilities. An emerging hypothesis is that cerebral venous sinus stenosis may be an important factor

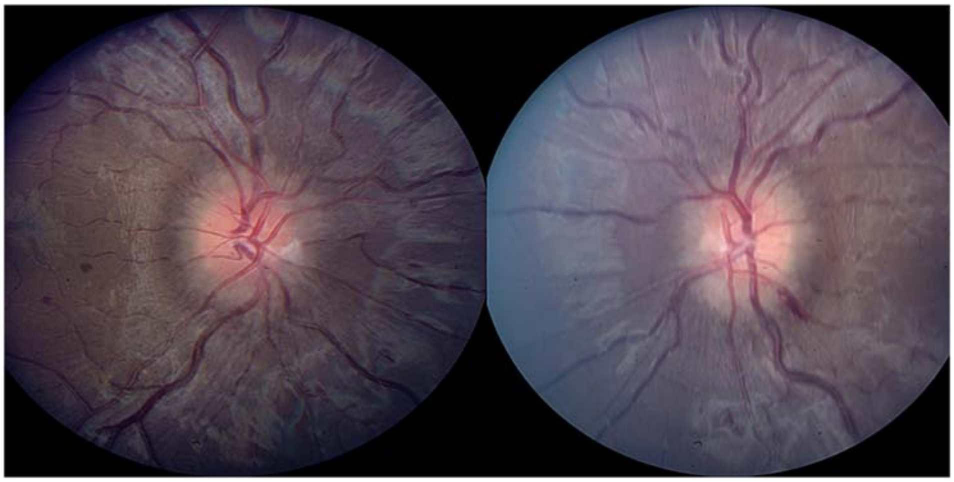

FIGURE 24-8 ■ Fundus photos showing papilledema. Both eyes are affected, as is typical. Features demonstrated include elevation of the retinal nerve layer, peripapillary flame-shaped hemorrhages, and engorgement of the retinal veins. Peripapillary blood vessels are obscured as they pass across the disc.

TABLE 24-6 ■ Causes of Increased Intracranial Pressure Resulting in Papilledema

Etiology	Concomitant Features
Space-occupying brain lesion	Subacutely worsening headache. Various neurologic defects depending on location
Meningoencephalitis	Meningismus, abnormal cerebrospinal fluid chemistries
Subarachnoid hemorrhage	Terson syndrome (intravitreal hemorrhage)
Cerebral edema	Vasogenic (due to loss of intracranial capillary integrity), cytotoxic (due to cell death, often as a result of ischemic stroke), or interstitial edema
Venous sinus thrombosis	Triad of seizure, encephalopathy, and headache is classic acute presentation
Cerebral aqueductal stenosis	May be asymptomatic until critical stenosis causes drowsiness and stupor
Superior vena cava syndrome	Dyspnea, face and arm swelling, Pemberton sign
Right heart failure	Peripheral edema, ascites, hepatomegaly
Sleep apnea	Hypertension, frequent napping, crowded oropharynx
Pulmonary hypertension	Parasternal heave, jugular venous distention, clubbing
Idiopathic intracranial hypertension	Obesity, female sex, childbearing age

contributing to the pathophysiology of this condition in some patients. Once the homeostatic mechanisms maintaining normal ICP have become impaired, elevated ICP can possibly create or worsen stenosis of the venous sinus, potentially causing a hemodynamically significant trans-stenotic pressure gradient. Higher pressure in the venous sinus may cause impaired function of the arachnoid villi that normally drain CSF into the venous sinuses, thereby perpetuating the cycle of events leading to elevated ICP.

The diagnostic evaluation of IIH requires brain imaging to exclude other etiologies of papilledema including venous sinus thrombosis and mass lesions; this is best accomplished with MRI and MRV. Radiologic features of IIH that are supportive of the diagnosis include an enlarged optic nerve sheath, optic nerve tortuosity, protrusion of the optic nerve head, an empty sella, and concavity or flattening of the posterior globes (Fig. 24-9).

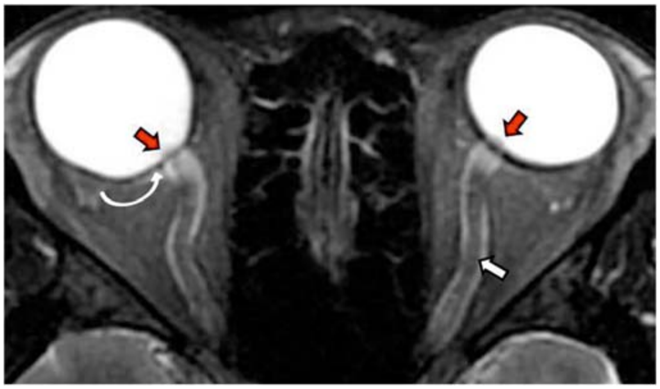

FIGURE 24-9 ■ Axial T2-weighted orbital MRI from a patient with idiopathic intracranial hypertension showing bulging of the papilla *(red arrows)*, flattening of the posterior globe *(curved arrow)*, and intraorbital nerve tortuosity *(white arrow)*.

Initial treatment for IIH may include weight loss, low-salt diet, and pharmacotherapy with acetazolamide. In cases relating to predisposing factors such as obstructive sleep apnea, excess vitamin A intake, tetracycline and related compounds, or chronic anemia, the underlying cause must be addressed. When visual loss is severe and progressive despite medical management, surgical options include optic nerve sheath fenestration, lumboperitoneal or ventriculoperitoneal shunting, or stenting of a hemodynamically significant venous stenosis.

Retrochiasmal Vision Loss

Lesions affecting postchiasmal afferent nerve pathways generally produce homonymous visual field loss, referring to visual loss on the same side of the vertical meridian of the visual field of each eye. Unless there is concomitant involvement of the optic nerve or the field loss is bilateral, visual acuity is typically spared. The most common causes of homonymous visual field loss are stroke, followed by trauma and tumors.

Higher order visual areas are organized into a ventral visual stream involving the temporal lobe (the "what" pathway) that is concerned with object recognition, and a dorsal stream including the parietal lobe (the "where" pathway) involved with spatial processing and motion. Ventral pathway dysfunction may produce difficulty with object recognition (specifically face recognition), whereas dorsal pathway lesions are associated with impaired spatial attention. While a unilateral right parietal lesion causes a rightward bias of attention (i.e., left-sided neglect), bilateral parietal lesions cause profound spatial impairment referred to as Balint syndrome. Balint syndrome is characterized by simultanagnosia (difficulty recognizing multiple components of a visual stimulus or scene), optic ataxia (difficulty reaching under visual guidance), and ocular apraxia (difficulty making accurate saccadic eye movements to an intended target).

Neurodegenerative disorders that cause predominant visual deficits early in the clinical course include dementia with Lewy bodies and posterior cortical atrophy, which is typically characterized by Alzheimer disease pathology. The Heidenhain variant of Creutzfeldt–Jakob disease affects the occipital regions first and presents with progressive visual processing deficits quickly leading to profound dementia, myoclonus, and death.

EFFERENT VISUAL DISTURBANCES

Clinical Assessment

The history in patients with diplopia should concentrate on whether the disorder is binocular or monocular, the orientation of the images, and symptom modifiers. Monocular diplopia—diplopia that remains when one eye is closed—is generally related to ocular causes (e.g., corneal or lens opacity, refractive error), and is not neurologic in origin. It typically resolves with the pinhole test and should prompt ophthalmology referral. In contrast, binocular diplopia resolves with closure of either eye; it is related to misalignment of the eyes and is typically neurogenic in origin. The direction of misalignment and the pattern of misalignment in each position of gaze allow accurate localization. Other factors such as age, associated features (e.g., ptosis, pain), modifiers, and diurnal variation (e.g., fluctuations) guide the differential diagnosis as discussed below.

Ocular misalignment refers to any deviation of the visual axis of one eye compared to the other. Ocular alignment can be measured on examination in several ways. An imprecise method involves estimation of misalignment by displacement of the corneal light reflex (Hirschberg method). Light reflects from the same position on both corneas if the eyes are orthophoric, whereas the light is displaced from the center in one eye when misalignment exists; each millimeter of light reflex displacement equals approximately 7 to 10 degrees or 15 to 20 prism diopters.

The red Maddox rod is a simple method to quantify small amounts of ocular misalignment. The Maddox rod is composed of a series of parallel cylindrical grooves in a piece of red glass, mounted in a circular rim (the original consisted of a single cylindrical rod, hence the name). The device converts a light source into a red line perpendicular to the axis of the rod. The patient views a white light source with the left eye, while the Maddox rod is placed over the right eye. The position of the red line relative to the light source (seen by the left eye) indicates the presence and amount of misalignment. The red line can be made to appear vertically (to measure horizontal deviation from the light) or horizontally (to measure vertical deviation from the light), and prisms can be placed over the Maddox rod until the line intersects the light. If the red line appears to the left of the light, then an exotropia exists. If the line appears to the right of the light, an esotropia is present. If the line appears below the light, then a right hypertropia is present, and a red line perceived above the light indicates a left hypertropia. By convention, vertical misalignment is always quantified by the hypertropic eye.

To perform the alternate cover test, the patient fixates on a target such as a specific letter of the Snellen chart, while the examiner alternately covers one eye and then the other. This technique forces the patient to fixate with the uncovered eye, disrupting binocular fusion and unmasking an underlying misalignment of the two eyes. If the eyes are orthophoric (aligned with each other), then no corrective eye movement will be required to fixate on the target when the occluded eye is switched. If an eye moves down to fix the target immediately after it is uncovered, then a hypertropia exists on that side. An exotropia is identified by an eye that moves in toward the nose to fixate the target once it is uncovered. In contrast, an outward eye movement to fixate a target indicates an esotropia. Prisms of increasing strength can be placed over one eye to neutralize this shift and quantify the misalignment.

These alignment tests are repeated in the nine cardinal positions of gaze to discern the pattern of involvement. If the misalignment is roughly the same amount in different directions of gaze, it is considered *comitant*, and may be a congenital form of strabismus that is not due to an acquired neurologic lesion. In contrast, if the deviation varies in different directions of gaze, it is considered *incomitant*, and the pattern of misalignment can help localize the neurologic lesion responsible for the diplopia. An incomitant esodeviation greatest in horizontal gaze indicates lateral rectus weakness on that side, often due to a partial sixth nerve palsy. An incomitant exodeviation indicates medial rectus weakness, often due to partial third nerve palsy or internuclear ophthalmoplegia. An incomitant hyperdeviation that increases in contralateral gaze and with ipsilateral head tilt is the pattern of a fourth nerve palsy. A hyperdeviation in downgaze that switches to the opposite hyperdeviation in upgaze often suggests a partial third nerve palsy, owing to combined weakness of the inferior and superior rectus muscles of the same eye. A hyperdeviation that does not fit the pattern of a fourth nerve palsy or third nerve palsy often represents a skew deviation, which is a supranuclear disturbance of vertical alignment caused by a brainstem or cerebellar lesion. For any pattern of ocular misalignment, orbital processes and ocular myasthenia gravis may also need to be considered.

The motility examination also includes assessment of pursuit, saccades, ductions, and versions. Pursuit is tested with the patient following a target moving slowly (less than 20 degrees/sec). Saccades are rapid eye movements that bring fixation from one target immediately to another. Binocular movements in various directions are known as versions, while ductions refer to the movements of one eye while the other eye is covered.

It can be worthwhile to note a patient's head position. Patients with diplopia may adopt a head posture to avoid the position of diplopia. For example, patients with impaired abduction of one eye may turn the head toward the side of the palsy. Patients with trochlear nerve palsy may present with a contralateral head tilt and chin-down position to avoid gaze into the diplopic field.

Examination of the eyelids, pupils, and position of the globe also provide important clues to the diagnosis. Ptosis should be quantified through measurement of the height of the palpebral fissure in millimeters. Pupil size should be measured in light, in dark, and with reactivity. Proptosis can be measured in millimeters of anterior displacement of each eye from the lateral canthus.

Anatomic localization is always the first task for a neurologist. The site of lesions causing binocular diplopia may be supranuclear (e.g., skew deviation or vergence dysfunction), or involve the ocular motor nerve nuclei or infranuclear segments of cranial nerves III, IV, and VI, the internuclear segment (i.e., medial longitudinal fasciculus [internuclear ophthalmoplegia]), neuromuscular junction (e.g., myasthenia gravis), or muscle (e.g., trauma, thyroid eye disease, neoplasm). A first step in localization is to consider the most specific patterns of ocular misalignment related to the ocular motor nerves or their nuclei as well as supranuclear and internuclear lesions (Tables 24-7, 24-8, and 24-9). If the misalignment pattern does not

TABLE 24-7 ■ Limitation of Upgaze

Entity	Motility	Globe Position	Eyelid	Pupil
Thyroid eye disease	Gaze in all directions may be limited	Proptosis, increased resistance to retropulsion	Eyelid retraction with lagophthalmos	Usually normal; RAPD if ON present
Orbital myositis	Gaze in all directions may be limited	Proptosis, increased resistance to retropulsion	None	Usually normal
Blow-out fracture with muscle entrapment	Isolated limitation of upgaze	Enophthalmos	Normal	Normal
Myasthenia gravis	Gaze in all directions may be limited; intrasaccadic slowing characteristic	Normal	Ptosis may be present	Normal
Parinaud syndrome	Skew deviation may be present	Normal	Eyelid retraction without lagophthalmos	Normal
Progressive supranuclear palsy	Symmetric limitation of vertical movement	Normal	Normal	Normal
Chronic progressive external ophthalmoplegia	Eventually gaze in all directions is limited	Normal	Normal	Normal
Superior division cranial nerve III	Isolated limitation of upgaze	Normal	Ptosis	Normal

RAPD, Relative afferent pupillary defect.
*Intrasaccadic delay refers to a saccade that is initially of normal or brisk velocity but slows as the eye moves laterally due to the decreased number and efficacy of the acetylcholine receptors.

conform to these specific patterns, attention should be directed toward neuromuscular junction disease, myopathy, or multiple cranial nerve palsies (e.g., Miller Fisher syndrome, Wernicke encephalopathy). One important caveat is that even if the pattern fits that of an ocular motor nerve, nucleus, or internuclear ophthalmoplegia, mimics such as myasthenia gravis must still be considered.

Supranuclear Causes of Ocular Dysmotility

The supranuclear ocular motor system is principally concerned with coordinating the movements of both eyes together, and when injured, produces gaze preferences or palsies. The set of inputs to the ocular motor nuclei in the brainstem arrive from the cerebral hemispheres, cerebellum, and portions of the brainstem, together governing distinct classes of eye movements including saccades, pursuit, the vestibular ocular reflex, gaze-holding, fixation, optokinetic nystagmus, and vergence. The hallmark of a supranuclear eye movement abnormality is that intact eye movements can be demonstrated when volitional pathways are bypassed, such as with the oculocephalic reflex.

The frontal eye fields of the cerebral hemispheres generate volitional contralateral saccades, and cerebral hemispheric lesions affecting these regions therefore produce a gaze deviation toward the side of the lesion. Occasionally, with deep lesions affecting the basal ganglia, the gaze deviation is toward the side of the lesion (so called *wrong-way eyes*).[10] Parietal lesions can interfere with smooth pursuit eye movements following a target moving toward the side of the lesion.

Supranuclear networks also control vergence eye movements. Convergence insufficiency is a relatively common example of vergence dysfunction, characterized by a larger exophoria (with diplopia) at near than far distance.

Within the pons, the paramedian pontine reticular formation just rostral to the abducens (VI) nucleus houses horizontal burst neurons. Lesions in this region produce slow or absent ipsilesional saccades. Burst neurons facilitating vertical saccades reside within the rostral interstitial medial longitudinal fasciculus, which is situated in the dorsal midbrain rostral to the oculomotor nucleus; dysfunction of this region produces slow or absent vertical saccades.

A dorsal midbrain syndrome, which is referred to by the eponym Parinaud syndrome, causes a supranuclear vertical gaze palsy. In its complete form, it is also accompanied by light-near dissociation of the pupils, eyelid retraction, and convergence retraction nystagmus.

The vestibulocerebellum, vermis, and fastigial nuclei perform critical coordination and calibration functions for the ocular motor system. The flocculus and paraflocculus are involved in smooth pursuit, gaze holding, and calibration of the vestibular ocular reflex. The vermis and fastigial nuclei are involved in saccadic and pursuit control. The nodulus and uvula participate in modulation of the vestibular system.

Skew deviation is a supranuclear cause of vertical diplopia, in which the nuclear and infranuclear third and fourth nerves are functioning normally but the supranuclear inputs that maintain normal vertical ocular alignment are perturbed. The vertical misalignment with skew is usually comitant (the same in all positions of gaze). Some cases of skew deviation may be incomitant, but usually not conforming to the pattern of misalignment of a third or fourth nerve palsy. The “high–high low–low rule” can be used to generally localize a lesion causing skew deviation; with lesions above the level of the pontine vestibular decussation, the ipsilesional eye is often hypertropic, and with lesions below this decussation, the ipsilesional eye is usually hypotropic. The ocular tilt reaction is a special circumstance of skew deviation with the additional features of involuntary head tilt and torsion of both eyes.

Ocular Motor Nuclei and Nerves

The three ocular motor nerves, which together are responsible for controlling the six extraocular muscles of each eye, are the oculomotor (III), trochlear (IV), and abducens (VI) nerves. Lesions of these individual nerves in the brainstem have characteristic patterns of clinical deficits with highly localizing value.

OCULOMOTOR NERVE (III) PALSY

The third cranial nerve innervates the superior, inferior, and medial recti, inferior oblique, levator palpebrae, iris sphincter, and ciliary muscles, thus controlling adduction, extorsion, supraduction, most of infraduction, lid opening, and pupil miosis. The collection of nuclei lie in the midline of the dorsal midbrain and are composed of a complex arrangement of subnuclei. The oculomotor nerve fascicles travel ventrally, traversing the red nucleus, substantia nigra, and cerebral peduncle before entering the subarachnoid space within the interpeduncular fossa. Within the subarachnoid space, the nerve projects between the superior cerebellar and posterior cerebral arteries, adjacent to the posterior communicating artery. It has an important anatomic relationship to the uncus, rendering the nerve vulnerable to compression with uncal herniation. Within the cavernous sinus, the nerve resides within the superior wall and divides into a superior division (innervating the levator palpebrae and superior rectus) and inferior division (innervating all its other muscles) prior to passing through the superior orbital fissure.

Lesions of the oculomotor nucleus are uncommon, and are characterized by ipsilateral third nerve deficits accompanied by bilateral superior rectus involvement and bilateral ptosis, owing to the anatomy of the individual ocular motor complex subnuclei. Lesions of the midbrain, often related to ischemia, are usually accompanied by hemiataxia, tremor, or hemiparesis.

Complete unilateral oculomotor nerve palsy produces complete ptosis, a mid-position light-fixed pupil, and an inability to adduct, supraduct, or infraduct the eye. The eye may appear depressed and abducted ("down and out"), and patients report binocular oblique diplopia when the lid is elevated. Partial oculomotor palsies may spare some aspects of this function.

The key diagnostic consideration in a patient presenting with an acute isolated third nerve palsy is aneurysmal compression, most commonly related to the posterior communicating artery. Rupture or enlargement of such an aneurysm typically produces an acute, painful, pupil-involved ipsilateral oculomotor nerve palsy. Prompt diagnosis is critical in facilitating treatment and reducing mortality. In contrast to potentially life-threatening aneurysmal oculomotor nerve palsies, ischemic (i.e., microvascular, "diabetic") palsies are much more common and nearly always improve. Ischemic injury often presents with pain, which may be indistinguishable from aneurysmal pain. In most cases of microvasculopathic third nerve palsy, the pupil is spared. Ischemic oculomotor palsies nearly always improve, never demonstrate aberrant regeneration, and usually resolve within approximately 3 months. Most patients with ischemic oculomotor nerve palsies are older, with some combination of vascular risk factors such as diabetes, hypertension, hyperlipidemia, and tobacco abuse. Treatment of ischemic palsies is focused on symptomatic relief, exclusion of other causes, and ischemic risk-factor modification.

The "rule of the pupil" is helpful in the evaluation, but must be applied correctly: in the face of a *complete* motor paresis, a normal pupil effectively eliminates compressive pathophysiologies such as aneurysm. It is critical to remember, however, that the rule of the pupil cannot be applied to rule out compression for incomplete motor palsies; in these cases, compressive etiologies remain a consideration regardless whether the pupil is involved or spared, and appropriate imaging is required to evaluate for lesions such as an aneurysm. Because the pupillomotor fibers reside on the dorsomedial peripheral aspect of the oculomotor nerve, and microvascular ischemic palsies tend to infarct the center part of the nerve, sparing the pupil occurs in approximately 70 percent of ischemic palsies.[11] When anisocoria does occur in microvasculopathic third nerve palsy, the pupillary inequality is typically less than 1 mm.

Oculomotor palsy from uncal herniation is related to ICP gradients and is always attended, in short order, by other features such as hemiparesis, diminished consciousness, or visual field defects. This neurologic emergency requires prompt therapy directed at the underlying cause as well as the intracranial hypertension itself in order to avoid morbidity and mortality. Many other conditions can cause oculomotor nerve palsy including pituitary apoplexy, giant-cell arteritis, trauma, infection, and tumor.

Because the oculomotor nerve innervates several muscles, palsies can heal with aberrant regeneration (synkinesis). The presence of such regeneration implies disruption of the perineural sheath from compression or trauma, and never follows microvascular palsies. Common aberrancy patterns include lid elevation with eye adduction or depression, eye adduction with vertical movements, and pupillary constriction with eye movements.

TROCHLEAR NERVE (IV) PALSY

The nucleus of the trochlear nerve resides in the dorsal periaqueductal gray of the caudal midbrain ventral to the aqueduct and dorsal to the medial longitudinal fasciculus. The fascicles of the trochlear nerve cross and exit the brainstem dorsally, tracing a long subarachnoid course around the midbrain and then through the cavernous sinus in its lateral wall. The nerve then passes through the superior orbital fissure to innervate the superior oblique muscle, which primarily intorts the eye (depression of the adducted eye is a secondary action).

Trochlear nerve palsies produce ipsilateral hypertropia and excyclotorsion, resulting in binocular oblique diplopia in contralateral and downgaze. The patient usually adopts a chin-down and contralateral head-tilt posture to diminish object separation. Examination of ductions, pursuits, and saccades is typically normal. Alignment testing typically reveals a hypertropia that is worse on contralateral gaze and with ipsilateral head tilt. The presence of ocular torsion can be demonstrated when viewing a straight horizontal line in a position of diplopia; the two horizontal lines will appear to converge toward the ipsilateral side with a trochlear nerve palsy.

Trauma is the most common cause of CN IV palsy, probably related to the long subarachnoid course of the nerve around the midbrain. Most patients with traumatic or ischemic (microvascular) trochlear nerve palsies improve with time; vertical prism may be useful if improvement is incomplete.

Abducens Nerve (VI) Palsy

The nucleus of the sixth cranial nerve resides in the dorsal pons, ventral to the facial nerve colliculus and adjacent to the medial longitudinal fasciculus. The nucleus contains abducens neurons innervating the lateral rectus and also internuclear neurons that travel through the medial longitudinal fasciculus to innervate the contralateral medial rectus subnucleus and mediate conjugate horizontal gaze. The fascicles of the abducens nerve emanate ventrally to emerge at the pontomedullary junction before ascending the clivus to enter the cavernous sinus and the superior orbital fissure.

Abducens nerve lesions cause binocular horizontal diplopia with an esotropia in ipsilateral gaze. In partial abducens nerve palsies, abduction may be only minimally impaired; alternate cover or red Maddox rod testing will demonstrate an incomitant esotropia. Abducens nuclear lesions cause an ipsilateral conjugate gaze palsy, where the abduction deficit of the ipsilateral eye is accompanied by an adduction deficit of the contralateral eye.

Duane type I retraction syndrome is a congenital dysinnervation syndrome that may be mistaken for an abducens palsy. This syndrome results from hypoplasia of the abducens nucleus, producing decreased abduction; however, in contrast to abducens palsies, patients with Duane type I retraction syndrome demonstrate retraction of the globe with adduction (evidenced by palpebral fissure narrowing).

Multiple Ocular Motor Nerve Palsies

Multiple ocular motor palsies should be localized either anatomically (e.g., all related to cavernous sinus disease) or through pattern recognition (e.g., ophthalmoplegia, ataxia, and confusion related to Wernicke encephalopathy). Cavernous sinus lesions commonly produce multiple cranial neuropathies, and may be related to neoplasms (e.g., meningioma, pituitary adenoma, metastasis), vascular causes (e.g., aneurysm, thrombosis, or carotid-cavernous fistulas), or inflammatory conditions (e.g., Tolosa–Hunt syndrome).

Miller Fisher Syndrome

Miller Fisher syndrome is an inflammatory polyneuropathy producing the classic triad of ophthalmoplegia, areflexia, and ataxia. It shares some features with acute inflammatory demyelinating polyradiculoneuropathy (AIDP) including increased cerebrospinal fluid (CSF) protein concentration without pleocytosis. Anti-GQ1b antibodies are present in the serum of most patients with Miller Fisher syndrome. Symptoms typically spontaneously remit in 2 to 3 months, perhaps accelerated by intravenous immunoglobulin or plasma exchange therapy.

Internuclear Ophthalmoplegia

Internuclear ophthalmoplegia is related to dysfunction of the medial longitudinal fasciculus, serving to connect the abducens nucleus to the contralateral oculomotor nucleus, coordinating binocular horizontal eye movements. Lesions may be unilateral or bilateral and commonly result from demyelination (the prototypic cause of diplopia in MS) or ischemia from basilar perforators.

Patients may report frank binocular horizontal diplopia (or oblique if the internuclear ophthalmoplegia is associated with skew deviation), but otherwise may note “dizziness” or visual blurring, or are asymptomatic. Slow adduction of the ipsilateral eye is the essential element; incomplete adduction is only present in a minority of cases, emphasizing the need to examine rapid horizontal saccades to make the diagnosis. Abducting and vertical gaze-evoked nystagmus are common accompaniments. Most improve spontaneously, whether due to demyelination or ischemia; the prognosis is less favorable with larger lesions accompanied by other signs of brainstem dysfunction.

Neuromuscular Junction Dysfunction

The estimated prevalence of myasthenia gravis (MG) is around 15 to 20 per 100,000 population in the United States. It has a bimodal distribution, tending to occur in the third decade among women and the seventh decade among men. MG presents with ocular signs and symptoms in up to 70 percent of cases. The rate of conversion from pure ocular disease to generalized MG is approximately 50 percent, typically in the first 2 to 3 years following presentation.

Antibodies against the nicotinic postsynaptic acetylcholine receptor are present in the serum of approximately 90 percent of patients with generalized MG but only about 50 percent of those with purely ocular MG. Some patients without these antibodies harbor antibodies to other neuromuscular junction components, such as muscle-specific kinase (MuSK) and low-density lipoprotein receptor-related protein (LRP-4).

Classically, MG causes ptosis of one or both eyelids and diplopia, but there are numerous variations. Ptosis or diplopia may be absent or intermittent, especially early in the course of the disease. Diplopia may be vertical, horizontal, oblique, or torsional, depending on the extraocular muscle involvement. The orientation and degree of diplopic object separation often vary over time, providing an important clue to the diagnosis, especially in seronegative cases. Associated clinical features of generalized MG include dysarthria, dysphagia, facial and orbicularis oculi weakness, and proximal limb weakness.

MG can cause weakness in any pattern of extraocular muscles; weakness of the medial rectus muscle is relatively common, sometimes closely mimicking the pattern seen with internuclear ophthalmoplegia. Patients often have gaze fatigue (gradual onset of extraocular weakness while attempting to hold eccentric gaze). Fatigable ptosis with sustained upgaze is also diagnostically helpful. The Cogan lid twitch is a sensitive (but not completely specific) sign of MG that is elicited by having the patient look at a target in downgaze for a few seconds, then saccade back to the primary position. A Cogan eyelid twitch appears as a 1- to 2-mm drop of eyelid elevation immediately after return to the primary position.

The ice and rest tests may be useful in the evaluation of suspected MG. The ice test is performed by placing an ice pack over a ptotic eyelid for 1 to 2 minutes and noting whether this reduces ptosis; it is likely that at least part of the ice test effect involves rest, as it is common for ptosis of both eyelids to improve somewhat after application of ice to one eyelid.

Edrophonium (Tensilon), a short-acting acetylcholinesterase inhibitor, can be used to demonstrate transient improvement in ocular signs related to neuromuscular junction defects. Dramatic improvement in ptosis is diagnostically useful. However, the test has both false-positive and false-negative results, and potentially dangerous side effects including bradycardia. Due to these limitations, Tensilon testing is rarely performed.

Nerve stimulation studies and electromyography provide the most sensitive method of quantifying neuromuscular defects. A decremental response to repetitive stimulation of a motor nerve is seen with postsynaptic neuromuscular junction disorders such as MG but is rarely seen in the pure ocular form of the disease. Single-fiber electromyography demonstrates increased variability in timing of activation of individual fibers within the same motor unit, referred to as jitter, in over 90 percent of MG cases.

Thymoma is present in approximately 10 percent of patients with MG, while thymic hyperplasia is present in approximately 70 percent. Thymectomy is routinely considered in thymoma cases, and a large multicenter trial showed its efficacy in younger patients with generalized MG to reduce the long-term corticosteroid requirement to maintain symptom control.[12] The decision to perform thymectomy in patients with purely ocular MG is made on an individual basis depending on the medication requirements for adequate symptom control, general medical health of the patient, and patient input.

Cholinesterase inhibitors such as pyridostigmine started at 30 to 60 mg three times daily are usually the first-line therapy in patients with ocular MG because of their relatively rapid onset of action and tolerable side-effect profile; however, most patients will also require immunomodulatory medications such as prednisone. Prednisone can be started in low-dose regimens, escalating as required; a corticosteroid-sparing medication such as azathioprine or mycophenolate mofetil can be started if long-term corticosteroid therapy is required.

Mechanical Causes of Diplopia

The most common acquired causes of extraocular muscle dysfunction in adults are thyroid eye disease, orbital trauma, and neoplasm.

Thyroid eye disease may occur with hyper-, hypo-, or euthyroid states and usually runs a course independent of the underlying thyroid disease (see Chapter 18). Thyroid eye disease typically produces painless proptosis, restriction of extraocular muscles with diplopia, eyelid retraction, and variable orbital inflammatory features. Lid retraction commonly leads to dry eye and corneal irritation, prompting treatment with corneal lubrication.

The inferior and medial recti are the most commonly involved muscles (typically with sparing of the tendinous insertions), producing hypotropia and esotropia. In approximately 10 percent of cases, extraocular muscle enlargement may produce an orbital apex syndrome resulting in compressive optic neuropathy. The diagnosis of thyroid eye disease is clinical, with imaging confirmation being somewhat helpful.

Treatment begins with correction of any thyroid derangements. Corticosteroids are used when proptosis is severe. Selenium and teprotumumab have been shown to be efficacious. Cases complicated by compressive optic neuropathy typically require urgent orbital decompression. Once stability has been established, which often takes 6 to 12 months, an orbital decompression can be performed to alleviate significant proptosis if necessary; diplopia may be addressed with strabismus surgery; and finally eyelid surgery can be performed to address eyelid retraction.

Orbital trauma not infrequently causes diplopia, often in the form of extraocular muscle entrapment. Blow-out fractures of the orbital floor may produce inferior rectus entrapment, often requiring surgical repair.

Orbital neoplasms (e.g., lymphoma, metastasis) or sinus-related processes that extend into the orbit (e.g., infection, nasopharyngeal carcinoma, mucoceles) may also produce mechanical dysfunction of the extraocular muscles and diplopia.

Excellent orbital imaging is achievable with computerized tomography (CT) or MRI, and the choice depends on the individual case. The advantages of CT include speed, multiplanar capability with newer scanners, and excellent bone detail, while MRI advantages include superior soft tissue resolution, multiplanar capability, and the lack of ionizing radiation.

Nystagmus and Other Abnormal Eye Movements

Nystagmus refers to abnormal spontaneous rhythmic eye movements that must include a slow phase. Jerk nystagmus is characterized by a series of slow phases followed by fast phases, while pendular nystagmus has back-to-back slow phases. Although nystagmus by convention is named for the direction of the fast phase, it is the slow phase that informs the clinician more about the pathophysiology.

The primary symptom directly correlating with nystagmus is oscillopsia, defined as the illusion of environmental movement, although patients with infantile-onset nystagmus are often asymptomatic.

Examination should emphasize looking for stability of the eyes in the primary position with and without ocular fixation and in sustained lateral and vertical positions of gaze. Abnormal involuntary eye movements should be evaluated for the presence of slow and fast phases, directionality, presence in one or both eyes, and the influence of position of gaze, posture, or time. Peripheral vestibular nystagmus is best observed without patient fixation, which can suppress the abnormality. Frenzel lenses provide a highly magnified view of the eyes and prohibit patient viewing, but this can also be accomplished by observing rhythmic movements of the fundus while performing ophthalmoscopy and occluding the opposite eye. Video-oculographic recordings provide objective and quantifiable assessment of ocular oscillations. The key patterns of commonly encountered nystagmus include gaze-evoked, peripheral vestibular, central vestibular, see-saw, and congenital patterns.

GAZE-EVOKED NYSTAGMUS

Once the eyes have moved to an eccentric position, elastic forces of the orbit pull the eyes back toward midline. To maintain steady eccentric gaze, centers in the brainstem and cerebellum known as the *neural integrators* provide the correctly calibrated amount of continued input (referred to as the *step function*) to the relevant ocular motor nuclei. Direction-changing nystagmus results from dysfunction of the neural integrators. The eyes develop slow phases back toward the primary position and require a fast corrective phase to return to eccentric gaze; the slow phase is always toward primary position. The neural integrator for horizontal gaze includes the flocculus and nodulus of the cerebellum, the nucleus prepositus hypoglossi, and the medial vestibular nuclei for horizontal movements, and for vertical gaze includes the interstitial nucleus of Cajal.

While physiologic endgaze nystagmus is characterized by a few beats of symmetric jerk nystagmus at the extremes of horizontal gaze, pathologic gaze-evoked nystagmus is characterized by sustained nystagmus, asymmetry (e.g., present in right but not left gaze), and sometimes other features such as rebound nystagmus. Rebound nystagmus is demonstrated by holding lateral gaze for several seconds during which sustained gaze-evoked nystagmus occurs, then observing a reversal of the direction of nystagmus upon return to the primary position (e.g., gaze-evoked right-beating nystagmus in right gaze is followed by a few beats of left-beating nystagmus after return to the primary position). Pathologic gaze-evoked nystagmus typically localizes to the ipsilateral cerebellum or its connections. Medications including anticonvulsants and sedatives may produce symmetric sustained gaze-evoked nystagmus.

PERIPHERAL VESTIBULAR NYSTAGMUS

Peripheral vestibular nystagmus typically contains torsional and either horizontal or vertical waveforms, and can be partially suppressed with visual fixation. In acute vestibular neuritis with dysfunction of all three semicircular canals, the typical nystagmus is characterized by a slow phase with horizontal and torsional components toward the paretic vestibular side followed by corrective fast phases away from the paretic side. This nystagmus is not direction-changing with different directions of gaze; the fast phase of the nystagmus is always away from the paretic side. Peripheral vestibular nystagmus generally obeys Alexander law: nystagmus is more pronounced in gaze in the direction of the fast phase and less pronounced (or perhaps not present at all) in gaze in the opposite direction. Large cerebellopontine angle tumors may produce Brun nystagmus, which is the combination of ipsilesional gaze-evoked nystagmus and contralesional peripheral vestibular nystagmus.

Benign paroxysmal positional vertigo (BPPV) presents with multiple brief episodes of vertigo, unlike the acute continuous vestibular syndrome caused by conditions such as vestibular neuritis or posterior circulation stroke. BPPV usually results from a canalith dislodged unto the posterior semicircular canal (with afferent connections to the ipsilateral superior oblique and contralateral inferior rectus). The pathognomonic finding on the Dix—Hallpike maneuver, therefore, consists of an upbeating torsional nystagmus toward the affected ear when the head is placed with that side down.

CENTRAL VESTIBULAR NYSTAGMUS

Central vestibular nystagmus typically results from lesions of the vestibulocerebellum (i.e., flocculus, nodulus, and vermis) or associated connections within the brainstem. Etiologies include brainstem and cerebellar processes such as infarcts, demyelination, neurodegenerative disorders, toxins, neoplasms, or Chiari malformations. Downbeat is the most common direction of central vestibular nystagmus; it is accentuated by, or may only be present in, down and lateral gaze. Upbeating nystagmus is much less common than downbeat nystagmus, and is usually associated with lesions in the medulla or cerebellum often related to demyelination, ischemia, or nutritional deficiency (e.g., Wernicke encephalopathy). Unlike peripheral nystagmus, central vestibular nystagmus is not influenced by visual fixation. Some patients with central vestibular nystagmus may respond partially to medications such as clonazepam, baclofen, gabapentin, memantine, or 4-diaminopyridine.

Periodic alternating nystagmus is a rare horizontal jerk nystagmus that rhythmically oscillates in direction, amplitude, and frequency; for example, nystagmus with slow phases leftward that increase in amplitude and frequency over 45 to 90 seconds, then wane and are followed by the development of nystagmus with slow phases to the right with predictable periodicity. Periodic alternating nystagmus may be congenital or acquired, localizes to the cerebellar nodulus, and often is related to multiple sclerosis, cerebellar degeneration, Chiari malformation, infarct, or bilateral visual loss. It is important to recognize due to its localizing value, and it may respond to baclofen.

Pendular nystagmus is characterized by sequential slow phases in the horizontal, vertical, or torsional planes, often combined into elliptical waveforms. Acquired pendular nystagmus is most commonly related to multiple sclerosis. Oculopalatal myoclonus or tremor is a special circumstance of pendular nystagmus, with palatal myoclonus synchronous with the nystagmus. This syndrome develops months to years after a lesion within the Mollaret triangle (i.e., cerebellar dentate nuclei, red nucleus, through the central tegmental tract to the inferior olivary nucleus in the medulla) leading to hypertrophic degeneration of the inferior olives that can be appreciated on MRI.

SEE-SAW NYSTAGMUS

See-saw nystagmus is an unusual phenomenon characterized by dysconjugate oscillations with one eye elevating and intorting, while the contralateral eye depresses and extorts. See-saw nystagmus is often pendular, but may be jerk, and is more commonly acquired than congenital. It tends to be associated with parasellar lesions (e.g., craniopharyngioma) often accompanied by bitemporal hemianopia.

CONGENITAL NYSTAGMUS

Congenital nystagmus, or infantile nystagmus syndrome, typically appears in the first few months of life as conjugate horizontal nystagmus that remains horizontal even in vertical gaze. It may have a complex waveform with both slow-phase velocity-increasing jerk nystagmus as well as pendular movements in varying positions of gaze. Patients with congenital nystagmus often turn the head to place the eyes in a direction of gaze with the least nystagmus (i.e., the null position), and do not typically report oscillopsia. Visual acuity may be relatively preserved, or may be decreased from the congenital nystagmus itself or from associated afferent conditions such as optic nerve hypoplasia or ocular albinism.

Latent nystagmus, or fusional maldevelopment nystagmus syndrome, involves horizontal jerk nystagmus that appears under monocular viewing conditions with the slow phase toward the nasal field of the viewing eye; the slow phase reverses direction when occlusion is switched from one eye to the other. Latent nystagmus is always accompanied by esotropia.

Monocular "shimmering" nystagmus in childhood, with very-low-amplitude vertical or elliptical movements, can occur with the relatively benign condition known as spasmus nutans, or in the setting of anterior visual pathway glioma, thus requiring neuroimaging.

SACCADIC INTRUSIONS

Saccadic intrusions are composed entirely of fast phases that disrupt fixation, in contrast to nystagmus that has pathologic slow-phase eye movements. Saccadic intrusions can be categorized by their intersaccadic interval. Square-wave jerks are horizontal small-amplitude (<5 degrees) saccades separated by an intersaccadic interval of approximately 200 msec. Square-wave jerks are very common, and normal elderly patients may exhibit a few per minute; however, they indicate underlying pathology when they are more frequent or accompanied by other features such as extrapyramidal signs. Ocular flutter is a purely horizontal saccadic intrusion without an intersaccadic interval, while opsoclonus consists of multiplanar saccadic intrusions without an intersaccadic interval. These disorders typically result from paraneoplastic or postinfectious autoimmune conditions, and less commonly from multiple sclerosis, brainstem encephalitis, toxins, or severe metabolic derangements (e.g., hyperosmolar coma). Voluntary "nystagmus" resembles flutter, with rapid conjugate back-to-back horizontal saccades without an intersaccadic interval. Because there is no slow phase, these movements are not truly nystagmus. Individuals who can produce voluntary nystagmus can typically sustain it for no more than a few seconds, and often converge when inducing this movement.

OTHER OCULAR MOVEMENTS

Patients with superior oblique myokymia describe brief episodes of monocular oscillopsia due to very low-amplitude, high-frequency, paroxysmal torsional oscillations of the superior oblique muscle of one eye. Episodes typically last only seconds, but may recur numerous times throughout the day. If an episode occurs during examination, the movements are more easily observed with magnification, such as during slit-lamp biomicroscopy. The condition is benign and often responds to carbamazepine, baclofen, gabapentin, or topical β-blockers.

Oculomasticatory myorhythmia is a rare pendular, vergence oscillation that occurs in synchrony with contractions of the masticatory muscles; it is essentially pathognomonic of Whipple disease, a rare infection caused by *Tropheryma whipplei*, which may also produce fever, diarrhea, cognitive dysfunction, and arthralgias (see Chapter 13).

Coma is caused by lesions involving either the brainstem or cerebral hemispheres bilaterally, and the eye examination can assist in this differentiation. Slow conjugate roving horizontal eye movements generally indicate a structurally intact brainstem. Rare "ping-pong" gaze, consisting of alternating conjugate horizontal gaze every few seconds, most often occurs with a large acute pontine lesion, but can also occur with bilateral destructive lesions of the cerebral hemispheres.

Ocular bobbing is a rare but ominous sign consisting of rapid conjugate downward eye movements followed by a slow return to the primary position, usually accompanied by bilateral horizontal gaze palsies. Ocular bobbing indicates a destructive pontine lesion and very poor prognosis for neurologic recovery. Other variations of this type of eye movement abnormality are ocular dipping (slow downward movement followed by rapid return) and reverse bobbing (fast upward, then rapid return to primary), but these have less localizing or prognostic value.

THE PUPIL

Examination of the pupils provides helpful information in a variety of clinical contexts. In contrast to other evaluations of visual function such as of acuity, color discrimination, and visual fields, pupil testing is objective and can be performed even without patient cooperation.

Anatomy

The axons of retinal ganglion cells travel through the optic nerve and then through the optic chiasm, where just over 50 percent of the fibers decussate to the contralateral optic tract. Within the optic tract, some axons bypass the lateral geniculate body to enter the brachium of the superior colliculus and synapse in the pretectal nucleus. The pretectal nuclei send efferent projections to each other and to both Edinger–Westphal nuclei, which issue fibers that innervate the iris sphincter via the oculomotor nerve.

Pupil dilatation involves the sympathetic pathways, which begin with first-order neurons in the hypothalamus. Axons from these neurons traverse the brainstem to the thoracic cord level, where the second-order cell bodies reside. Axons from these neurons enter the paravertebral sympathetic chain, before coursing over the lung apex to the superior cervical ganglion, where the final third-order cell body originates. These third-order sympathetic axons ascend as a plexus surrounding the internal carotid artery to enter the cavernous sinus before passing through the superior orbital fissure into the orbit to innervate the iris dilator muscles.

Because the midbrain receives retinal input from each eye, afferent visual dysfunction does not produce a difference between the size of the pupils. For example, the unilateral optic nerve section does not produce anisocoria; the pupil will not exhibit a direct light reaction, but will react consensually to light stimulation of the opposite eye.

A relative afferent pupillary defect results from asymmetric light input and is elicited by the swinging flashlight test. With the patient viewing a distance object, the examiner shines a bright light alternately in each eye for 1 to 2 seconds. Normally, both pupils constrict when the light is swung from one eye to the other. A relative afferent pupillary defect exists if, instead, both pupils dilate each time the light is shined into one eye. This phenomenon occurs because the brain perceives less light when stimulating the impaired optic nerve compared to the amount of light perceived with stimulation of the normal optic nerve, and then the Edinger–Westphal nuclei appropriately cause dilation of both pupils. A relative afferent pupillary defect is a sensitive and objective indication of asymmetric optic nerve dysfunction and does not occur with functional visual loss, refractive error, media opacity, or mild retinopathies. The swinging flashlight test requires two eyes, but just one working pupil (the pupils are isocoric with afferent lesions, so viewing either pupil provides the same information).

The Near Response

The near response consists of convergence, pupillary miosis, and accommodation. If the examiner encounters a pupil with an impaired light reaction, the next step should be to assess the pupillary response to a near target, which is a more potent stimulus to cause pupillary constriction. Several conditions are characterized by light-near dissociation, most notably Parinaud dorsal midbrain syndrome, Adie tonic pupil (see later), Argyll Robertson pupils, and severe afferent visual loss. Argyll Robertson pupils are bilaterally small, irregular pupils with limited light response compared to a brisk near response and prompt dilatation to distance viewing. This pupil abnormality is most associated with neurosyphilis. Severe afferent visual loss from pregeniculate causes such as optic neuropathy or widespread retinopathy will also produce light-near dissociation, but the clinical picture is dominated by visual loss in this setting. Oculomotor nerve aberrancy with a pupil that constricts in attempted adduction also produces light-near dissociation, as can a widespread neuropathy with autonomic involvement (e.g., severe diabetic neuropathy).

Anisocoria

Anisocoria may have many causes ranging from benign to life-threatening. An approach emphasizing the pupil size and reaction in light and dark will help categorize possible causes.

PHYSIOLOGIC ANISOCORIA

Physiologic anisocoria is characterized by briskly reactive pupils that differ in size by less than 1 mm. Patients are asymptomatic, and, accordingly, old photographs may assist in dating the onset of the asymmetry. Physiologic anisocoria is present in 20 percent of the population and typically produces anisocoria that is equal in light and darkness or slightly greater in the dark with normally reactive pupils to light, darkness, and accommodation.[13]

TRANSIENT ANISOCORIA

Transient anisocoria is usually related to benign etiologies such as migraine. Ominous potential causes include aneurysm or uncal herniation, but are unlikely in the asymptomatic patient with a normal examination.

HORNER SYNDROME

Horner syndrome refers to sympathetic paresis causing miosis, ptosis, and anhidrosis, although the full triad is rarely present.

Sympathetic fibers from the hypothalamus descend through the brainstem, where they may be affected by a lateral medullary lesion (Wallenberg syndrome), and then descend into the spinal cord to the level of C8 to T1, where the second-order fibers begin. Radiculopathy may affect this segment of the nerve before it ascends the lung apex to reach the carotid artery, moving toward the superior cervical ganglion, the site of the third-order neuron. The third-order fibers ascend on the carotid artery (pupillomotor fibers via the internal carotid and vasomotor plus sudomotor fibers via the external carotid branches) into the cavernous sinus, and then traverse the superior orbital fissure with the first division of the trigeminal nerve into the orbit to innervate the pupil dilators and the Müller muscles of the eyelid.

Horner miosis is related to impaired dilatation, and accordingly the anisocoria is greatest in darkness. Slowed dilatation in darkness over the course of 15 to 40 seconds is quite suggestive of sympathetic paresis. The ptosis of Horner syndrome relates to impairment of the Müller muscles, which are small ancillary muscles that assist in lid opening. Upper-lid ptosis in Horner is typically only 1 to 2 mm, and lower-lid or "upside down" ptosis can be present. The anhidrosis in Horner syndrome varies with the site of the sympathetic lesion, including hemibody with lesions of the first-order neurons, hemiface with lesions of the second-order neurons, or just a small patch above the brow with lesions of the third-order neurons. Many Horner syndromes are incomplete; the miosis is the most recognizable and reliable feature to guide diagnosis.

When the clinical features of miosis and anisocoria are greater in darkness, and dilation lag and mild ptosis are somewhat ambiguous, pharmacologic studies may aid in the diagnosis. Cocaine instilled into the eye blocks norepinephrine reuptake, thus increasing norepinephrine's action at the synapse and producing pupil dilatation if the sympathetic chain is intact. In addition to mydriasis, cocaine causes lid retraction and blanching of the conjunctiva. Postcocaine anisocoria of 1 mm is specific for Horner syndrome as opposed to physiologic anisocoria.[14]

Apraclonidine testing has emerged as a convenient way to perform pharmacologic testing to identify Horner syndrome. It is an α_2-adrenergic agonist, but also has weak α_1 agonist properties. This α_1 activation is too weak to cause dilation of a normal pupil, but will dilate an iris dilator that shows denervation hypersensitivity, thus producing a reversal of the pre-existing anisocoria.[15] Ptosis associated with Horner syndrome often also temporarily resolves with apraclonidine testing. One caveat to bear in mind is that false-negative testing can occur with apraclonidine testing in the acute period after Horner syndrome develops. While apraclonidine is safe in adults, it has risks of causing respiratory depression in children, so cocaine pharmacologic testing is still used when necessary to confirm Horner syndrome in that population.

Distinguishing whether Horner syndrome is due to involvement of third-order neurons or to preganglionic (first- or second-order) neurons can be accomplished with the instillation of hydroxyamphetamine drops. This agent releases acetylcholine from intact third-order neurons; postinstillation increase in anisocoria of 1 mm generally indicates a Horner syndrome due to a lesion of third-order neurons. In general however, hydroxyamphetamine testing has insufficient specificity to be clinically valuable to direct additional diagnostic evaluation once Horner syndrome is diagnosed.

Localization of the lesion causing Horner syndrome can generally be accomplished based on other associated neurologic findings. Lesions of first-order neurons are always associated with other CNS features. Lesions of second-order neurons may be caused by lung lesions (Pancoast tumor) or tumors within the neck or mediastinum. Pain or cephalgia with a third-order Horner syndrome raises concern for carotid dissection or skull-base neoplasm, but can also be seen in association with trigeminal autonomic cephalgias, especially cluster headaches. In the case of isolated Horner syndrome without associated features to aid in localization, it is prudent to obtain imaging of the brain, vascular imaging of the neck, and imaging of the upper chest, in order to identify a structural cause. Approximately 50 percent of cases of isolated Horner syndrome remain idiopathic, without an identifiable underlying cause.

ANISOCORIA GREATER IN LIGHT WITH ABNORMAL PUPILLARY LIGHT REACTION

Mechanical disruption of the iris may produce a pupil that reacts poorly to light (and often dilates poorly to dark). Surgery is the most common mechanism that mechanically impairs the iris, but infection or inflammation with synechiae tethering the iris to the lens; trauma; and angle-closure glaucoma may also be responsible. Distorted pupil shape, a history of intraocular surgery, and poor reaction to mydriatic drops are all clues of a mechanical origin.

Angle-closure glaucoma is an important condition to recognize as it may lead to irreversible visual loss. In its most severe form, the pupil is mid-position and nonreactive to light, associated with a cloudy edematous cornea, conjunctival injection, and pain. Precipitating factors include darkness or mydriatic drops. The diagnosis is made clinically including documentation of elevated intraocular pressure, and treatment involves an urgent reduction in pressure by pharmacologic and then surgical means.

The parasympathetic fibers innervating the pupil sphincter travel with the oculomotor nerve; however, palsies of the third cranial nerve never cause isolated mydriasis as a general rule, and accompanying eye movement limitations or ptosis are almost always present.

Several pharmacologic agents may produce mydriasis if instilled in the eye, either intentionally or by accident. Both anticholinergics and sympathomimetics will produce mydriasis. Commonly encountered anticholinergic agents include atropine, scopolamine patches, inhalers, insecticides, and many plant sources (e.g., belladonna). These agents typically produce maximal mydriasis (around 9 mm) with no response to 1 percent pilocarpine drops. Sympathomimetics such as epinephrine, phenylephrine, hydroxyamphetamine, cocaine, decongestants, and adrenergic inhalers produce mydriasis with a dampened light response. These pupils retain some reactivity to 1 percent pilocarpine drops.

TONIC PUPIL

Tonic pupil results from an idiopathic parasympathetic lesion involving the ciliary ganglion or postganglionic short ciliary nerves within the orbit. Acutely, the pupil is dilated with partial paresis of accommodation and light reaction. This partial paresis produces sectoral palsy of the iris, with limited sections partially reacting; this phenomenon is best observed with the slit lamp. Patients may report photophobia and complain of blurring of vision when reading or looking at near objects. The muscle stretch reflexes in the legs may be depressed, constituting the Adie-Holmes syndrome. Some patients develop segmental anhidrosis (Ross syndrome). With time (at least 1 week), supersensitivity develops, and even dilute pilocarpine (0.1%) may produce pupillary miosis (a normal pupil has no response to this dilute preparation of pilocarpine). As the short ciliary nerves regenerate, they give rise to aberrant innervation of the iris sphincter subserving the near response, thus creating light-near dissociation. Once the pupil constricts to a near stimulus, dilatation occurs only very slowly on release of convergence. Over years, the Adie pupil tends to become the smaller pupil, but retains the light-near dissociation and tonic response to accommodation.

ANEMIA

Iron-Deficiency Anemia

Nonspecific neurologic symptoms of tiredness, fatigue, weakness, poor concentration, irritability, faintness, dizziness, tinnitus, and headache are commonly associated with anemia. Occasionally, more concrete neurologic syndromes arise, such as the association of both idiopathic intracranial hypertension and cerebral venous sinus thrombosis with iron-deficiency anemia. The intracranial hypertension may resolve and recur with resolution and recurrence of the iron-deficiency anemia. In some patients with iron-deficiency anemia, thrombocytosis may be so high that it suggests a myeloproliferative disorder. The increased platelet mass may result in transient ischemic attacks (TIAs) or cerebral infarction. Profound anemia, particularly when associated with thrombocytopenia, may produce a retinopathy with papilledema, cotton-wool exudates, flame-shaped hemorrhages, retinal edema, and even retinal detachment. Blindness is a rare but well-recognized complication of massive hemorrhage; swelling of the optic discs is followed within a few weeks by optic atrophy.

Focal neurologic signs may arise from severe anemia in conjunction with severe cerebral atherosclerosis; symptoms may resolve completely over hours as the hemoglobin is increased. Severe anemia may also produce signs and symptoms that mimic Guillain–Barré syndrome.

Transient erythroblastopenia of childhood may present with papilledema and transient hemiparesis.

Restless legs syndrome may also be associated with various forms of iron-deficiency anemia including that related to frequent blood donation. Diminished iron and iron storage protein is found in the substantia nigra in restless legs syndrome, even in the presence of normal serum levels of iron and ferritin. It is recommended that patients with ferritin levels less than 75 μg/L, receive iron supplementation with the goal of achieving a ferritin level exceeding 100 μg/L. Restless legs syndrome may be associated with genes involved in iron metabolism and a third of the population carries genetic or systemic factors making them susceptible to the syndrome when peripheral iron is reduced. Iron deficiency and a strong family history (present in 72%) are characteristic of childhood-onset restless legs syndrome.

The US Health, Aging and Body Composition (Health ABC) study identified an association between anemia and an increased 10-year risk of dementia. The precise relationship is unclear.

Vitamin B_{12} Deficiency

Vitamin B_{12} (cobalamin) is a water-soluble micronutrient that serves as a coenzyme for cytosolic methionine synthase and mitochondrial methylmalonyl-CoA mutase. Cellular deficiency of cobalamin results in elevated levels of the B_{12}-dependent metabolites, methylmalonic acid (MMA), and homocysteine. Serum vitamin B_{12} has limited diagnostic value as a stand-alone marker; low serum levels of vitamin B_{12} do not always represent deficiency, and severe functional deficiency has been identified in the presence of normal or even high levels of serum vitamin B_{12}. There are no well-defined cut-offs for deficiency—likely deficiency has been defined as a value of less than 148 pmol/L and possible deficiency as a value between 148 and 258 pmol/L. Falsely normal or elevated levels of vitamin B_{12} have been reported when high-titer intrinsic factor antibodies interfere with the competitive-binding luminescence assay. Falsely low levels have been associated with multiple myeloma, oral contraceptive use, folate deficiency, and pregnancy. MMA levels increase in the presence of cellular deficiency of biochemically active tissue vitamin B_{12}, often preceding reduced plasma cobalamin levels, such that elevated MMAs can be found in the presence of a serum cobalamin within the reference range. Elevated total serum homocysteine is a sensitive marker of cobalamin deficiency but may also be related to familial hyperhomocysteinemia, levodopa therapy, renal insufficiency, and folate deficiency.

Among elderly individuals with low vitamin B_{12} levels, 20 to 40 percent have normal homocysteine and MMA blood levels and therefore should not be considered deficient in vitamin B_{12}. Holotranscobalamin (metabolically active fraction of vitamin B_{12}) represents up to 20 percent of the total vitamin B_{12} present in serum. It has been suggested that it is more accurate in assessing the biologically active fraction of vitamin B_{12} in circulation than the serum B_{12} itself. It is not known whether and how holo-transcobalamin levels vary in patients with inborn errors of intracellular vitamin B_{12} metabolism.[1]

Vitamin B_{12} deficiency may be caused by Addisonian pernicious anemia (elevated intrinsic factor and parietal cell antibodies), vitamin B_{12} malabsorption syndromes (including gastric and ileal resections, terminal ileal removal for lower urinary tract reconstruction, blind loops, and infestation with fish tapeworm), and dietary deficiency, particularly in vegans. A range of medications such as metformin and proton-pump inhibitors may also transiently induce reversible cobalamin deficiency, as does nitrous oxide inhalation. Advanced-stage patients with Parkinson disease receiving continuous intraduodenal infusion of levodopa-containing intestinal gel develop peripheral neuropathies thought to arise from transient deficiency of vitamins B_6 and B_{12}.

Subclinical vitamin B_{12} deficiency rarely evolves into clinical deficiency and the need for its treatment has not been fully established in spite of its much higher prevalence than clinical B_{12} deficiency.

The neurologic complications of vitamin B_{12} deficiency may occur without appreciable alteration in the peripheral blood; erythropoiesis may even be normoblastic, notably when vitamin B_{12} deficiency coincides with iron-deficiency anemia. Elevated MMA and total homocysteine are useful in establishing the diagnosis.

Functional vitamin B_{12} deficiency is defined by elevated levels of the B_{12}-dependent metabolites, MMA, and/or homocysteine, despite normal serum vitamin B_{12} values. Failure of intracellular transport or metabolism of vitamin B_{12}, for example by mutations in the transcobalamin 2 gene, can lead to cellular B_{12} deficiency. Such patients may respond to high-dose injections of vitamin B_{12}.[2] Functional vitamin B_{12} deficiency is common in subjects with advanced malignancy and cancer-related neuropathic pain and may respond to vitamin B_{12} therapy.

Peripheral Neuropathy

Sensory symptoms of peripheral neuropathy may be identical to those of vitamin B_{12} myelopathy. Somatosensory evoked potentials become abnormal before changes develop in peripheral nerves. Electrophysiologic studies indicate that the length-dependent neuropathy is secondary to a dying-back type of axonal degeneration, and neuropathologic studies have demonstrated loss of large myelinated fibers in distal sensory nerves as well as axonal degeneration in teased-fiber preparations.

Myelopathy

Demyelination followed by axonal degeneration affects the most heavily myelinated fibers first, which may explain why lesions appear primarily in the posterior columns and then later in the lateral columns. Progression may be subacute or rapid.

Suspicion that a sensory neuropathy may be related to vitamin B_{12} deficiency should be raised by upper-limb onset or an associated Lhermitte phenomenon. Myelopathy is accompanied by early and severe impairment of proprioception and vibration sense, sometimes accompanied by motor signs of the neuropathy. A severe sensory ataxic spastic paraparesis may be the sole manifestation of the myelopathy. Bladder symptoms may occur later. Pseudoathetosis is rare but may be prominent. Magnetic resonance imaging (MRI) may reveal hyperintense T2 signal in the dorsal cervical cord. Similar changes may occur with copper deficiency that may also arise from malabsorption following upper gastrointestinal surgery.

Encephalopathy

Multiple foci or diffuse areas of demyelination occur with little evidence of glial cell proliferation or axonal degeneration. Symptoms include disorders of mood, mental slowing, poor memory, confusion, agitation, delusions, visual and auditory hallucinations, aggression, dysphasia, and incontinence.

Neuropsychiatric assessment in patients presenting to general physicians with vitamin B_{12} or folic acid deficiency identifies organic mental change of unspecified nature in around 25 percent of patients, and affective disorders in around 20 percent of patients. The response to vitamin B_{12} therapy is variable.

Optic Neuropathy

Optic neuropathy is rare and may be the presenting feature. Optic atrophy may ensue.

Disordered Eye Movements

Downbeat nystagmus, paralysis of upward gaze, and internuclear ophthalmoplegia have all been attributed to vitamin B_{12} deficiency and have responded to therapy.

INFANTILE VITAMIN B_{12} DEFICIENCY

Infantile vitamin B_{12} deficiency may result from maternal vitamin B_{12} deficiency causing encephalopathy, epilepsy, and microcephaly. Long-term cognitive impairment and developmental delay may ensue.

IMERSLUND–GRAESBECK SYNDROME

This is an autosomal recessive condition caused by a defect in the receptor of the vitamin B_{12}–intrinsic factor complex of the ileal enterocyte and resulting in megaloblastic anemia, proteinuria, and mild multiple neurologic abnormalities.

NITROUS OXIDE

Nitrous oxide, which is commonly used as a recreational drug, irreversibly binds to, oxidizes, inactivates, and depletes vitamin B_{12}. Prolonged use typically presents as subacute combined degeneration of the spinal cord, but other presentations include sensorimotor peripheral neuropathy with demyelinating features in the absence of clinical or imaging evidence of myelopathy. Recovery is variable.

Folate Deficiency

In adults, the neurologic manifestations of folate deficiency include impaired cognition, dementia, depression, peripheral neuropathy, and subacute combined degeneration of the spinal cord. Cerebral folate deficiency typically presents in early infancy with seizures, delayed motor and cognitive development, cerebellar ataxia, spasticity, and visual and hearing impairment. Juvenile and adult-onset cases also occur. Peripheral neuropathy caused by folate deficiency has been described in a few cases in the absence of thiamine and vitamin B_{12} deficiency and alcoholism. Subacute combined degeneration of the cord accompanying diet-induced folic acid deficiency may occur and improves after treatment with folic acid. A variety of folate transport and metabolic disorders have been described, and blocking antibodies against folate receptors have been found in the serum in 25 of 28 children with cerebral folate deficiency and in none of matched controls.

Sickle Cell Disease

The complications of sickle cell anemia (HbSS) or of sickle C disease (HbSC) arise from formation of sickle cells and from hemolysis, with free hemoglobin and other erythrocyte products scavenging nitric oxide. Sickle cells adhere to various receptors on vascular epithelium producing aggregates, activation of platelets, production of inflammatory cytokines, vasomotor dysfunction with vessel occlusion, and proliferative vasculopathy. Children with sickle cell disease have reduced levels of the majority of endothelial coagulation inhibitors, further enhancing the adhesive interactions between sickle cells and injured cell membranes and endothelial cells.

Sickling occurs when PO_2 is low. In the presence of circulatory stasis or reduced cardiac output, oxygen extraction is increased such that sickling is more likely to occur. In sickle cell trait, the severity of sickling depends on the amount of HbS; the percentage of HbS in sickle cell trait can vary from 25 to 45 percent. In circumstances of severe hypoxemia, even patients with sickle cell trait (HbSA) may develop symptoms.

One-quarter of patients with sickle cell disease have neurologic manifestations, with cerebral infarction being most common. Cerebral infarction on brain MRI in the absence of a history or physical findings of stroke occurs in 27 percent of patients before their sixth birthday, and 37 percent by their fourteenth birthday. Intracranial hemorrhage is much rarer; subarachnoid hemorrhage is the most common form and is usually aneurysmal in etiology. In children, hemorrhage tends to be primary and possibly related to vasculopathy leading to stenosis of large extracranial or intracranial vessels from fibrous proliferation of the intima. Moyamoya syndrome has been described in sickle cell disease and trait.

Less common neurologic features include cranial neuropathies, radiculopathy, ischemic mononeuropathy, radiculomyelopathy from vertebral collapse as a result of bone infarction, spinal cord infarction, hypopituitarism, ischemic optic neuropathy, TIAs, and seizures.

Hydroxyurea reduces the frequency of painful episodes by raising the level of HbF, reducing vaso-occlusive events and mortality, and is the accepted standard of care. Voxelotor, a hemoglobin oxygen-affinity modulator, inhibits hemoglobin S polymerization, increases hemoglobin oxygen affinity and reduced red cell sickling, hemolysis, and anemia, and is a promising and significant disease modifier.

Subcortical cerebral infarction and venous sinus thrombosis have also been described in sickle cell trait. Measurement of IQ in children with hemoglobin SS demonstrates modest reductions, suggesting diffuse brain injury.

Cerebrovascular complications are relatively uncommon in HbSC disease, but a proliferative retinopathy is described. Recurrent transient impairment of vision due to occlusion of major retinal vessels is an unusual manifestation of HbSS disease.

Thalassemia

Chronic anemias are associated with extramedullary hematopoiesis. There have been a few reports of spinal cord compression, most commonly in the middle to lower thoracic region. Surgical decompression plus radiotherapy is curative. Treatment with corticosteroids, blood transfusions, and local radiotherapy has also been successful. Transfusion to maintain the hemoglobin level above 12.5 g/dL may resolve minor compression of the spinal cord, with near-complete resolution of the extradural hematopoietic mass. Visual failure secondary to suprasellar extramedullary hematopoiesis in β-thalassemia has been described.

Severe forms of β-thalassemia, particularly following splenectomy, can be associated with hypercoagulability, with an increased risk of cerebral venous thrombosis. There is a reported association with moyamoya syndrome. Neurophysiologic evaluation demonstrates polyneuropathy in 39 percent, myopathy in 28 percent, and both in 17 percent of patients, correlating with iron overload.

Hereditary Spherocytosis

Hereditary spherocytosis has few neurologic sequelae. It is associated with a state of chronic anemia which results in a reduced cholesterol level and therefore a reduced rate of carotid occlusion and stroke. There have been reports of moyamoya syndrome in children with hereditary spherocytosis, and of anterior ischemic optic neuropathy in adults.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is a rare acquired hematopoietic stem-cell disorder arising from a range of mutations in the phosphatidylinositol glycan class A (*PIGA*) gene, resulting in a deficiency of a glycosyl phosphatidylinositol–anchored protein. It may occur de novo or in association with marrow hypoplasia, ranging from pancytopenia to aplastic anemia. It results in deficiency in the binding of several protective red cell membrane proteins and leads to hypersensitivity to complement. The disorder is characterized by intravascular hemolysis and manifested by episodes of hemoglobinuria and venous thrombosis. Hemolysis occurs throughout the day and is not paroxysmal, but hemoglobinuria is seen when the first concentrated urine is passed in the morning. The commonest manifestation is large-vessel venous thrombosis particularly in the brain and portal system. The spinal cord is not affected. An occasional patient suffers TIAs that have been attributed to the hypercoagulable state induced when excess thromboplastin is released from lysing red blood cells. Increased sensitivity of the red cells to lysis by complement stimulates platelet aggregation, leading to hypercoagulability. The hemoglobin released by hemolysis binds with circulating nitric oxide and inhibits the relaxation of smooth muscle, which results in abnormal tone of vascular smooth muscle, vasculopathy, and endothelial dysfunction. A neurologic cause of death is described in 10 percent of patients, including cerebral venous thrombosis, subarachnoid hemorrhage, and intracerebral hemorrhage. Moyamoya has been associated with paroxysmal nocturnal hemoglobinuria. The majority of patients without neurologic symptoms have brain MRI white matter abnormalities related to chronic ischemic small-vessel disease.

Eculizumab, a humanized monoclonal antibody that inhibits complement component C5, is an effective treatment, but allogeneic bone marrow transplantation is the only cure.

Cold Agglutinin Disease

Cold agglutinin disease is a form of autoimmune hemolytic anemia usually associated with IgM antibodies (rarely IgG and IgA cold-reactive autoantibodies) directed against erythrocytes with binding activity that increases as the temperature approaches

0°C. Cold-associated circulatory symptoms are very common. It is associated with a low-grade lymphoproliferative B-cell disorder in 90 percent of cases, but with a very low rate of developing overt lymphoma. Cold-induced circulatory symptoms with characteristic seasonal variations in anemia occur. The anemia is variable and usually not severe, though approximately 50 percent of patients are transfusion dependent at some time during the disease. Cold agglutinin–associated asymmetric sensory-motor neuropathy has been described as a feature of transformation to Waldenström macroglobulinemia.

Cryoglobulinemia

Cryoglobulins are serum proteins or protein complexes that undergo reversible precipitation at low temperatures. Three main types are recognized. Type I, most commonly monoclonal IgM or IgG, is seen in association with multiple myeloma, Waldenström macroglobulinemia, and other lymphoproliferative disorders. Type II consists of mixed immunoglobulin complexes in which the monoclonal antibody has specificity for polyclonal IgG and occurs in association with lymphoproliferative diseases, autoimmune disorders, and hepatitis. Type III cryoglobulin is composed of polyclonal immunoglobulin and is found in infections and autoimmune disorders. Neurologic complications are common in types II and III, with mononeuritis multiplex, peripheral symmetric sensorimotor axonal or demyelinating polyneuropathy, and small-fiber sensory neuropathy being the most common findings. More rarely, cerebral ischemia or vasculitis may occur.

Kernicterus

Kernicterus may be produced by any hemolytic process of sufficient severity in neonates, particularly in premature infants with physiologic jaundice. It is part of the spectrum of symptoms of acute bilirubin encephalopathy. In the developed world, an underlying cause is found in most patients. Glucose-6-phosphate dehydrogenase is a major source of protection from bilirubin-induced oxidative stress, and its deficiency syndrome leads to a high incidence of kernicterus. Whenever the serum unconjugated bilirubin level exceeds 20 mg/dL during the first few weeks of life, kernicterus may occur, though there is a poor correlation between bilirubin levels and disease severity. Unconjugated bilirubin is highly lipid soluble; it enters the brain and binds to neurons resulting in neuronal loss, demyelination, and gliosis, particularly in the basal ganglia and cerebellum. The neurologic features range from decreased alertness, hypotonia, and poor feeding to retrocollis, opisthotonos, and long-term sequelae. Chronic changes may evolve over a number of years, including the development of eye movement abnormalities, hearing loss, and extrapyramidal disorders (particularly athetosis and, less commonly, chorea). Cognitive function is relatively well preserved.

RARE NEUROLOGIC SYNDROMES AND RED CELL ABNORMALITIES

The term *neuroacanthocytosis* describes a number of conditions associated with abnormal erythrocyte membrane constituents, resulting in the formation of spiculated cells.

Pantothenate kinase–associated neurodegeneration, or neurodegeneration with brain iron accumulation type I (NBIA-1), is an autosomal recessive disorder in which classic forms are associated with *PANK2* mutations on chromosome 20. Patients are normal at birth but then develop acanthocytosis, dystonia, dysarthria, rigidity, occasional spasticity, cognitive impairment and dementia, pigmentary retinal degeneration, optic atrophy, and iron accumulation in the brain, particularly in the globus pallidus. MRI shows the "eye-of-the-tiger sign"—hyperintensity within the hypointense medial globus pallidus—but this sign may not be present in early cases. The classic form presents in the first decade, with progression and loss of independent ambulation within 15 years. Atypical forms develop in the second decade and progress slowly, with retained independent ambulation up to 40 years later. Intermediate forms are described. Early onset is associated with pigmentary retinopathy, whereas a later onset is associated with speech disorders and psychiatric features. Pantothenate kinase catalyzes the first committed step in the universal biosynthetic pathway leading to CoA and is located in the mitochondrial intermembrane space. Mutations in *PANK2* are also found in HARP syndrome (hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration).

Bassen–Kornzweig disease (neuroacanthocytosis with abetalipoproteinemia) is a recessively inherited syndrome characterized by acanthocytosis, retinitis pigmentosa, increasing cerebellar ataxia, peripheral neuropathy, steatorrhea, and complete or almost complete lack of serum β-lipoproteins, with onset during childhood. The microsomal triglyceride transfer protein (*MTTP*) gene is essential for synthesizing β-lipoproteins for the absorption and transport of fats and cholesterol. Mutations in the gene result in deficiency of fat-soluble vitamins, A, D, E, and K, though deficiency of vitamin E is the primary cause of the degeneration in spinocerebellar and dorsal columns of the spinal cord. Treatment with vitamins A and E as early as possible is helpful.

Chorea-acanthocytosis is an autosomal recessive disorder linked to the *VPS13A* gene on chromosome 9 which encodes chorein. The neurologic features commence between 25 and 45 years with behavioral change and obsessive-compulsive disorder, followed later by the development of progressive choreiform movements of the limbs, face, mouth, lips, and throat—lip and tongue biting is characteristic. Myopathy and neuropathy may occur. In addition, motor or vocal tics, dystonia, parkinsonism, progressive supranuclear palsy, and apraxia of eyelid opening have been described. Serum creatine kinase levels are elevated; serum lipoproteins are normal.

McLeod neuroacanthosis is an X-linked syndrome with absent expression of Kx erythrocyte antigens, weak expression of Kell glycoprotein antigens, and increased serum creatine kinase levels. A range of other features may include hemolytic anemia, myopathy, limb chorea, facial tics, lip and tongue biting, neuropathy, dystonia, seizures, psychiatric changes, cognitive impairment, and dilated cardiomyopathy.

Huntington disease-like syndrome (HDL2) is an autosomal dominant disorder found almost exclusively in people of African ancestry. It is characterized by a trinucleotide repeat in the junctophilin-3 gene. Acanthocytosis is a variable feature. There is striatal and cortical atrophy, as well as intranuclear protein aggregates. HDL2 is clinically and radiologically indistinguishable from Huntington disease, with typical juvenile and late-onset forms.

A progressive spinocerebellar syndrome and sideroblastic anemia occur together in an X-linked recessive mutation in the *ABCB7* gene that encodes the ATP-binding cassette subfamily B member 7, mitochondrial. It is a mitochondrial disorder caused by a mutation in the nuclear genome. Cerebellar ataxia and dysarthria develop by 1 year of age, with accompanying long-tract signs. The neurologic signs tend to be stable until the fifth decade, when slow progression may occur. Neuropathy and myopathy have been described in association with sideroblastic anemia.

Triosephosphate isomerase deficiency is a rare autosomal recessive metabolic disorder characterized by chronic hemolytic anemia, progressive neurologic dysfunction, and an increased susceptibility to infection. The neurologic features consist of a dystonic-dyskinetic syndrome with gross intention tremor and amyotrophy and hypotonia of the trunk and limbs, sometimes with corticospinal signs. There is electromyographic evidence of denervation with normal nerve conduction velocities, suggestive of anterior horn cell impairment. It has been suggested that low triosephosphate isomerase activity leads to a metabolic block in the glycolytic pathway and hence to an impairment of the cellular energy supply.

PROLIFERATIVE DISORDERS

Leukemia

Involvement of the central nervous system (CNS) is primarily due to infiltration with leukemic cells, but may occur as the result of hemorrhage, infection, drug- and radiation-induced neurotoxicity, electrolyte disturbance, and impairment of cerebral circulation from leukostasis.

MENINGEAL LEUKEMIA

The most common presenting symptoms are headaches, nausea, and vomiting, sometimes associated with lethargy and irritability, neck stiffness, drowsiness, coma, and convulsions. Diffuse meningeal infiltration impairs the circulation of CSF and can result in communicating hydrocephalus. Papilledema is the most common sign. The leukemic deposits may compress or infiltrate the cranial nerves or spinal nerve roots and spread between the nerve fibers.

The diagnosis of meningeal leukemia is confirmed on CSF examination in approximately 90 percent of cases. Flow cytometric analysis of CSF has the highest diagnostic yield. The CSF pressure is usually elevated and reduced glucose concentration may be found. In 10 percent of cases the CSF is normal and repeated CSF examinations may be required.

Acute myelomonocytic leukemia accompanied by pericentric inversion of chromosome 16 is a unique subtype associated with a high incidence of CNS involvement in the form of leptomeningeal deposits and granulocytic sarcoma (chloroma).

LOCALIZED LEUKEMIC DEPOSITS

Leukemic deposits may involve any part of the CNS (Figs. 25-1 and 25-2). The symptoms and signs are therefore numerous, varied, and depend on the extent and site of infiltration. Blindness may occur from infiltration of the optic nerve head or chiasm, and visual impairment from retinal infiltration. Bilateral serous macular detachment with visual blurring may be the presenting symptom of acute lymphoblastic leukemia. Mental nerve involvement that produces sensory impairment of the lower lip and painless traumatic ulceration of the buccal mucosa along with "numb chin syndrome" has been reported.

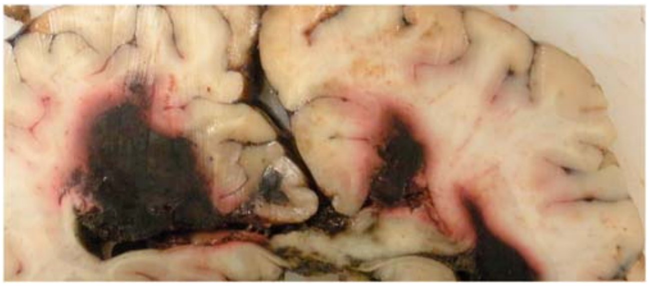

FIGURE 25-1 ■ Young male with relapse of acute B lymphoblastic leukemia complicated by multicentric intracerebral leukemic infiltrates with secondary intratumoral hemorrhage.

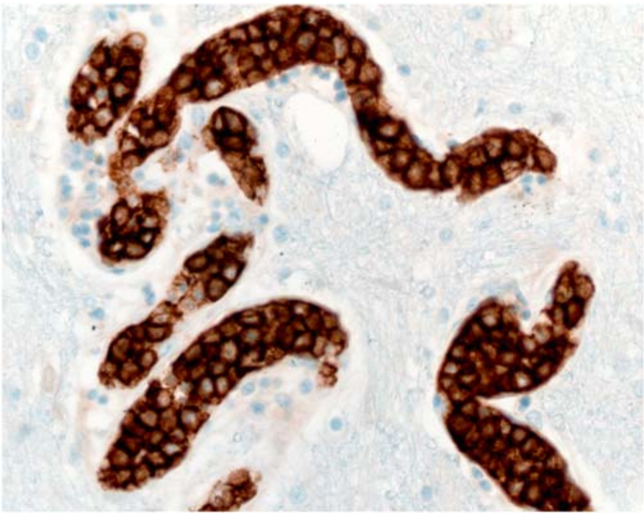

FIGURE 25-2 ■ Magnified image from Fig. 25-1 showing B-cell leukemic cells. Hematoxylin and eosin. Original magnification ×200.

Hypothalamic and pituitary dysfunction is well recognized and may be associated with hydrocephalus.

Clinically significant spinal cord involvement is unusual in leukemia; it is encountered most commonly with acute myeloid leukemia. Spinal cord syndromes arise from compression by extradural deposits; direct infiltration of the spinal cord and nerve roots; vascular occlusion by thrombus, leukemic cells, or some combination of these; or hemorrhage. Exceptionally, an acute paraneoplastic necrotizing myelopathy occurs, often with retinal changes.

Peripheral neuropathy caused directly by leukemia is rare.

CHLOROMAS (GRANULOCYTIC SARCOMA OR EXTRAMEDULLARY MYELOBLASTOMA)

Chloromas are solid tumors of nonlymphatic leukemia that are more common in children than adults. Granulocytic sarcoma develops in approximately 2.5 percent of cases of acute myeloid leukemia, and it may occur in myelofibrosis or myelodysplastic syndromes as part of transformation to acute leukemia. The majority of chloromas have a distinctive green color that fades on exposure to light. Most occur subperiosteally, usually in the cranial and facial bones, especially the paranasal sinuses, mastoid air cells, or orbits; they are usually attached to the dura mater and rarely invade cerebral tissue. Chloromas are radiosensitive.

INTRACRANIAL HEMORRHAGE AND THROMBOSIS

The overall incidence of intracranial hemorrhage (ICH) is around 3 percent among adult patients with hematologic malignancies. The incidence is greatest in patients with acute myeloid leukemia. Patients with intracranial lymphoma are more prone to ICH than those with acute leukemia. Chemotherapy-related endothelial injury and reduction of coagulation factors may each play a role in the pathogenesis.

Thrombocytopenia is a frequent feature of ICH and may in some cases be the result of disseminated intravascular coagulation (DIC) or leukemic infiltration of the bone marrow. Platelet production may also be impaired as a result of the myelotoxic effects of chemotherapy. Bleeding in the CNS is usually multifocal and may be confluent. DIC is a prominent feature of promyelocytic leukemia but, in other forms of leukemia, DIC is particularly marked in those with high peripheral white cell counts. It appears soon after the beginning of chemotherapy, presumably because tissue thromboplastins are released from destroyed leukocytes.

Both acute and chronic subdural hematoma may occur. Cisternal, cervical, or lumbar puncture in a thrombocytopenic patient with acute leukemia may cause a spinal subdural hematoma with resulting compression of the spinal cord or cauda equina. Cranial irradiation causes intracranial vessel narrowing and thrombotic occlusion in later life. Weakening of the vessel wall can also result in arterial dilatation and tortuosity. The sequelae of these changes are vascular malformation, aneurysmal dilatation, and arterial thrombosis.

CELLULAR HYPERVISCOSITY

Marked elevation of the white cell count may produce a significant increase in whole-blood viscosity. The signs and symptoms include headache, somnolence, and impairment of consciousness. All types of leukemia may produce this syndrome, but neurologic symptoms may occur more readily in myelogenous leukemias at lower leukocyte counts, reflecting the larger cell size.

Treatment with leukapheresis may abolish the symptoms. Blood transfusions may be hazardous because they may further elevate viscosity.

INFECTIONS

In all leukemias, but particularly in the lymphoblastic leukemia of childhood, viruses (especially mumps, measles, and varicella) are the most common infective organisms of the CNS. Bacterial and fungal infections, especially aspergillosis, also occur. The increased incidence of involvement of the CNS with rare organisms or organisms that are normally nonpathogenic is contributed to by the widespread use of corticosteroids, chemotherapy, and broad-spectrum antibiotics.

LEUKOENCEPHALOPATHY AND OTHER ENCEPHALOPATHIES

A variety of encephalopathic complications of chemotherapy, radiotherapy, and opportunistic infection are discussed in detail in Chapters 28 and 44.

Myelomatosis

Myelomatosis is the best-recognized expression of the plasma cell dyscrasias, which include Waldenström macroglobulinemia, monoclonal gammopathy of unknown significance (MGUS), paraproteinemias, plasmacytoma, plasma cell leukemia, primary amyloidosis, and the heavy-chain diseases. The major neurologic complications are: (1) compression of the spinal cord, cauda equina, or solitary nerve roots; (2) cranial nerve involvement; (3) intracranial myeloma; and (4) peripheral neuropathy. Pure meningeal myeloma is rare and presents with confusion, altered consciousness, and cranial nerve palsies. In 20 percent of cases, it is associated with plasma cell leukemia. Multiple myeloma with hyperviscosity may result in cerebral infarction.

SPINAL MYELOMA

The vertebrae are commonly infiltrated by myeloma cells, which may extend into the extradural space. Vertebral body collapse may produce neurologic deficits. Acute paraplegia sometimes occurs due to spontaneous epidural hematoma.

Extradural myeloma tumor may occur without local bone involvement, and intradural deposits may arise by spread along nerve roots via intervertebral foramina, causing radicular symptoms and signs. Spinal cord compression is sometimes caused by amyloid deposits. Infiltration of the spinal cord by myeloma cells and paraneoplastic myelopathy is rare. The lower thoracic area of the spinal cord is the most commonly affected. Patients with IgA myeloma seem to be at greater risk of spinal cord compression.

Neurologic symptoms usually develop comparatively slowly but may do so over 1 or 2 weeks. Back pain for several weeks or months commonly precedes evidence of spinal cord compression.

CRANIAL MYELOMA

Cranial myeloma is rare. The predominant sites of occurrence are the region of the sella and cavernous sinus, the body of the sphenoid, and the apex of the petrous bones. Orbital myeloma is well recognized and may present as an orbital mass with proptosis and ophthalmoplegia. Infiltration of the optic nerve may occur with features of optic neuritis. Ophthalmoplegia results from amyloid infiltration of the extraocular muscles. Primary plasmacytomas may originate in the cranial vault or the dura. Direct infiltration of the brain by myeloma cells is exceptionally rare, as is diffuse meningeal involvement.

Symptoms and signs of elevated intracranial pressure are often the earliest indications of intracranial myeloma. Other manifestations depend on the site of the lesion. Concomitant renal failure, anemia, hypercalcemia, and hyperviscosity contribute to symptoms.

PERIPHERAL NEUROPATHY

Five types of neuropathy have been described in association with myelomatosis:

1. Paraneoplastic neuropathy producing demyelination and axis cylinder degeneration
2. Ischemic neuropathy due to amyloid deposition in the vasa nervorum
3. Amyloid infiltration of the peripheral nerves
4. Infiltration of the peripheral nerves by myeloma tissue
5. Drug-induced neuropathy

Neuropathy occurring in myelomatosis is heterogeneous, arising from perineural or perivascular immunoglobulin deposition, with or without amyloid infiltration. It is particularly associated with IgG and IgM myeloma. The neuropathy is a typically mild, progressive, length-dependent, symmetric, sensory, or sensory-predominant mixed neuropathy. Amyloid deposition leads to a painful small-fiber neuropathy. Direct infiltration by myeloma or amyloid tissue may produce an asymmetric or mononeuritic picture.

Although it is a complication of the established disease in diffuse myelomatosis, a paraneoplastic neuropathy is usually the presenting feature of a solitary, commonly sclerotic, plasmacytoma. This combination has a distinct male predominance. The neuropathy is usually sensory-motor, with the motor component predominating. Localized radiotherapy to the bone lesion effectively arrests and usually alleviates the neuropathy with good long-term survival.

The POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) is a type of plasma cell dyscrasia associated with osteosclerotic myeloma. The major criteria for the diagnosis are the presence of polyneuropathy, with a clonal plasma cell disorder, sclerotic bone lesions, elevated vascular endothelial growth factor (VEGF), and the presence of Castleman disease (lymphoid hyperplasia with marked follicular capillary proliferation and endothelial hyperplasia, which may be restricted to a single lymph node or may be a more generalized lymphadenopathy). POEMS syndrome should be distinguished from the Castleman disease variant of POEMS syndrome, which has no clonal plasma cell disorder and typically little or no peripheral neuropathy. POEMS syndrome can be distinguished from standard multiple myeloma by a number of features; the dominant symptoms are typically neuropathy, endocrine dysfunction, and volume overload. Bone pain, extremes of bone marrow infiltration by plasma cells, or renal failure are not major features. VEGF levels are high (and correlate with disease activity), sclerotic bone lesions are present in the majority of cases, overall survival is better, and lambda clones predominate.

The bone marrow contains less than 5 percent plasma cells in POEMS syndrome (in multiple myeloma, the bone marrow contains more than 10% plasma cells) but demonstrates megakaryocyte hyperplasia and clustering reminiscent of a myeloproliferative disorder (significantly, the *JAK2* V617F mutation is absent). Patients with osteosclerotic myeloma usually have multiorgan involvement including skin change, lymphadenopathy, papilledema, peripheral edema, hepatomegaly, splenomegaly, and ascites. New criteria have been developed for POEMS syndrome and any patient with a diagnosis of chronic inflammatory demyelinating polyneuropathy not responding to standard therapy should undergo investigations to rule in or exclude the diagnosis of POEMS syndrome.[3]

The neuropathy is of a symmetric sensory-motor demyelinating type, with clinical similarities to chronic inflammatory demyelinating polyneuropathy, including an elevated CSF protein concentration. Possibly as a result of thrombocytosis, there is a 13 percent risk of stroke over 5 years.

A particularly localized form of neuropathy due to infiltration of the carpal tunnel by amyloid deposits is well recognized. Concurrent neuropathy and myositis due to sarcolemmal deposits of IgD in IgD myeloma has been described.

Neuropathy may also be a consequence of drug treatments for myeloma. Thalidomide induces a length-dependent sensory-motor neuropathy with autonomic involvement in 70 percent of patients treated for 12 months. Bortezomib and vincristine may also result in neuropathy, although there appears to be an interaction between myeloma-related factors and the patient's genetic background in the development of treatment-induced peripheral neuropathy.

Neurologic Effects of Metabolic Complications

Neurologic complications may result from hypercalcemia, uremia, and hyperviscosity. Symptomatic hyperviscosity is much more common in Waldenström macroglobulinemia (10 to 30%) than it is in myeloma (2 to 6%). Symptoms of hyperviscosity usually appear when the normal serum viscosity of 1.4 to 1.8 centipoise (cP) reaches 4 to 5 cP, corresponding to a serum IgM level of at least 3 g/dL, an IgG level of 4 g/dL, and an IgA level of 6 g/dL.

Hypercalcemia and uremia cause increasing headaches, confusion, disorientation, somnolence, stupor, coma, uremic convulsions, and myoclonic twitching.

Neurologic Complications of Immunodeficiency

Immunodeficiency is a common feature of myelomatosis. In the CNS, this is reflected by the development of meningitis (bacterial, viral, fungal) and cerebral abscess. Pneumococcal infection is particularly implicated, as is herpes zoster virus and, more rarely, cryptococcosis and toxoplasmosis. Profound septicemia may be complicated by cerebral DIC. Progressive multifocal leukoencephalopathy may also occur.

Macroglobulinemia (Waldenström Disease)

This is a lymphoplasmacytic lymphoma with IgM monoclonal protein. Almost all patients have a preceding phase of IgM MGUS. Clinical features include anemia, thrombocytopenia, hepatosplenomegaly, lymphadenopathy, and rarely hyperviscosity. The L265P mutation in the *MYD88* gene is found in more than 90 percent of cases, approximately 50 percent of patients with IgM MGUS, and the majority of patients with anti-MAG paraprotein-associated peripheral neuropathy, sometimes in the absence of an identifiable IgM MGUS.

Neurologic symptoms occur in 25 percent of patients with macroglobulinemia. An antibody-related neuropathy is found in 5 to 10 percent of cases and is associated with IgM kappa antimyelin-associated glycoprotein antibodies. Other mechanisms such as lymphocytic infiltration of the peripheral nerves, amyloidosis, and a bleeding tendency may also result in neuropathy.

Bing Neel syndrome is a rare disease manifestation of Waldenström macroglobulinemia, usually presenting as a feature of relapsing disease, although it may occur at first diagnosis. Malignant lymphoplasmacytic cells invade the CNS. Cells may be found in the CSF, the meninges, and/or the cerebral parenchyma. Symptoms are progressive and reflect involvement of the central and, rarely, the peripheral nervous system. Headache, nausea and vomiting, visual disturbances, hearing loss, and cranial neuropathies, mostly of the facial or oculomotor nerves, usually accompany meningeal involvement. Seizures, cognitive decline, aphasia, psychiatric symptoms, cerebellar dysfunction, impairment of consciousness including coma, and sensory and motor symptoms and signs result from involvement of the brain and spinal cord.

Other neurologic complications relate to hyperviscosity and bleeding tendency. Exceptionally, Waldenström disease is complicated by primary intracerebral lymphoma, progressive multifocal leukoencephalopathy, or a humorally mediated immune myopathy from IgM-κ antibodies directed against muscle surface protein. A wide range of therapies are available, many of which have neurotoxicity.

Light/Heavy-Chain Deposition Disease

A variety of lymphoplasmacytic processes may produce abnormal light or heavy chains such as chronic lymphocytic leukemia or lymphoma and nodal marginal cell lymphoma. These may be the result of the emergence of a mutated clone of plasma cells that occurs after the use of certain chemotherapeutic agents such as melphalan. Light/heavy-chain deposition disease may occur in the absence of detectable underlying systemic neoplastic lymphoproliferative processes, even after prolonged follow-up for more than 10 years. Light-chain deposition disease may be associated with a local clone of plasma cells (extramedullary plasmacytomas), most commonly in the sixth decade.

Peripheral neuropathy is found in approximately 20 percent of cases. Light-chain deposits may be seen in the endoneurium. In cases of light-chain deposition disease, peripheral nerve involvement has been reported occasionally. Serum-free light-chain testing is more sensitive than urine electrophoresis for diagnosis.

Paraproteinemias

Monoclonal gammopathy of unknown significance (MGUS) is characterized by low-titer (<3 g/dL) bands of IgM, IgG, or IgA. They are found in 1 percent of healthy individuals over the age of 25 years, increasing to 3 percent in those over 70 years. The majority are IgG; less than 15 percent are IgM. The somatic point mutation of the *MYD88* gene has been identified in more than 90 percent of patients with Waldenström macroglobulinemia, in approximately 50 percent of patients with IgM MGUS, and the majority with anti-MAG neuropathy, not all of whom have an identifiable IgM MGUS. The prevalence of MGUS in those with idiopathic neuropathy is 10 percent, of which IgM accounts for 50 percent of cases, especially those with demyelinating neuropathies. Immunoelectrophoresis or immunofixation may be required to detect smaller bands. Urine light chains are rare. In MGUS, the marrow contains less than 5 percent plasma cells; blood counts are normal, and lymphadenopathy, organomegaly, and skeletal lesions do not occur. Investigation may identify primary systemic amyloidosis, myeloma, plasmacytoma, macroglobulinemia, cryoglobulinemia, lymphoma, or lymphoproliferative disorder. Approximately one-third of patients with MGUS will develop myeloma, macroglobulinemia, amyloidosis, or a lymphoproliferative disorder over 20 years; this is sometimes heralded by an unusually rapid, progressive course of the neuropathy. The risk of progression of MGUS to multiple myeloma or related disorders is influenced by the underlying cytogenetic type; patients with t(4;14) translocation, del(17p), and gain(1q) are at a higher risk of progression to multiple myeloma.

Approximately 5 percent of patients with MGUS will develop a polyneuropathy, associated in the majority with an IgM band. The median age of onset is in the sixth decade with a slowly progressive, distal, symmetric sensory–motor polyneuropathy or, less commonly, a predominantly sensory neuropathy. A presentation resembling chronic inflammatory demyelinating polyneuropathy is well recognized, although this condition differs from the typical form due to more dominant sensory symptoms, an older age at onset, and a slower, more progressive course. Neurophysiologic studies commonly demonstrate a mixed axonal and demyelinating picture. Predominant axonal degeneration is uncommon; pure demyelination is particularly associated with IgM MGUS. CSF protein levels may be markedly elevated.

Antibody to MAG expressed on Schwann cells may be seen with lymphoid malignancy such as myeloma, plasmacytoma, or Waldenström macroglobulinemia, and in as many as half of the cases of IgM MGUS. The neuropathy has a particular phenotype of a distal acquired demyelinating symmetric sensory and motor neuropathy. About 17 percent of patients with anti-MAG neuropathy present with an atypical clinical phenotype including acute or chronic sensorimotor polyradiculoneuropathies and asymmetric or multifocal neuropathy. It is slowly progressive with prominent sensory ataxia and tremor. Histologically there is widening of the myelin lamellae.

The clinical pattern of antisulfatide antibody neuropathy is a sensory-predominant, distal, symmetric polyneuropathy, which may be axonal or demyelinating in type. There is significant coexpression with anti-MAG antibodies. Isolated antisulfatide antibody-associated neuropathy accounts for about 5 percent of the cases of IgM gammopathy. The clinical pattern is similar to that of the neuropathy associated with anti-MAG antibodies but pain and small-fiber symptoms are more common, and they are more likely to be refractory to treatment.

Other binding specificities are described, including GM1 ganglioside and disialosyl gangliosides. If the anti-MAG assay is negative in the presence of an IgM-associated peripheral neuropathy, testing for IgM antibodies against GM1, GD1a, GD1b, GT1b, GM2, and GM3 and the paragloboside, sulfate-3-glucuronyl paragloboside (SGPG), should be undertaken. If these antibodies are present, the probability of an association is increased but not proven. Up to 40 percent of IgM-related demyelinating neuropathies have no identifiable antibody.

IgG and IgA MGUS are less likely than IgM MGUS to be associated with identifiable antineuronal antibodies and are comparatively less common than IgM neuropathies, less likely to be demyelinating or sensory, and more likely to respond to plasmapheresis.

Chronic ataxic neuropathy with ophthalmoplegia, M-protein, cold agglutinins, and disialosyl antibodies (CANOMAD) is an IgM MGUS with a characteristic phenotype. Pathologically, antiganglioside antibodies, anti-GD1b and anti-GQ1b, produce both demyelinating and axonal features. Weakness affects oculomotor and bulbar muscles with similarities to Miller Fisher syndrome and may either be fixed or follow a relapsing-remitting course.

Lymphoma

The nervous system is involved through direct spread from primary nodal and extranodal sites. Occasionally, primary Hodgkin disease and primary non-Hodgkin lymphoma (including microglioma, reticulum cell sarcoma, and histiocytic lymphoma) of the CNS are seen. Neurologic complications result from direct invasion and compression of the nervous system or from secondary paraneoplastic syndromes. CNS involvement occurs most commonly with lymphoblastic lymphoma, large B-cell lymphoma, diffuse undifferentiated lymphoma, and diffuse histiocytic lymphoma.

SPINAL CORD AND MENINGEAL INVOLVEMENT

Spinal cord and meningeal involvement is relatively common. Extradural deposits arise as the result of direct spread from the retroperitoneal or postmediastinal spaces via the intervertebral foramina from tumor growth along nerve roots, or by direct invasion from an affected vertebral body. Intramedullary metastases of lymphoblastic lymphoma are a rare but recognized complication. The segmental arterial supply may also become compressed, resulting in ischemic myelopathy. Rarely, an acute necrotizing myelopathy appears as a remote paraneoplastic effect of a lymphoma. Subacute paraneoplastic myelopathy may occur in Hodgkin disease.

Spinal cord segments C5 to T8 are most commonly involved, although compression may occur at any level, including the cauda equina. Nerve roots may be invaded and enlarged by the lymphoma, causing pain and sensorimotor segmental syndromes.

INTRACRANIAL INVOLVEMENT

Intracranial involvement usually arises from infiltration via the skull base by direct extension from involved cervical lymph nodes, or by lymphatic spread. On rare occasions, lymphoma of the skull bones spreads to form an intracranial mass. Tumor is usually found extradurally but may present as a subdural mass that sometimes invades the underlying brain, or it may be purely intracerebral. Almost all cases of lymphomatous meningitis are found in patients with diffuse non-Hodgkin lymphoma.

Meningeal lymphoma may have a protracted course with spontaneous remission. Intracranial deposits seem to be associated more often with histiocytic lymphoma, and orbital deposits more commonly with lymphocytic lymphoma. Intracranial deposits are rarely seen in lymphocytic lymphoma unless leukemia has supervened.

PARANEOPLASTIC SYNDROMES AND OTHER NEUROLOGIC COMPLICATIONS

A range of paraneoplastic syndromes and treatment-associated complications associated with the lymphomas are discussed in Chapters 27 and 28.

Burkitt Lymphoma

Burkitt lymphoma is an aggressive peripheral B-cell lymphoma. It is endemic in equatorial Africa where it is frequently found in children with reduced immunity to Epstein–Barr virus (EBV), often affecting the mandible. It is found internationally in a sporadic form in adolescents and young adults, but is also common in individuals infected with human immunodeficiency virus (HIV); 90 percent of the endemic form, 20 percent of sporadic cases, and 40 percent of HIV-related cases are associated with EBV infection, which causes an upregulation of *c-myc*, a gene controlling transcription regulation.

Burkitt lymphoma is frequently complicated by nervous system involvement, most commonly paraplegia, cranial neuropathies, and CSF pleocytosis. Tumor spreads through the bones of the face, skull, and orbit and along cranial nerves. Spinal cord compression from direct extension from the vertebral bodies or via the intervertebral foramina is well recognized, and ischemic myelopathy may result from compression of radicular arteries. Patients with facial tumors are likely to develop orbital involvement and ophthalmoplegia. Infiltration of the skull base may produce other cranial nerve palsies and an inflammatory CSF.

Primary CNS Lymphoma

Primary CNS lymphoma (PCNSL) is rare, accounting for about 2.5 percent of primary brain tumors. Recently reported incidence rates in the United States population increased from 0.02/100,000 persons in the first two decades of life, to 0.3/100,000 in patients aged 35 to 44 years, and up to 2.13/100,000 in patients 75 to 84 years old. The incidence amongst HIV-positive individuals has dropped markedly, but PCNSL rates have increased among immunocompetent elderly adults.

Bruton tyrosine kinase, which links the B-cell antigen receptor and Toll-like receptors with NF-κB, may play a critical and therapeutically important role. This pathway is frequently affected by mutations in *MYD88* and *CD79B*. Other mutations suggest that immune invasion might also play a role in PCNSL.

Although all cytologic types are observed, 90 percent belong to the high-grade category of non-Hodgkin lymphoma, the majority being clonal and of B-cell origin, as evidenced by their monoclonal expression of either κ or λ light-chain immunoglobulin. Less common histologic types include low-grade lymphomas, Burkitt lymphomas, and T-cell lymphomas.

Non-Hodgkin PCNSL has an extremely poor prognosis. Tumor masses are usually multicentric and ill-defined. Immunocompromised individuals are at greatest risk. The incidence of these tumors is increasing, and their association with HIV only partly accounts for this rise. Primary CNS lymphoma in immunodeficient patients is often associated with EBV, which is detected frequently in the CSF.

Imaging displays discrete, often large, enhancing tumors with bilateral hemispheric involvement spreading through the corpus callosum. Despite the fact that these tumors are highly radiosensitive, the prognosis for PCNSL is worse than for other extranodal lymphomas, and late morbidity and mortality may occur from radiation necrosis. Treatment with chemotherapy and radiation usually leads to remission but with a significant recurrence rate.

Primary lymphoma of the spinal cord is exceptionally rare, as is primary lymphoma of the nerve roots, including the cauda equina.

Peripheral neuropathy of the paraneoplastic type may occur in association with PCNSL.

Intravascular Lymphoma

Intravascular lymphoma is a rarely diagnosed subtype of generalized lymphoma. It is characterized by proliferation of blastic, neoplastic B cells within the lumina of small- or intermediate-sized blood vessels and capillaries, producing vascular occlusion of arterioles, capillaries, and venules (Figs. 25-3 and 25-4). There is a high prevalence of *MYD88* and *CD79B* mutations. More than 25 to 50 percent of cases present with neurologic symptoms, and two-thirds develop neurologic symptoms during the course of the disease. The presentation may be diffuse or focal, and suggestive of vascular disease. Dementia, stroke-like episodes, myelopathy, cranial neuropathy, peripheral neuropathy, and brainstem syndromes predominate. Establishing the diagnosis is often difficult because of marked variability in clinical presentation and nonspecific laboratory and radiologic findings, especially when CNS symptoms are the only manifestation. Imaging demonstrates multifocal lesions in the brain suggestive of microvascular or demyelinating disease. Angiography may

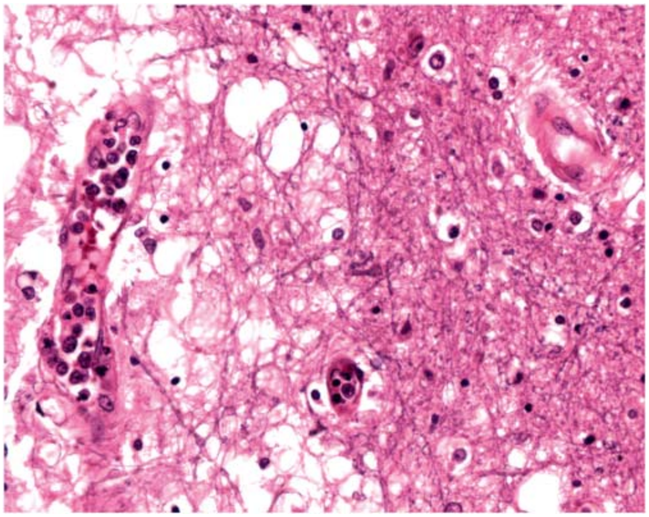

FIGURE 25-3 ■ Intravascular lymphoma. Section showing focus of cerebral ischemia with blood vessels plugged by large atypical lymphocytes (on left). Vessels in adjacent brain (right) not affected. (Hematoxylin and eosin. Original magnification × 400.)

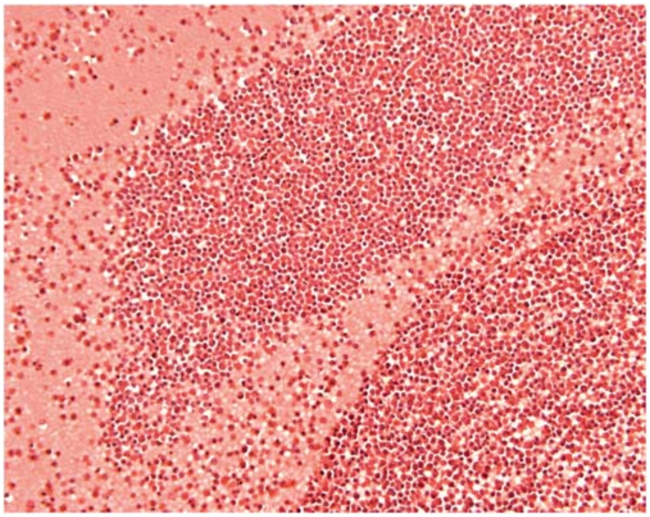

FIGURE 25-4 ■ Immunostained brain section showing distension and plugging of intracerebral vessels by CD20-stained malignant B-lymphocytes confirming intravascular lymphoma. (Original magnification ×400.)

show a beaded appearance reminiscent of vasculitis. The CSF findings are nonspecific, and cerebral biopsy should be undertaken in suspected cases.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare aggressive angiocentric and angiodestructive EBV-positive B-cell lymphoproliferative disease involving predominantly the lung. It is thought to be caused by dysregulated immune surveillance of EBV. It is uncertain whether it represents a unique disease or is part of the spectrum of EBV B-cell lymphoproliferative diseases. The nervous system is involved in one-third of patients, with occasional cases isolated to the CNS. It may occur in patients with Sjögren syndrome, chronic viral hepatitis, rheumatoid arthritis, renal transplantation, and HIV infection. The usual presenting symptoms are fever, weight loss, malaise, cough, dyspnea, and neurologic symptoms, which can include encephalopathy, seizures, hemiparesis, cranial neuropathy, optic neuropathy, peripheral neuropathy, and mononeuritis multiplex. Pathologically, there is a nodular polymorphic mononuclear cell infiltrate with prominent vascular infiltration and often necrosis. Varying numbers of large, often atypical, CD20-positive B-lymphocytes are present within a background containing numerous polyclonal reactive CD3-positive small T-lymphocytes and scattered admixed plasma cells in the meninges and cerebral blood vessel walls within the brain parenchyma and along nerve roots and peripheral nerves. The appearance may mimic vasculitis and can result in vascular occlusion. Morphologically, there is an overlap in higher-grade forms (grades 2 and 3) with variants of large B-cell lymphoma, and multiple lesions in a single patient may show wide variation in histologic grade. Treatment depends on grade, with grade 3 being managed as diffuse large B-cell lymphoma.

Polycythemia

A group of conditions previously thought to be distinct entities has been shown to have a common genetic etiology in exon 14 V617F mutations of the *JAK2* (Janus kinase 2) gene, including essential polycythemia, essential thrombocythemia, and myelofibrosis—the classic *bcr/abl*-negative myeloproliferative disorders. Each disease represents a stem cell–derived clonal myeloproliferation. The presence of this *JAK2* mutation may be used as a diagnostic test. Approximately 5 percent of patients who test negative for the *JAK2* exon 14 V617F mutation have one of a number of mutations known collectively as the *JAK2* exon 12 mutations.

There are many causes of polycythemia, including erythropoietin-producing neoplasms and nonmalignant renal cysts and inappropriately elevated erythropoiesis induced by hypoxemia such as from right-to-left cardiac or pulmonary shunts.

An increased incidence of thrombotic and hemorrhagic complications is a well-recognized phenomenon in polycythemia, in part arising from accelerated atherosclerosis. There is growing evidence that the increased risk of thrombosis is not caused directly by erythrocytosis alone but by interactions amongst white cells, red cells, platelets, and endothelium, with increased blood viscosity, reduced perfusion, vascular engorgement, atheromatous degeneration of vessel walls, and possibly chronic DIC. Patients with polycythemia whose hematocrit is below 45 percent have a significantly lower rate of cardiovascular death and major thrombosis than those with a hematocrit of 45 to 50 percent. Approximately 15 percent of patients with polycythemia die of cerebral thrombosis, 87 percent of them after repeated episodes. Thromboembolism often continues to be a major clinical problem even after hematologic control has been achieved. Hemorrhage may be related to imperfect clot retraction, abnormal thromboplastin generation, and abnormalities of platelet count and function. CNS hemorrhage may be cerebral, epidural, subdural, or subarachnoid.

The clinical course of polycythemia vera is often complicated by the transition to myeloid metaplasia with myelofibrosis or acute myeloid leukemia.

Nonspecific symptoms of fullness in the head, vertigo, tinnitus, and lack of concentration are common. More specific signs such as hemiparesis, hemianesthesia, hemianopia, and aphasia depend on the site of infarction or hemorrhage. Brainstem vascular syndromes occur, as do bulbar and pseudobulbar palsy, convulsions, and coma. Amaurosis fugax, blindness, scotomas, and cerebral or brainstem TIA are features as well. More rarely, signs and symptoms of a progressive cerebral lesion arise because of a subdural hematoma, an expanding intracerebral blood clot, or cerebral infarction accompanied by edema. Distention and congestion of the retinal veins, central retinal venous or arterial occlusion, and papilledema may be present. Idiopathic intracranial hypertension has been reported. Aseptic cavernous sinus thrombosis associated with internal carotid artery occlusion may occur; treatment with repeated phlebotomies and heparin may result in resolution of proptosis, pain, periorbital edema, lacrimation, venous congestion, ptosis, and ophthalmoplegia, and may restore sight. The one-and-a-half syndrome may occur and has been ascribed to brainstem ischemia.

Transient spinal cord ischemia may be the presenting feature of polycythemia vera, but spinal cord infarction is an exceptionally rare complication. Spinal cord compression due to spontaneous subdural hematoma and extramedullary hematopoiesis in the proliferative phase of polycythemia is uncommon.

Chorea, dystonia, and hyperkinetic movement disorders are also uncommon complications of polycythemia. Chorea may be of sudden onset and tends to occur in women older than 50 years. It may resolve before any significant reduction of the red cell count, but more often it resolves with correction of the polycythemia. The chorea is generalized, with predominant involvement of the face, mouth, tongue, and arms. It is not apparently related to the rare finding of a small infarct in the caudate nucleus.

A prospective clinical and electrophysiologic study of 28 patients with polycythemia identified 46 percent with clinical features of neuropathy and 71 percent with neurophysiologic evidence of sensory axonal polyneuropathy, probably arising from endoneurial ischemia. Oculomotor nerve paresis as a presenting sign of acute myeloblastic leukemia complicating polycythemia has been reported.

Mutations in the *SLC30A10* gene, which is highly expressed in the liver and brain and encodes a protein belonging to a large family of membrane transporters, may result in polycythemia with parkinsonism and dystonia.

Cerebellar Hemangioblastoma

Cerebellar hemangioblastoma may be associated with polycythemia, and 34 percent of these patients have von Hippel–Lindau disease, which is caused by mutations in the *VHL* gene. Germline mutations of the *VHL* gene can arise de novo in approximately 5 percent of cases. The VHL protein is involved in the inhibition of hypoxia inducible factor 1 α, which accumulates, causing the production of vascular endothelial growth factor, platelet-derived growth factor B, erythropoietin, and transforming growth factor α. von Hippel–Lindau disease is subdivided according to clinical manifestations, which largely correlate with the types of mutations present. Type 1 mostly have hemangioblastoma and renal carcinoma, but pheochromocytomas are rare. Patients with type 2A are at risk of both hemangioblastoma and pheochromocytoma, but not renal carcinoma. Those with type 2B are at risk of all three tumors, with a higher risk of clear-cell renal carcinoma; persons with type 2C are only at risk of pheochromocytoma. Type 3 disease has a risk of Chuvash polycythemia.

The symptoms of cerebellar hemangioblastoma are those of increased intracranial pressure and "dizziness," with either truncal and gait ataxia or hemiataxia with accompanying nystagmus. Neck stiffness and rarely cerebellar "fits" may occur. On examination, the symmetric or lateralized cerebellar ataxia is associated with papilledema, hemiparesis, bilateral pyramidal signs, or any combination of deficits from cranial nerve V, VI, VII, or VIII involvement. Recurrence many years after surgical treatment is typical of hemangioblastoma.

Pseudopolycythemia

Pseudopolycythemia is a condition in which an increased hematocrit is associated with normal red cell mass; plasma volume may be reduced in the absence of apparent fluid loss, related to aberrations in catecholamine metabolism. It is associated with hypertension, obesity, and stress, especially in middle-aged men who are smokers. In this condition, as in polycythemia, there is an increased risk of thromboembolism arising from an increase in whole-blood viscosity and reduced cerebral blood flow. In patients with a packed cell volume exceeding 54 percent, regular venipuncture with withdrawal of 100 to 250 ml blood is recommended to reduce the packed cell volume to around 46 percent.

Essential Thrombocythemia

Essential thrombocythemia is a clonal stem cell disorder with overproduction of megakaryocytes. Mutations in the *JAK2*, *CALR*, and *MPL* genes account respectively for 55, 25, and 3 percent of cases. Approximately 17 percent are triple-negative. The presence of *JAK2*V617F has been associated with an increased risk of arterial thrombosis and a lower risk of subsequent myelofibrosis.

Essential thrombocythemia is characterized more frequently by thrombotic than hemorrhagic complications; the presence of extreme thrombocytosis (platelets $>1{,}000 \times 10^9/\text{L}$) may be associated with acquired von Willebrand syndrome and a risk of bleeding.

The condition is diagnosed on the basis of a persistently elevated platelet count without evidence of trauma, inflammation, hemorrhage, hyposplenism, or any other condition known to be associated with thrombocytosis. Amaurosis fugax, transient hemiparesis or hemianesthesia, recurrent vertigo, and confusion are the characteristic symptoms. Most patients have circulating platelet aggregates or spontaneous platelet aggregation, and reduced platelet survival. Considerable clinical improvement can be achieved with antiplatelet drugs and, where appropriate, by reduction of platelet count. Evolution to myelofibrosis occurs in 3 to 10 percent of patients in the first decade after diagnosis, and in 6 to 30 percent in the second decade. Progression to acute myeloid leukemia occurs in 1 to 2.5 percent in the first decade after diagnosis, 5 to 8 percent in the second decade, and continues to increase subsequently, though this may be a consequence of treatment rather than due to the underlying disorder.

Myelofibrosis

Myelofibrosis is an uncommon myeloproliferative disorder arising predominantly in patients older than 50 years and characterized by replacement of the bone marrow by fibrous tissue. Activation of the JAK/STAT signaling pathway is a hallmark feature of myelofibrosis, and is driven by mutations in *JAK2*, *CALR*, and *MPL*. It is associated with extramedullary hematopoiesis and marked hepatosplenomegaly. Patients are anemic, may be slightly jaundiced, and have a leukoerythroblastic blood picture. Neurologic complications are rare. A number of reports describe meningeal hematopoietic masses. Spinal cord compression from extramedullary hematopoiesis is recognized but uncommon.

Eosinophilic Syndromes

Eosinophilia is defined as an increase in peripheral blood eosinophil count to greater than 450 cells/μL, with accompanying eosinophilic infiltration of muscle, nerve, or CSF. Eosinophilia may be observed in a wide range of conditions (Table 25-1).

Eosinophilic infiltration into skeletal muscle is rare. It has been described in parasitic infection as focal eosinophilic myositis, in systemic hypereosinophilic conditions such as the eosinophilia-myalgia syndrome, and in idiopathic hypereosinophilic syndrome. Diffuse fasciitis or Shulman syndrome can be limited to the fascia or associated with perimyositis. Eosinophilic myositis corresponds to focal muscle involvement, and it is associated with skin lesions in approximately 40 percent of cases, including deep subcutaneous induration, erythema, angioedema, urticaria, and papular lesions. The overall prognosis of eosinophilic myositis is good, particularly when muscle lesions are focal, and the principal histopathologic finding is perimysial infiltrates.

Compound heterozygous or homozygous *CAPN3* mutations have been found in a subgroup of children in the first decade of life with autosomal recessive inheritance, variable peripheral eosinophilia, and elevated serum creatine kinase levels, but with little or no weakness. The *CAPN3* gene encodes calpain-3, a muscle-specific intracellular nonlysosomal protease. Mutations in this gene are responsible for the commonest autosomal recessive limb-girdle muscular dystrophy, calpainopathy (LGMD2A). Very rare cases of adult-onset eosinophilic polymyositis have now been described with mutations in the calpain-3 gene. Whether this represents the well-known inflammatory feature of muscular dystrophy or is a true eosinophilic myositis is uncertain.

TABLE 25-1 ■ Nervous System Involvement With Eosinophilic Syndromes

- Trichinosis
- Eosinophilic meningitis or meningoencephalitis (angiostrongyliasis, gnathostomiasis, visceral larva migrans)
- Connective tissue diseases
    - Churg–Strauss vasculitis
    - Eosinophilic fasciitis
    - Polyarteritis nodosa
- Eosinophilia-myalgia syndrome (due to tryptophan in the United States in 1989)
- Toxic-oil syndrome (due to contaminated rapeseed oil in Spain in 1981)
- Coccidioidomycosis
- Helminth infections
- Ascariasis
- Schistosomiasis
- Trichinosis
- Visceral larva migrans
- Gnathostomiasis
- Strongyloidiasis
- Fascioliasis
- Paragonimiasis
- Neoplasia
    - Lymphoma (e.g., Hodgkin lymphoma, non-Hodgkin lymphoma)
    - Human T-cell lymphotropic virus I (HTLV-I)
    - Adult T-cell leukemia/lymphoma (ATLL)
    - Eosinophilic leukemia
    - Gastric or lung carcinoma (i.e., paraneoplastic eosinophilia)
- Allergic/atopic diseases
- Adrenal insufficiency in ill patients

When it is a manifestation of the hypereosinophilic syndrome, eosinophilic myositis may be life-threatening. Hypereosinophilic syndrome is a heterogeneous group of rare disorders defined by persistent blood eosinophilia of at least 1,500 eosinophils/μL without a cause, along with evidence of eosinophil-associated organ damage. There are a number of subtypes which may overlap with chronic eosinophilic leukemia. These subtypes are associated with dramatic differences in clinical presentation, prognosis, and responses to therapy. Abnormal or clonal T-cell populations are present in 17 percent of cases. There is pathologic evidence of multiorgan infiltration by eosinophils. Cardiac disease is common with valvular disease resulting in embolization. Systemic manifestations other than eosinophilia include anemia, hypergammaglobulinemia, vascular involvement (subungual petechiae, livedo reticularis, diffuse microangiopathy, Raynaud phenomenon), skin rash and subcutaneous edema, pulmonary infiltrates and pleuritis, cardiac involvement (congestive heart failure, arrhythmias, heart block, pericarditis, myocardial and endocardial fibrosis), and peripheral neuropathy. One-third of the patients have neurologic symptoms such as encephalopathy, multiple cerebral infarcts (possibly embolic in origin), peripheral neuropathy, and mononeuropathy multiplex. Patients may respond well to corticosteroids. Additional agents that have been used to rapidly lower counts in steroid-refractory patients include high-dose hydroxyurea, vincristine, and mepolizumab (humanized anti-interleukin-5 antibodies).

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a rare nonmalignant syndrome of pathologic immune activation. It is characterized by uncontrolled proliferation of T lymphocytes, NK cells, and macrophages, with infiltration of multiple organs including the CNS. Excessive activation of $CD8^+$ T lymphocytes results in the release of tumor necrosis factor-α, IL-1β, IL-6, IL-8, and interferon-gamma. It occurs most commonly in children aged under 1 year. Primary HLH is caused by loss of function in a variety of genes required to kill virus-infected cells. Secondary HLH is associated with malignancy, infections, and a range of immunosuppressive disorders and therapies. It may contribute to the hyperinflammation seen in H1N1 and H1N5 influenza outbreaks. It has been described within a few months to 4 years of treatment with alemtuzumab for relapsing-remitting multiple sclerosis.

It is diagnosed by either a proven genetic mutation or by fulfilling at least five of eight clinical criteria; fever, splenomegaly, cytopenias of at least two cell lines, hypertriglyceridemia and/or hypofibrinogenemia, hyperferritinemia, abnormally low NK-cell activity, high levels of soluble IL-2 receptor, and pathologic evidence of hemophagocytosis in tissues.

Seizures, irritability, disturbance of consciousness, and encephalopathy are common. Meningism is reported in approximately one-third of patients. Focal signs, such as hemiparesis, cranial neuropathies, and ataxia, are seen in 10 to 20 percent of cases.

The differential diagnosis for CNS HLH includes acute disseminated encephalomyelitis, acute necrotizing encephalopathy, CNS vasculitis, multiple sclerosis, encephalitis, CNS manifestations of rheumatologic disease (such as systemic lupus erythematosus; SLE), and other genetically mediated CNS inflammatory disorders such as interferonopathies.

CNS disease has been divided into three stages: stage I with leptomeningeal inflammation, stage II with perivascular infiltration, and stage III with massive tissue infiltration, blood vessel destruction, and tissue necrosis. Treatment is with immuno- and chemotherapy followed by hematopoietic stem cell transplantation.

Macrophage Activation Syndrome

The similarities between primary HLH and macrophage activation syndrome (MAS) are striking. Although the final pathways are shared, the initiating factors may be different. Both are characterized by widespread inflammation and end-organ damage. MAS is classically associated with rheumatologic conditions such as systemic juvenile idiopathic arthritis and adult-onset Still disease, in contrast to HLH which is characteristically associated with viral infections, malignancy, and certain chemotherapies. Mutations in genes associated with the lymphocyte cytolytic pathway are common to both syndromes, and both MAS and HLH present clinically with marked hyperferritinemia, cyclic fevers, cytopenias, hepatosplenomegaly, coagulopathy, and if not treated, end-organ failure and death.

Characteristic clinical features of MAS are high, nonremitting fever, hepatosplenomegaly, generalized lymphadenopathy, hemorrhage, and CNS dysfunction in 35 percent, including seizures, headache, or encephalopathy.

NEUROLOGIC COMPLICATIONS OF THERAPIES FOR HEMATOLOGIC MALIGNANCIES

Chimeric Antigen Receptor T-Cell Therapies

Chimeric antigen receptor (CAR) T cells (CAR-T) have emerged in recent years as powerful treatments for relapsed and refractory hematologic malignancies. CAR-T cells are engineered to express synthetic receptors that redirect polyclonal T cells to surface antigens for tumor elimination. Many CARs are designed with elements that augment T-cell persistence and activity. A variety of targets have been used including CD19 in B-cell ALL, Burkitt lymphoma and non-Hodgkin lymphoma, CD22 in B-cell malignancies, and B-cell maturation antigen in multiple myeloma.

Toxicity occurs as two related but distinct syndromes: a cytokine release syndrome and neurotoxicity, referred to as immune effector cell therapy–associated neurotoxicity syndrome (ICANS).

Cytokine release syndrome is a multisystem clinical syndrome characterized by fever, hypotension, hypoxia, and in more severe cases multisystem organ dysfunction. It is caused by the release of proinflammatory cytokines by the activated CAR-T cells. CRS is extremely common; in some trials, 100 percent of patients experienced at least some symptoms of CRS. Treatment with tocilizumab, which blocks the IL-6 signal receptor pathway, can effectively mitigate the symptoms of CRS without impairing the antitumor efficacy of the CAR-T cells. Neurotoxicity associated with CAR-T cell therapy includes encephalopathy (57%), headache (42%), tremor (38%), aphasia (35%), and focal weakness (11%). The mortality rate depends on patient selection and therapy, but a recent series suggested 5 percent. Focal neurologic deficits are associated with regional electroencephalographic abnormalities, FDG-PET hypometabolism, and elevated velocities on transcranial Doppler ultrasound. Structural imaging is frequently normal.[4]

Neurotoxicity may fluctuate with fever and recur after cytokine release symptoms have subsided. Clinical or subclinical seizures may develop, often following the development of global aphasia. Cerebral edema may follow seizures and may commence with a fulminant onset.

A consensus grading system for CRS and ICANS has been developed to enable monitoring and to identify neurotoxicity requiring treatment.[5]

Checkpoint Inhibitors

The tumor microenvironment in most lymphomas and solid cancers has multiple mechanisms for inhibiting an efficient immune response against it.

PD-1 is a negative regulator of T-cell activity and limits the activity of T cells by interaction with its two ligands, PD-L1 and PD-L23. When PD-1 is engaged by one of these ligands, it inhibits kinase signaling that leads to T-cell activation, thereby suppressing T-cell function.

CTLA-4 competitive binding can prevent the co-stimulatory signal normally provided by CD28:B7 binding. This stops potentially autoreactive T cells at the initial stage of naive T-cell activation, typically in lymph nodes.

Inhibitors of PD-1 and CTLA-4 are now being used to treat a range of solid tumors, particularly metastatic melanoma, lung cancer, and hematologic malignancies.

The immune checkpoint inhibitor pembrolizumab is a highly selective, humanized monoclonal immunoglobulin G4/κ antibody that blocks the interaction between PD-1 and its ligands. A range of neuroimmunologic complications has been described including limbic encephalitis, chronic inflammatory demyelinating polyneuropathy, myasthenia, necrotizing myelopathy, and subacute multifocal CNS demyelination.

Ipilimumab is a human $IgG_1κ$ monoclonal antibody specific for CTLA-4 expressed on activated T cells. Checkpoint inhibitors to CTLA-4 can result in a range of neurologic disorders including Guillain–Barré syndrome, myasthenia, transverse myelitis, encephalopathies, and autoimmune meningoencephalitis.

Combined use of PD-1 inhibitors and CTLA-4 inhibitors may induce anti-NMDA (*N*-methyl-D-aspartate) receptor encephalitis, which was not seen when the agents were used individually.

Myasthenia seems commonly to be triggered by checkpoint inhibitors. The literature suggests 72.7 percent are de novo presentations, 18.2 percent are exacerbations of pre-existing myasthenia gravis, and 9.1 percent are exacerbations of subclinical myasthenia. Only 60 percent were seropositive for acetylcholine receptor antibodies. A 30 percent myasthenia-specific related mortality, probably a result of multiple morbidities, emphasizes the need for vigilance.

With increasing use of checkpoint inhibitors and their predilection for triggering exacerbations of pre-existing or de novo autoimmunity, neurologic autoimmunity is likely to occur more frequently, and any relationship between the resulting disease and the malignancy and mechanism of checkpoint inhibitor is likely to become clearer.[6,7]

HEMORRHAGIC DISORDERS

Hemophilia A

The severity of bleeding in hemophilic patients correlates with the factor VIII level. Severely affected hemophiliacs with levels of less than 1 percent commonly have spontaneous bleeding into muscles and joints. With factor VIII levels of 1 to 5 percent, spontaneous bleeding is much less frequent. Patients with factor VIII levels greater than 10 percent can lead normal lives, as excessive blood loss occurs only after more severe trauma and surgery. Hypertension is an important additional factor in older patients. Lyonization (X-inactivation) may result in severe factor VIII deficiency in some females.

Intracranial bleeding is the leading cause of death. The incidence of intracranial hemorrhage ranges approximately from 2 to 14 percent. Bleeding tends to occur predominantly in young hemophiliacs, and may occur into the subdural, epidural, or subarachnoid spaces or into the cerebral or cerebellar hemispheres and brainstem. The symptoms and signs depend on the site of the hemorrhage and its extent. Prognosis in intracranial hemorrhage has been considerably improved by the early use of factor VIII concentrates, and there is now no contraindication to surgical intervention, provided that adequate control of coagulation factors is maintained. Seizures occur in 25 percent of survivors of intracranial hemorrhage.

Bleeding into the spinal canal is rare. Patients with small epidural hemorrhages and only minimal nonprogressive signs of spinal cord dysfunction may recover completely with intensive factor VIII replacement therapy alone.

Peripheral nerve lesions are the most frequent neurologic complication of hemophilia. In most instances, nerve involvement is a complication of intramuscular hemorrhage, most commonly into the iliac muscle leading to femoral neuropathy. Median, ulnar, and radial neuropathies result from hemorrhage into the arm or forearm muscles. Nerve compression by pseudotumors (subperiosteal hemorrhages producing expanding lesions) also occurs.

Severe hemophilic arthropathy of the elbow may result in ulnar nerve palsy. Intraneural hemorrhage as a cause of peripheral nerve palsy is exceptional but may, for example, affect the ulnar nerve in the cubital tunnel. On exploration of the ulnar nerve, free blood may be seen when the epineurium is divided; recovery is rapid and complete.

During the early to the mid-1980s, many patients with severe hemophilia became infected with HIV through contaminated plasma-derived clotting factors. From 1979 to 1998, 47 percent of people with hemophilia A died of HIV-related disease.

About one-third of patients with severe hemophilia A develop neutralizing alloantibodies against factor VIII replacement treatments. Emerging treatment options for these patients include factor IXa– and factor X–directed antibody that can restore blood clotting.

Early trials of gene therapy have normalized factor VIII activity. Bleeding rates and factor VIII use were very significantly reduced in all trials.

von Willebrand Disease

von Willebrand disease is a family of related disorders characterized by deficiency or malfunction of von Willebrand factor (VWF), a protein that mediates platelet adhesion to the endothelium and protects factor VIII from degradation. An earlier age of onset is associated with more severe VWF deficiency.

There is a partial deficiency of functionally normal VWF in type 1 disease caused by heterozygous missense mutations exerting a dominant-negative effect, which results in a disturbance of the entire multimer. Almost all cases of type 2 von Willebrand disease are caused by missense mutations, and inheritance is mostly autosomal dominant. This type is associated with an increased risk of abnormal bleeding after invasive procedures. Type 2N is associated with decreased affinity of VWF for factor VIII; it is suspected when the decrease in factor VIII levels is much more profound than that of VWF, and its diagnosis is confirmed by factor VIII binding assay. There is a complete deficiency in type 3 disease. Some heterozygous carriers have mild symptoms and receive a diagnosis of type 1 disease. Patients may be either homozygous for two type 2N mutations or compound heterozygous for a type 1 defect and a type 2N defect. Rarer acquired forms are associated with hematologic malignancies, such as extreme thrombocytosis (platelets $>1000 \times 10^9/L$), SLE, and other autoimmune disorders, and with the use of valproic acid, griseofulvin, and ciprofloxacin.

The bleeding complications of von Willebrand disease are relatively mild, and spontaneous hemorrhage into joints and muscles does not occur. Acute onset of neurologic dysfunction is not a feature of this disease. Nevertheless, more significant hemorrhage may result from trauma, particularly in the rarer autosomal recessive 2N and 3 types. Patients who sustain head injuries should receive immediate factor VIII replacement therapy. The goal of treatment is to increase VWF levels by administering desmopressin or by the infusion of exogenous VWF-containing concentrates.

Hemophilia B: Factor IX Deficiency

Hemophilia B (Christmas disease) is an X-linked recessive disorder; approximately one-third of patients have no family history and have novel mutations. The neurologic complications are identical to those of hemophilia A. Thus, peripheral nerve compression occurs as a consequence of spontaneous intramuscular hemorrhage, and intracranial hemorrhage, an important cause of death in both disorders, may occur spontaneously in severely affected patients or following trauma in less severely affected individuals. Clotting factor IX is the deficient factor requiring replacement. Early trials of gene therapy using factor IX Padua transgene appear very promising, having achieved the near elimination of bleeding and of factor IX replacement therapy.

Other Clotting Factor Deficiencies

Spontaneous and post-traumatic hemorrhages are features of disorders resulting from deficiencies of other clotting factors. Surgical evacuation of any intracranial hemorrhage, when indicated, must be done in the setting of adequate replacement therapy with the relevant deficient factor or with fresh frozen plasma or cryoprecipitate if the specific factor is not available. Replacement therapy should probably be given routinely following head injuries in these patients.

Acquired Hemophilia A

Acquired hemophilia is a rare condition resulting from the production of autoantibodies against factor VIII. The mean age at diagnosis is 74 and both sexes are affected. Cutaneous purpura and internal hemorrhage are common, whereas extensive bleeding into the joints is not a prominent feature. The condition is associated with systemic autoimmune disorders; malignancies such as lymphoma, acute or chronic lymphocytic leukemias, and solid tumors; and pregnancy. Drugs such as the penicillins, phenytoin, phenylbutazones, or chloramphenicol have also been implicated. It has been reported during the immune reconstitution following the use of alemtuzumab for multiple sclerosis, sometimes years after the last infusion.

No cause can be found in around half of patients. Neurologic involvement is rare, but cases of life-threatening intracranial hemorrhage and recurrent spontaneous subdural hematoma have been reported.

The diagnosis is based on unexpected prolongation of the activated partial thromboplastin time (aPTT) and the identification of a low factor VIII level associated with the presence of a time-dependent inhibitor in the plasma. Treatment of bleeding episodes requires the use of an activated prothrombin complex concentrate or recombinant activated factor VIII. Immunoglobulin administration does not improve outcome. Immunosuppression with corticosteroids, cyclophosphamide, or rituximab achieves a 73 percent complete remission, and is usually effective at reducing inhibitor production and bringing about a sustained rise in the factor VIII level.

Hemorrhagic Disease of the Newborn

Newborns are at risk for vitamin K deficiency bleeding caused by inadequate prenatal storage and deficiency of vitamin K in breast milk. Vitamin K deficiency results in a deficiency of factors II, VII, IX, X, along with protein C and protein S. Intracranial hemorrhage is the most serious complication and occurs from the second day to the end of the first week, particularly after breech deliveries. Bleeding appears to occur from capillary lesions rather than major vessels. Subdural and subarachnoid hemorrhages are the most frequent forms of intracranial bleeding, and intracerebral hemorrhage is rare. Intracranial bleeding is reported to occur earlier and with greater frequency in infants born to mothers receiving anticonvulsant therapy, but late-pregnancy exposure to anticonvulsant drugs that induce cytochrome P-450 enzymes seems not to increase the risk in comparison with noninducing anticonvulsants. A recent systematic review of the literature on antiepileptic drug use in pregnancy concluded that evidence was insufficient to support vitamin K supplementation in the last weeks of pregnancy to reduce risk of vitamin K deficiency bleeding.

Late-onset vitamin K deficiency usually occurs 2 to 12 weeks after birth but may occur up to 6 months of age. It is associated with failure to receive vitamin K prophylaxis at birth but also occurs in exclusively breast-fed babies. The majority present with acute intracerebral bleeding.

Thrombocytopenia

If platelet function is normal, satisfactory hemostasis may be achieved with a platelet count as low as $80 \times 10^9/L$. Clinically significant spontaneous hemorrhage does not usually occur if the platelet count exceeds $25 \times 10^9/L$, but below $20 \times 10^9/L$ spontaneous hemorrhage is not uncommon. Intracerebral, subarachnoid, and subdural hemorrhages are the most serious complications; the risk of spontaneous intracranial hemorrhage appears to be greatest during the first 2 weeks after onset of the disorder. An uncommon complication of recurrent bleeding is superficial siderosis.

Drug-induced immune thrombocytopenias arise when a drug acts as a hapten, binding to platelets and resulting in complement fixation and intravascular lysis. The platelet count typically falls within 7 or more days after initiation of the responsible drug. Heparin-induced thrombocytopenia is the most common disorder of this type. It is defined as a platelet count that drops below 100 to $150 \times 10^9/L$ for no apparent reason other than heparin administration. Type I heparin-induced thrombocytopenia is characterized by a moderate reduction in platelet counts, usually within the first 7 to 12 days of the initiation of heparin therapy. The platelet count rarely drops below $100 \times 10^9/L$ and normalizes in spite of continued heparin therapy. Type II heparin-induced thrombocytopenia is immunologically mediated and paradoxically is often associated with thrombosis. Most patients produce IgG antibodies against complexes of platelet factor 4 and heparin.

Delayed-onset thrombocytopenia, a mean of 14 days after initiation of therapy is increasingly being recognized and is usually associated with heparin-induced antibodies. It may begin rapidly in patients who have received heparin any time within the previous 100 days. Heparin-dependent antibodies do not invariably reappear with subsequent heparin use. Up to 60 percent or more develop serious thrombotic complications, including ischemic damage to limbs, CNS, myocardium, and lungs. A study of 120 cases of immune-mediated heparin-induced thrombocytopenia showed that 9 percent developed neurologic complications, including ischemic cerebrovascular events (6%), cerebral venous sinus thrombosis (2.5%), and a transient confusional state in one case. Primary intracerebral hemorrhage was not observed. Importantly in three cases, neurologic complications preceded the onset of thrombocytopenia.

In severe thrombocytopenia, massive intracranial hemorrhage may be instantaneous and treatment of no avail. It is often heralded by headaches of varying severity. In these circumstances, platelet transfusion should be instituted without delay, as it should after head injury in patients with significantly reduced platelet counts.

During the immune reconstitution following the use of alemtuzumab, a humanized anti-CD52 monoclonal antibody, in the treatment of relapsing-remitting multiple sclerosis, secondary autoimmune diseases can develop, including dose-related idiopathic thrombocytopenic purpura. Between 2 and 3 percent of patients are affected within 2 years of their last infusion.

Disorders of Platelet Function

Regardless of the platelet count, abnormal bleeding states may result from abnormalities of platelet function, that is, disorders of platelet adhesion, aggregation, secretion, and procoagulant activity, or a combination of abnormalities of number and function. Bleeding due to these disorders is treated primarily with platelet transfusions.

Bernard–Soulier syndrome is an inherited, usually autosomal recessive disorder of platelet adhesion caused by deficiency of the component subunits of the glycoprotein 1b-IX-V complex. As a result, platelets fail to stick and clump together at the site of the injury, resulting in bleeding after trauma or surgery.

Glanzmann thrombasthenia is caused by the absence of platelet aggregation due to deficiencies of αIIbβ3 integrin, an aggregation receptor on platelets. This absence prevents fibrinogen bridging from occurring and thus prevents clot retraction and significantly prolongs bleeding time. It has been associated with fatal cerebral hemorrhage. Platelet count, volume, and morphology are normal in classic Glanzmann thrombasthenia, though some reports have suggested a role for αIIbβ3 in megakaryocytopoiesis, and point mutations have been described that lead to platelet anisotropy and thrombocytopenia.

The gray platelet syndrome is a rare, mostly autosomal recessive disorder of the megakaryocyte lineage. Patients present with macrothrombocytopenia, mild splenomegaly, increased serum vitamin B_{12}, and markedly decreased or absent platelet α-granules.

Storage pool deficiency and abnormalities of the granule secretion mechanism all result in malfunction of platelet secretion of substances required for platelet adhesion and aggregation.

Scott syndrome is characterized by the absence of calcium-stimulated transport of phosphatidylserine from the inner leaflet of the plasma membrane bilayer to the cell surface, which is required to provide an appropriate surface for the assembly of the complexes of the coagulation network. This results in moderately severe bleeding.

A variety of hereditary disorders may be associated with low platelet counts or platelets of abnormal size, including Wiskott–Aldrich syndrome.

The commonest acquired disorders of platelet function arise from drugs such as aspirin, nonsteroidal anti-inflammatory drugs, and ticlopidine. A wide range of other drugs may affect platelet function, including antihistamines, some antibiotics, antidepressants, and anesthetics. Platelet function may also be affected by chronic renal failure, the use of blood-bank platelets, leukemia, and cardiopulmonary bypass. In myelomatosis or macroglobulinemia, abnormal platelet function results from interference by circulating paraproteins, and bleeding may be readily controlled by plasmapheresis.

Disseminated Intravascular Coagulation

DIC is an acquired syndrome characterized by the intravascular activation of coagulation. It can originate from and cause damage to the microvasculature, which if sufficiently severe, may produce organ dysfunction. It is characterized by the unregulated generation of thrombin and the failure of the physiologic control mechanisms which normally keep a check on excess thrombin generation, and should be considered as indicating the presence of an underlying disorder. The coagulation system is activated by the rapid release of thromboplastic substances into the circulation to form either soluble or insoluble fibrin. Clotting factors and platelets are consumed, and there is defective and activated fibrinolysis and impairment of the coagulation inhibition system. The clinical syndromes result from vascular obstruction from fibrin-rich thrombi. Globules of fibrin are occasionally seen free in the circulating blood. Red blood cells are forced through fine networks of fibrin resulting in fragmentation, with the development of a microangiopathic hemolytic anemia. The overwhelming consumption of α_2-antiplasmin and platelets together with the anticoagulant properties of fibrin degradation products may also result in a bleeding tendency that can vary in severity from slight oozing at venepuncture sites with purpura and spontaneous bruising to massive uncontrollable hemorrhage (Fig. 25-5). Simultaneous hemorrhage and thrombosis may occur. Primary brain damage releases powerful thromboplastins into the circulation that may precipitate DIC, and all patients with evidence of brain injury are at risk for its development. DIC has been described in association with status epilepticus, possibly related to widespread endothelial injury secondary to seizure-induced hyperpyrexia.

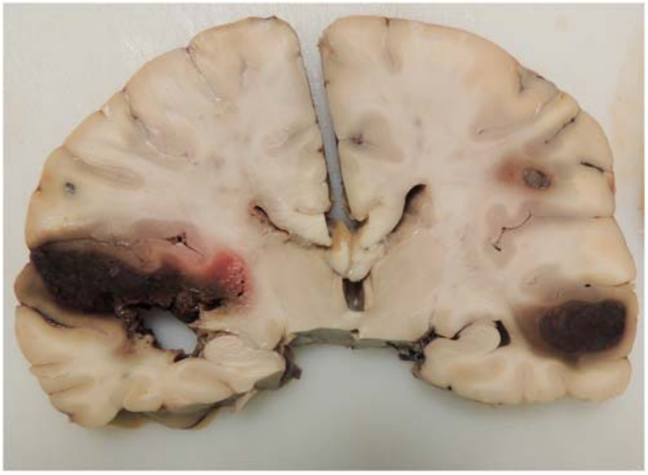

FIGURE 25-5 ■ Young male with promyelocytic acute myeloid leukemia complicated by DIC resulting in intracerebral and intraventricular hemorrhage.

The hemorrhagic complication may be so marked that massive cerebral, intraventricular, or subarachnoid hemorrhage occurs. When DIC affects the nervous system, the symptoms and signs are related to the thrombotic and hemorrhagic complications as well as to the primary disorder triggering the DIC (Table 25-2). Any part of the brain may be affected, producing focal or generalized encephalopathic manifestations. Symptoms and signs may fluctuate markedly with time, presumably because

TABLE 25-2 ■ **Clinical Conditions Complicated by Disseminated Intravascular Coagulation**

Mechanism	Clinical Condition
Tissue damage	Trauma (including neurotrauma), fat embolism
	Surgery
	Heat stroke
	Burns
	Dissecting aneurysm
	Neuroleptic malignant syndrome
	Pancreatitis
	Status epilepticus
Infection	Bacterial
	Viral
	Protozoal
	Rickettsial
Immunologic disturbance	Immune complex disorders
	Allograft rejection
	Incompatible blood transfusion
Obstetric complications	Abruptio placentae
	Amniotic fluid embolism
	Retained fetal products
	Eclampsia
Metabolic disorder	Diabetic ketoacidosis
Neoplasms	Myeloproliferative and lymphoproliferative disorders
	Mucin-secreting adenocarcinoma
Miscellaneous	Cyanotic congenital heart disease
	Hepatic failure
	Cavernous hemangioma
	Shock
	Snake venoms

of the continuing deposition and lysis of fibrin, which results in intermittent obstruction of vessels and blood flow. Patients may remain in a coma for several days and then make a good recovery if the circulation is reestablished.

In DIC secondary to carcinoma, microvascular obstruction of the brain may produce signs indistinguishable from those of metastatic deposits. Such signs may be found before clinical recognition of the underlying malignancy. Ischemic myelopathy due to DIC is rare.

No single test is available that is sufficiently sensitive or specific to permit a diagnosis of DIC. The presence of soluble fibrin in plasma has high sensitivity but low specificity for the diagnosis. The protamine sulfate test detects circulating fibrin monomers and is specific but not sensitive. The diagnosis frequently may be made using a combination of platelet count, measurement of global clotting times, measurement of one or two clotting factors and inhibitors (e.g., antithrombin), and a test for fibrin degradation products. Serial coagulation tests are often required and a reduced platelet count or a clear downward trend is a sensitive if not specific sign of DIC.

It is important to recognize coagulation syndromes that resemble DIC, especially thrombocytopenic purpura and fulminant antiphospholipid antibody syndrome. At the onset of the neurologic disorder in DIC, the coagulation profile may be normal. Plasma fibrinogen is an acute-phase reactant. During pregnancy, postoperatively, following trauma, and in association with malignancy it is invariably elevated so that increased fibrinogen consumption may serve only to reduce plasma fibrinogen to normal levels. For this reason, the only laboratory evidence of DIC in this situation may be thrombocytopenia and an elevated level of fibrin degradation products. The International Society on Thrombosis and Haemostasis has proposed a useful algorithm for the diagnosis of DIC.[8,9]

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a severe form of thrombotic microangiopathy resulting in organ failure of variable severity. The only consistent abnormalities are red cell fragmentation and thrombocytopenia, which are also found in other conditions. The condition results from excessive systemic platelet aggregation caused by the accumulation of unfolded high-molecular-weight von Willebrand factor multimers in plasma. The failure to degrade the multimers into less adhesive forms is related to a severe deficiency in a von Willebrand factor cleaving protease, ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). There are three types: (1) hereditary TTP, caused by mutations in *ADAMTS13* gene; (2) acquired idiopathic TTP, caused mainly by polyclonal IgG that inhibits plasma ADAMTS13 activity; and (3) acquired nonidiopathic TTP, which is associated with pregnancy, hematopoietic progenitor cell transplantation, infection, disseminated malignancy, and certain drugs such as ticlopidine and clopidogrel.

Severe deficiency of plasma ADAMTS13 activity or the presence of anti-ADAMTS13 autoantibodies is highly specific for the diagnosis. Treatments that eliminate anti-ADAMTS13 autoantibodies such as cyclosporine, cyclophosphamide, and rituximab are effective in treating acquired TTP.

TTP presents most commonly between the ages of 20 and 50 and affects women more commonly than men. Neurologic deficits may not be present, and the current diagnostic criteria no longer require the presence of renal and neurologic abnormalities or fever. Plasma exchange may therefore be introduced earlier, with a corresponding decline in the mortality rate. There may be complete recovery, but a chronic relapsing form has been described.

With the use of less restrictive diagnostic criteria, care must be taken to exclude conditions that may mimic TTP. These include DIC, disseminated malignancy, Evans syndrome (simultaneous or sequential development of autoimmune hemolytic anemia and immune thrombocytopenia with or without immune neutropenia), sepsis, accelerated hypertension, eclampsia, the catastrophic form of the antiphospholipid antibody syndrome, and HELLP syndrome (hemolysis, elevated liver function tests, low platelets), which is found in 10 percent of cases of eclampsia and pre-eclampsia. Unlike TTP, fetal involvement is present in the HELLP syndrome, with fetal thrombocytopenia reported in 30 percent of cases. In none of the mimics of TTP is there a reduction in ADAMTS13.

Pathologically, TTP is characterized by hyperplasia of endothelial and adventitial cells in arterioles, capillaries, and venules associated with platelet-rich and hyaline thrombi in these vessels, in which microaneurysms may also form.

Neurologic features are the most frequent presenting manifestations of TTP, occurring in 60 percent of cases. As the result of involvement of any part of the CNS, there is an endless variety of neurologic manifestations. Symptoms are typically transient and fluctuating and sometimes may resemble TIAs. Permanent neurologic complications may occur, and therefore neurologic symptoms should be treated vigorously with daily repeated plasma exchange, antiplatelet drugs, corticosteroids, and possibly chemotherapeutic agents such as vincristine.

The neurologic abnormalities in TTP may precede the full syndrome by months or even years. In a typical case, there may be a variety of nonspecific prodromal symptoms. At the time of presentation, the patient is usually pale, icteric, and febrile; has petechial hemorrhages in the skin; exhibits mental changes and neurologic abnormalities; and has splenomegaly, hepatomegaly, lymphadenopathy, arthropathy, and some degree of hypertension and renal insufficiency.

Posterior reversible encephalopathy syndrome is the most common brain imaging abnormality in severe TTP. The main laboratory abnormalities are microangiopathic hemolytic anemia, thrombocytopenia, hyperbilirubinemia, uremia, and erythroid and myeloid hyperplasia of the bone marrow with increased megakaryocytic activity. Although laboratory evidence of DIC may be present, it occurs in only a few patients. Demonstration of low levels ($\leq 5\%$) of normal ADAMTS13 is indicative of the diagnosis.

Treatment of acquired TTP consists of early plasma exchange to remove autoantibodies and ultralarge von Willebrand factor multimers and to replenish ADAMTS13. Caplacizumab, a humanized anti-von Willebrand factor immunoglobulin fragment, inhibits interaction between von Willebrand factor multimers and platelets and has an immediate effect on platelet aggregation and the ensuing formation and accumulation of platelet-rich microthrombi.

Hemolytic-Uremic Syndrome

The hemolytic-uremic syndrome (HUS) is characterized by renal impairment, thrombocytopenia, and microangiopathic hemolytic anemia, typically preceded by abdominal pain and diarrhea. Involvement of the nervous system is common. As with TTP, the diagnosis may be made on the basis of microangiopathic hemolytic anemia and thrombocytopenia, but there are important differences between the two entities. Deficiency of von Willebrand factor-cleaving protease has not been shown in HUS. Unlike TTP, 91 percent of children with HUS survive with only supportive care, and plasma exchange treatment is not indicated. Most cases arise as a complication of gastroenterologic infections by organisms producing Shiga toxins such as *Escherichia coli* O157:H7 or *Shigella.* Sporadic cases result from familial or autoimmune diseases, a variety of drugs (cyclosporine, mitomycin, and other forms of chemotherapy), tumors, bone marrow transplant, HIV infection, or are idiopathic.

Familial HUS constitutes 5 to 10 percent of cases. Several members of the alternative complement pathway are mutated in these patients, resulting in overactivation of the alternative pathway, either by losing regulatory functions or by gaining persistent or enhanced activation. Mutations in thrombomodulin, which regulates complement and the coagulation cascade, have also been described. There is thought to be a role for complement in diarrhea-associated HUS; Shiga toxin circulates bound to blood cells but not attached to Gb3 receptors. Instead, it binds to an as-yet undetermined receptor for which it has less affinity. Therefore, when the Shiga toxin finds its way to an organ which expresses Gb3, it preferentially detaches from circulating blood cells and binds to these receptors.

The most common neurologic manifestations are focal and generalized seizures. Behavioral changes, cerebral, cerebellar, and brainstem syndromes, and reversible cerebrovascular constriction syndrome have been described. Axonal neuropathy has been described in a patient with *E. coli* serotype O157:H7–associated HUS. Striatal involvement due to small areas of infarction, with resulting involuntary movements, may occur. MRI of the brain may show features of infarction or hemorrhage, and changes characteristic of posterior reversible encephalopathy syndrome are sometimes found. Patients in coma or with pyramidal signs may have normal imaging. In the German Shiga toxin-producing *E. coli* 0104:H4 outbreak, cognitive impairment, aphasia, and seizures were common but the outcome was good. There were no signs of microbleeds, thrombotic occlusions, or infarction. MR imaging and neuropathology seemed to indicate mixed toxic and inflammatory mechanisms. There is a risk of residual hypertension and chronic renal failure, which is greatest in those children with neurologic complications. Seizures, alone or as part of an encephalopathic illness, are associated with mortality or long-term neurologic sequelae.

There is increasing experience of the use of antibiotics, plasma exchange, and immunoabsorption, with the choice of therapy depending on the etiology. The recent use of eculizumab in the management of severe diarrhea-associated HUS has improved the outcome for patients with neurologic involvement.

Gaucher Disease

Gaucher disease is the most common lipid storage disorder, an autosomal recessive deficiency of glucocerebrosidase resulting in an accumulation of glucocerebroside in lipid-laden macrophages (Gaucher cells) in various organs. It is classified according to the presence of neurologic manifestations into three types: type 1, without neuropathic findings, type 2 with acute infantile neuropathic signs, and type 3, the chronic neuropathic form. More than 400 mutations have been identified accounting for the continuum of phenotypes. Patients with uniparental disomy or new mutations who do not inherit a mutation from each parent add to the complexity.

Type 1, resulting from accumulation in bones, liver, spleen, and lungs, is characterized by hepatosplenomegaly, bone pain and fractures, thrombocytopenia, and bleeding diathesis. It may develop at any time in childhood. It occurs worldwide in all populations, but 60 percent of cases are found in Ashkenazi Jews. Despite type 1 being considered a non-neuronopathic form, neurologic symptoms arise secondarily to skeletal disease, and cognitive impairment, developmental delay, microcephaly, behavioral disorder, mild spasticity, and polyneuropathy are described. Patients with type 1 Gaucher disease are predisposed to develop Parkinson disease.

Carriers of *GBA1* mutations with Parkinson disease are predisposed to particular motor and nonmotor features. Depending on the variant, this includes excessive daytime sleepiness, treatment-related wearing-off and dyskinesias, possible REM sleep behavior disorder, and motor and cognitive decline.[10]

Type 2, the acute neuronopathic form, shows no ethnic predilection. Hepatosplenomegaly arises in the first few months of life. Characteristic brainstem abnormalities then develop with strabismus, horizontal supranuclear palsy, opisthotonic posturing, and trismus arising in response to noxious stimuli. There is diffuse spasticity and developmental regression, and the disease is usually fatal during the first 3 years of life.

Type 3 Gaucher disease, the chronic neuronopathic form, is also without ethnic predilection and is estimated to occur in 1 in 50,000 live births. The neurologic symptoms are slowly progressive and appear later in childhood than the symptoms of type 2 disease. The disease has a more chronic course, with variable hepatosplenomegaly and the progressive development of incoordination, myoclonic seizures, impairment of olfaction, parkinsonian motor signs, pyramidal signs, cerebellar ataxia, and cranial nerve palsies. The cognitive disturbance ranges from a mild memory disorder to severe dementia, which is most frequent. Seizures may be tonic-clonic, focal with dyscognitive features, or myoclonic with prominent jerking of the face, limbs, or palate. Oculomotor apraxia has been described as the presenting feature. In addition, thrombocytopenia and prolonged prothrombin and partial thromboplastin times may cause bleeding. The patient may be anemic, and Gaucher cells may be found on bone marrow examination. Symptoms vary between individuals, so that some children have cirrhosis with portal hypertension, varices, pulmonary interstitial involvement, and heart disease. Type 3 Gaucher disease has been classified further as types 3a and 3b based on the extent of neurologic involvement and the presence of progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Norbottnian Gaucher disease, a genetic form identified in Sweden, has features of types 2 and 3. The slowly progressive neurologic symptoms may not occur until early adulthood.

Treatment is through enzyme replacement and substrate reduction therapy. Studies on the effectiveness of therapy have used hemoglobin concentrations, platelet counts, reduction in spleen and liver volumes and parameters of bone disease as primary outcome measures, but rarely neurologic symptoms. Therapy has modified phenotypes of disease. The risk of skeletal disease or even multiple myeloma may be reduced or prevented but the effect on other complications is less clear. Enzyme replacement therapy with recombinant forms of macrophage-targeted acid β-glucosidase is beneficial for types 1 and 3 Gaucher disease, reducing liver and spleen size, improving blood counts, and reducing skeletal anomalies. It does not cross the blood–brain barrier and is therefore not effective in the management of neurologic symptoms. Substrate reduction therapy with *N*-butyl-deoxynojirimycin inhibits the enzyme glucosylceramide synthase, a glucosyl transferase responsible for the first step in the synthesis of glycosphingolipids. Unlike enzyme replacement therapy, this drug does cross the blood–brain barrier, but no data are yet available on whether it has a role in neuronopathic Gaucher disease.

Compounds that bind to and increase the stability of mutant enzymes are used as chaperones to increase the transfer of mutant enzyme from the endoplasmic reticulum to lysosomes. Their small molecular size means that they are able to cross the blood–brain barrier. Early studies of ambroxol, a mucolytic drug licensed as an expectorant, shows that it binds to mutant, misfolded glucocerebrosidase. Encouraging improvements in neurologic symptoms are reported.[11]

Bleeding and the New Anticoagulants

A number of new nonvitamin K antagonist oral anticoagulant drugs have been introduced in recent years. They act by direct thrombin or factor Xa inhibition, with the advantage of providing a stable level of anticoagulation on a regular dose, and do not require monitoring and dose adjustment as with warfarin.

Dabigatran, a direct thrombin inhibitor, is used for the prevention of stroke in patients with nonvalvular atrial fibrillation. When compared to people treated with warfarin, patients taking dabigatran have fewer life-threatening bleeds and fewer minor and major bleeds, including intracranial bleeds, but the rate of gastroenterologic bleeding is higher, mostly in patients over 75 years old. The most common side effect of dabigatran, seen in more than 10 percent of patients, is bleeding.

Idarucizumab, a humanized monoclonal antibody fragment, specifically binds to dabigatran with higher affinity than thrombin, rapidly neutralizing its anticoagulant effect without increasing the risk of thrombosis or controlling bleeding. In case reports it has been used successfully to reverse anticoagulation prior to the administration of intravenous recombinant tissue plasminogen activator (t-PA) thrombolysis for acute ischemic stroke.

Rivaroxaban and apixaban are highly selective direct inhibitors of factor Xa. They have been trialed successfully for postoperative thromboembolic prophylaxis and for the prevention of stroke associated with atrial fibrillation. The effects of these agents may be reversed by 4-factor prothrombin complex concentrate, and plasma exchange.

In comparison with warfarin, a very large retrospective study suggested that in patients with nonvalvular atrial fibrillation, apixaban was associated with lower risks of both stroke and major bleeding, dabigatran was associated with similar risk of stroke but lower risk of major bleeding, and rivaroxaban was associated with similar risks of both stroke and major bleeding.

COAGULATION DISORDERS

Thrombosis may arise from abnormalities of the blood-vessel wall, alterations in blood composition, and abnormalities in the dynamics of blood flow—the triad of Virchow. The intact vessel wall modulates thrombin activity, platelet reactivity, and the release of vasodilators, and it promotes local fibrinolytic activity. Injury of a vessel wall may therefore lead to the exposure of the prothrombotic subendothelium as well as interfere with its antithrombotic properties.

A number of blood components exhibit prothrombotic and antithrombotic effects, so that under normal circumstances platelet degranulation and aggregation as well as thrombin generation occur only at sites of tissue injury. Thrombin production is the major step in thrombosis that results in fibrin deposition. The fibrinolytic system prevents the deposition of excess fibrin, a negative-feedback process that is catalyzed by fibrin through plasmin production and also breaks down platelet-adhesive glycoproteins, further reducing platelet recruitment. The balance between prothrombotic and antithrombotic activity determines the degree of thrombus progression.

There are a number of well-recognized circumstances under which this balance may be altered. Tissue injury may lead to increased synthesis of plasminogen activator inhibitor type 1, with an increased risk of thrombosis. Congenital deficiencies of anticoagulant proteins are well recognized. Antiphospholipid antibodies are associated with venous and arterial thrombosis. Pregnancy is associated with a variety of changes in hemostatic components, giving rise to thrombosis or hemorrhage; increased fibrinogen production and placental production of a plasminogen activator inhibitor type 2 contribute to the increased risk of thrombosis in the later stages of pregnancy. Cigarette smoking, estrogen use, tissue injury, infection, and inflammation each result in increased production of components of the cascade, particularly fibrinogen.

Diminished blood flow may lead to the local accumulation of platelets and thrombin, and, if the stasis is sufficient, endothelial hypoxia may result in impairment of the antithrombotic properties of the endothelium. Blood viscosity is a significant determinant of blood flow. Under low-flow conditions, platelets have only a minor role in the generation of thrombosis; stasis is the dominant factor in the pathogenesis of venous thrombosis in which activated clotting factors circulate to areas of venous stasis, where fibrin is generated. This process is exacerbated by defects in innate anticoagulant mechanisms. In the arterial system, thrombosis usually arises from endothelial damage, commonly in association with atherosclerosis. Procoagulant mechanisms may be involved in the initiation and progression of atherosclerosis, but local platelet degranulation results in plaque growth. Plaque rupture or ulceration is often the final event that exposes procoagulant material with rapid formation of platelet thrombus, which may break up and embolize or become consolidated and enlarged by fibrin deposition.

It follows from the physiology of thrombosis that differing risk factors are responsible for the generation of venous and arterial thrombosis. Furthermore, the multifactorial nature of thrombophilia is becoming increasingly apparent, and individuals with more than one inherited thrombophilia risk factor or those with an inherited and an acquired risk factor are particularly prone to thrombosis.

Routine evaluation for hypercoagulability, such as assays for deficiencies of coagulation inhibitors or genetic analysis for the factor V Leiden or prothrombin 20210 mutation, is not helpful in identifying risk factors for adult patients with stroke, other than in the context of an associated systemic venous clot that may travel through a right-to-left shunt, such as a patent foramen ovale.

Antiphospholipid Antibodies

The lupus anticoagulant and anticardiolipin are members of a group of antiphospholipid antibodies that are associated with venous and, to a lesser degree, arterial thrombosis. A diagnosis of antiphospholipid syndrome requires the combination of at least one clinical and one laboratory criterion which is persistent over time. Anticardiolipin and anti-β_2-glycoprotein I antibodies, detected by the use of enzyme-linked immunosorbent assay, and the lupus anticoagulant, detected by clotting assays, are the recommended tests for the syndrome. Antiphospholipid antibodies comprise a family of antibodies that react with serum phospholipid-binding plasma proteins, among which β_2-glycoprotein I (GPI) is the most important. This results in endothelial nitric oxide synthase antagonism via apolipoprotein E receptor 2–dependent processes.

Antibodies to protein S, protein C, prothrombin, annexin V, and annexin II have also been described. Affinity for coagulation-active negatively charged lipids is the basis for phospholipid-dependent coagulation assays for lupus anticoagulant.

In SLE, predisposition to thrombosis is associated with the presence of antinuclear antibodies and antiphospholipid antibodies. The primary antiphospholipid syndrome is the association between arterial and venous thrombosis with the lupus anticoagulant, anticardiolipin, or other phospholipid antibodies, along with a history of recurrent early miscarriage and sometimes thrombocytopenia, in the absence of SLE or other connective tissue disorders. In a cohort of 1,000 patients with the antiphospholipid syndrome, 82 percent were female, primary antiphospholipid syndrome was present in 53 percent, and SLE was associated in 36 percent. Antiphospholipid antibodies may arise de novo or may be associated with a variety of underlying disorders, as discussed in Chapters 11 and 50. The risk of thrombosis is variable; antiphospholipid antibodies associated with infections and a variety of drugs are associated with a smaller risk of thrombosis than those of primary or secondary antiphospholipid syndromes. The presence of more than one class of antiphospholipid antibody increases thrombotic risk. Patients with triple positivity (anticardiolipin, the lupus anticoagulant, and anti-β_2-glycoprotein 1) have a 30 percent chance of thrombosis even when anticoagulated.

Since patients with clinical manifestations may have multiple antiphospholipid antibodies, testing must include at least two sensitive coagulation assays, usually the kaolin-cephalin clotting time (KCCT) and the dilute Russell viper venom time

(DRVVT) with a platelet neutralization step, as well as the solid-phase assays for IgG and IgM anticardiolipin antibody. Long kaolin-cephalin clotting times may arise from coagulation factor deficiency, and false-negative antiphospholipid antibody testing may occur from binding of the antibodies to platelets in samples not processed rapidly and appropriately. Low-titer antibodies and IgM antibodies are most likely to be nonpathogenic. Transient positive antibodies, particularly IgM, may follow a variety of infections, so positive tests should be repeated after at least 12 weeks as in the current revised Sapporo classification criteria.[12]

Isolated anti-β_2-GPI antibodies are not associated with thrombosis. The combination of the IgG anti-β_2GPI domain I antibody and IgG/IgM antiphosphatidylserine/prothrombin complex antibody tests shows a high positive predictive value for the diagnosis of antiphospholipid syndrome.

Annexin V is a natural anticoagulant with a high calcium-dependent binding affinity for negatively charged phospholipids that acts competitively with coagulation factors to inhibit the prothrombin complex. High levels of antiannexin V antibodies have been found in 20 to 30 percent of patients with SLE. There is growing evidence that the antiphospholipid antibody-mediated disruption of the annexin V anticoagulant crystal shield is a mechanism for pregnancy losses and thrombosis in patients with antiphospholipid syndrome. There is early evidence that annexin antibodies may relate to clinical manifestations in SLE and with the course of the disease in Behçet disease.

Depression, cognitive dysfunction, psychosis, seizures, chorea, and transverse myelitis have been associated with the presence of antibodies, although there is evidence that not all arise from ischemia. Neuropsychiatric lupus manifestations, especially the common disorders of mood and cognition, may be mediated by cytokines or by antibodies. A subset of anti-DNA antibodies binds the NMDA receptor. High titers are present in 30 to 40 percent of SLE patients and are associated with cognitive impairment.

Sneddon syndrome is a noninflammatory thrombotic arteriopathy affecting medium- and small-sized arteries, characterized by the combination of multiple cerebral infarcts and livedo reticularis. It may be idiopathic or associated with a primary antiphospholipid syndrome or with SLE with or without antiphospholipid syndrome.

Epilepsy occurs in 8.6 percent of patients with the antiphospholipid syndrome. Multivariate logistic regression analysis identified CNS thromboembolic events as the most significant risk factor for epilepsy in these patients, with an odds ratio (OR) of 4.1, followed by SLE (OR 1.4) and valvular vegetations (OR 2.9).

The clinical features have been described in 1,000 patients with antiphospholipid syndrome. Neurologic manifestations include migraine (20.2%), stroke (19.8%), TIA (11.1%), epilepsy (7.0%), amaurosis fugax (5.4%), vascular dementia (2.5%), retinal artery thrombosis (1.5%), chorea (1.3%), acute encephalopathy (1.1%), optic neuropathy (1.0%), retinal vein thrombosis (0.9%), transient amnesia (0.7%), cerebral venous sinus thrombosis (0.7%), cerebellar ataxia (0.7%), transverse myelopathy (0.4%), and hemiballismus (0.3%).

Many studies have examined the association between antiphospholipid antibodies and stroke. A study of unselected adults presenting with stroke suggested that the presence of anticardiolipin antibodies is an independent risk factor for stroke but does not predispose to subsequent thrombotic events. The Antiphospholipid Antibodies and Stroke Study (APASS), a prospective cohort study within the Warfarin vs Aspirin Recurrent Stroke Study (WARSS), did not predict an increased risk for subsequent vascular occlusive events over 2 years. Routine screening for antiphospholipid antibodies in unselected adults with ischemic stroke is therefore not recommended. With the introduction of assays for antibodies directed specifically against β_2-glycoprotein I, however, a relative risk of 2 to 3 for stroke has been suggested. Studies of a wider range of antiphospholipid antibodies in the pathogenesis of cerebral ischemia suggest a relevant role for a combination of antiphosphatidylserine IgG and anti-β_2-glycoprotein-I IgA in stroke etiology.

Among younger patients, the association appears stronger, with antiphospholipid antibodies present in 46 percent of patients younger than 50 years who present with stroke or TIA compared with 8 percent of matched control subjects with nonthrombotic neurologic disease. In young adults, the presence of antiphospholipid antibodies, particularly the lupus anticoagulant, has been identified as an independent risk factor for first and possibly also for recurrent ischemic stroke, although a prospective study of young patients with recent TIA or ischemic stroke failed to show that antiphospholipid antibodies are a strong risk factor for recurrent stroke or TIA. Isolated IgM antiphospholipid syndrome patients represent 14.3 percent of the antiphospholipid syndrome population. They are older at diagnosis and have a significantly increased risk of stroke.

Hereditary Thrombophilia

The inherited thrombophilias are a group of disorders in which a defect or deficiency in the natural anticoagulant mechanisms predisposes to the development of venous thrombosis. Investigation into potentially inherited disorders must include assessment of family members.

Within the cerebral venous sinuses, the superior sagittal and transverse sinuses are frequently involved, whereas cavernous sinus thrombosis is much less common. Antithrombin III, protein C, and protein S deficiencies, factor V Leiden mutations, the prothrombin G20210A gene mutation, and *MTHFR* C677T mutations (resulting in hyperhomocysteinemia) all predispose to thrombosis. Other inherited disorders, such as deficiency of heparin cofactor 2, plasminogen, t-PA, factor XII, or prekallikrein may result in a modestly increased risk of thrombosis.

The genetic risk factors for venous thrombosis can be categorized by their level of increased risk. Strong risk factors include deficiencies of antithrombin III, protein C, and protein S, which collectively affect less than 1 percent of the population. Because these deficiencies are rare, most reports on risk come from family studies, which suggest that these deficiencies can lead to highly penetrant phenotypes with a 10-fold risk for heterozygote carriers. Studies from unselected consecutive patients, however, indicate that the risks are much less, raising the possibility that these families may carry other unrecognized defects. Moderately strong risk factors for thrombosis are the factor V Leiden mutation, prothrombin 20210A mutations, non-O blood group mutations, and the fibrinogen 10034 T mutation. There are many weak genetic risk factors identified, including fibrinogen, factor XIII, and factor XI variants. Even for moderately strong risk factors (relative risks 2 to 5), the majority of carriers will never develop thrombosis.

A large genome-wide association study suggested that common variants could explain about 35 percent of venous thrombosis susceptibility, of which only 3 percent could be attributable to the main identified genes. The relevance of the findings to cerebral venous thrombosis remains unclear.

The combined retrospective and prospective multicenter VENOST study of Cerebral Venous Thrombosis in Caucasian patients studied 1,144 patients. In 26.4 percent, prothrombotic conditions were identified, with 19 percent having more than one cause identified. These causes included *MTHFR* (methylenetetrahydrofolate reductase) homozygote mutation in 6.3 percent and heterozygote mutation in 5.1 percent. Factor V Leiden homozygote mutation occurred in 5.1 percent, prothrombin gene mutation in 2.6 percent, PAI mutation in 1.4 percent, protein C or S deficiency in 5.0 percent, hyperhomocysteinemia in 4.8 percent, activated protein C resistance in 1.5 percent, and antithrombin III deficiency in 0.5 percent.

Antithrombin III Deficiency

Antithrombin is a plasma glycoprotein that inhibits thrombin and other activated serine proteases, including factors IXa, Xa, XIa, XIIa, and kallikrein. Heterozygous antithrombin III deficiency affects 1 in 2,000 to 5,000 of the population and may arise as a new mutation. Deficiency is associated with sagittal sinus and other cerebral venous sinus thromboses. A more rare disorder is recognized in which a nonsense mutation results in a dysfunctional variant of antithrombin causing recurrent venous thrombosis. Acquired antithrombin III deficiency associated with cerebral venous sinus thrombosis may also arise from reduced antithrombin synthesis due to liver disease or increased loss in nephrotic syndrome, oral contraceptive use, DIC, protein malnutrition, and heparin therapy. A retrospective cohort family study that assessed the risk of venous thromboembolism in individuals with thrombophilia suggested that antithrombin III deficiency may be associated with a higher risk of thrombosis than the other genetic defects.

Protein C Deficiency

Cerebral venous sinus thrombosis is associated with deficiency of protein C, which is a vitamin

K–dependent protein that binds to thrombomodulin, an endothelial cell surface protein, and is converted to an active protease by the action of thrombin. In conjunction with protein S, protein C proteolyses factors Va and VIIIa, thereby reducing thrombin formation and promoting fibrinolysis. Inheritance of protein C deficiency is usually autosomal dominant, although in some families heterozygotes with plasma concentrations of less than 50 percent of normal remain asymptomatic, giving an autosomal recessive–like pattern of inheritance. Dysfunctional molecules that are present in normal levels are described.

Population studies suggest that 1 in 200 to 300 subjects have levels of protein C consistent with congenital deficiency, although the incidence of protein C deficiency and venous thromboembolism suggests a prevalence of 1 in 30,000. This represents 4 percent of subjects with venous thromboembolism presenting before the age of 45 and demonstrates that other inherited and acquired risk factors are frequently required for thrombosis to occur.

PROTEIN S DEFICIENCY

Sagittal sinus and other cerebral venous sinus thromboses are reported in association with deficiency of protein S, which is a vitamin K-dependent glycoprotein that acts as a cofactor for activated protein C. Approximately 60 percent of protein S is protein bound, so that total and free levels must be measured. Only the unbound protein is biologically active, and since its level may fall in acute disease, repeat measurement and the demonstration of a persistently reduced level are required to prove association. Acquired protein S deficiency has been identified in hepatic disease, vitamin K deficiency, pregnancy, and hormonal contraceptive use. In the presence of the factor V Leiden mutation, functional assays of protein S may give a falsely low reading.

FACTOR V LEIDEN (RQ506Q)

The factor V Leiden mutation is a common gain-of-function mutation in factor V at Arg 506. Protein C cleaves and inactivates the Va procoagulant, resulting in factor V Leiden becoming resistant to inactivation by activated protein C. Factor V Leiden is the most commonly inherited prothrombotic state, accounting for at least 90 percent of the cases of resistance to activated protein C. The mutation is inherited as an autosomal dominant trait and has a prevalence of approximately 5 percent in the Caucasian population. It is found in 20 percent of patients with venous thrombosis and approximately 50 percent with familial thrombophilia. A number of clinical studies, using different inclusion criteria, show a prevalence of activated protein C resistance ranging from 20 to 60 percent among patients with venous thromboembolism at any site, and 20 to 25 percent in cerebral venous sinus thrombosis. The actual thrombotic risk is moderate, but its high prevalence makes it by far the most important inherited risk factor. The risk appears to be greatest in neonates and children.

Acquired activated protein C resistance, not due to the factor V Leiden mutation, is also a risk factor for venous thrombosis. Thrombotic events often occur in the presence of noninherited risk factors (e.g., oral contraceptive intake, pregnancy, puerperium, trauma, or prolonged immobilization) which are also present in many cases of cerebral venous sinus thrombosis with the factor V Leiden mutation.

PROTHROMBIN G:A 20210 MUTATION

Prothrombin is a precursor of the serine protease thrombin, a key enzyme in the production of fibrin from fibrinogen. A single nucleotide substitution (G to A) at position 20210 is associated with an increased risk of deep venous thrombosis and cerebral venous sinus thrombosis. Carriers have a two- to threefold increased risk of venous thrombosis at any site, and the variant is found in approximately 6 percent of patients with venous thrombosis. The mutation is found in 18 percent of selected patients with a family history of venous thrombosis, and 1 to 2 percent of control subjects, making it the second most common cause of hereditary thrombophilia after the factor V Leiden mutation. The prevalence of the prothrombin gene mutation is 20 percent in patients with cerebral venous sinus thrombosis in comparison with 3 percent of healthy control subjects. The prevalence of this mutation varies, contributing to cerebral venous thrombosis in European and South American populations but apparently not in the Middle East and East Africa.

Hyperhomocysteinemia

Meta-analyses have been reported as showing an increased risk of venous thromboembolism of two- to threefold in hyperhomocysteinemia. However, after extensive adjustments for confounding factors, no association with an increased risk of venous thrombosis has been shown.

A C-to-T mutation at position 677 in the methylene tetrahydrofolate reductase gene (*MTHFR*) gives rise to a thermolabile variant with reduced activity accompanied by elevated plasma homocysteine. Homozygosity for the thermolabile form is found in 5 to 15 percent of the general population who have significantly elevated plasma homocysteine levels.

Moderate hyperhomocysteinemia is now recognized as a risk factor for arterial disease, including carotid artery stenosis and stroke. It has also been suggested that hyperhomocysteinemia plays a role in the development of small-vessel ischemia. Further discussion of hyperhomocysteinemia is provided in Chapter 11.

Factor VIII

The levels of the procoagulant factor VIII are associated with an increased risk of arterial and venous thrombosis. High factor VIII levels appear particularly to be a risk factor for thrombosis in children. The MEGA follow-up study demonstrated a strong predictive value of factor VIII levels with a dose-response such that those with the highest levels have a triple risk of recurrent thrombosis compared with those with lower levels. In patients with a first venous thrombosis, the risk of recurrence is not high enough to outweigh the bleeding risk associated with continued anticoagulant treatment.

Interactions Between Inherited Thrombophilias

The multifactorial nature of thrombophilia is well-recognized. Among 162 patients and 336 control subjects, two or more polymorphisms were detected in 16.7 percent of patients and 0.9 percent of controls. The odds ratios for venous thrombosis with the joint occurrence of the factor V Leiden and prothrombin G20210A mutations was 58.6; for the factor V Leiden mutation and *MTHFR* polymorphisms was 35.0; and for the prothrombin G20210A mutation and *MTHFR* polymorphisms was 7.7. Coexistence of additional antithrombin III, protein C, or protein S deficiency has been reported in 14.5 percent of patients with the factor V Leiden mutation. As factor V Leiden and prothrombin 20210A mutations are both common, compound heterozygotes are not particularly rare and have a 20-fold increased risk of thrombosis; this combination of thrombophilias is associated with an increase in the prevalence of more unusual sites of venous thrombosis, such as the cerebral venous sinuses.

Thrombophilic Disorders and Arterial Thrombosis

Although there are numerous reports of cerebral arterial thrombosis and infarction occurring in antithrombin III, protein C, and protein S deficiencies, as well as with factor V Leiden mutations, the risk is extremely small compared with the risk of venous thrombosis. The prospectively conducted FUTURE study showed that prothrombotic factors do not increase the risk of recurrent ischemic events after cryptogenic stroke at young age. A stroke in the presence of a strong risk factor for venous thrombosis should therefore always raise the suspicion of paradoxical venous embolism.

Only rarely has familial thrombophilia been diagnosed conclusively following arterial thrombosis, by demonstrating that the deficiency persists after the acute event is over. This is particularly important in the case of protein S, since it binds to an acute-phase reactant (C4bBP), resulting in an acquired reduction in free or functional protein S. Low protein S levels are also found in acute nonvascular illness and during pregnancy, and protein C levels may fall in liver disease, postoperatively, and in association with DIC. Serial protein C measurements demonstrate that it may take 3 months for levels to return to normal following a stroke. Case-control studies have failed to identify an association between factor V Leiden and arterial stroke.

In interpreting the reports suggesting that hereditary thrombophilia may be associated with stroke in childhood, it should be noted that reference ranges are lower than for adults, so the association may be erroneous. Ethnic differences have also been noted in the levels of markers of thrombophilia in stroke, emphasizing the need for care in interpreting these tests.

Interactions between genetic and noninherited risk factors, particularly oral contraceptives, should be considered, although progesterone-only contraceptives do not add to risks of thrombosis. Any association between the inherited thrombophilias and arterial stroke is therefore weak and is likely to be enhanced by other prothrombotic risk factors.

Patent Foramen Ovale

In patients 55 years or younger with cryptogenic (presumed embolic) stroke, patent foramen ovale has been shown to be a more common finding (56%) than in controls (18%) and in those patients with stroke of undetermined cause (17%). An association has been shown between the presence of coagulation abnormalities, especially the factor V Leiden and prothrombin G20210A mutations, and a history of Valsalva maneuver-like activity at stroke onset. Such activity was more common at stroke onset in patients with, rather than without, patent foramen ovale, suggesting paradoxical embolism as a mechanism. Coagulation abnormalities have been found in 30 percent of patients with cryptogenic infarction who also had patent foramen ovale; however, the combined presence of patent foramen ovale and antiphospholipid syndrome does not increase the risk of subsequent cerebrovascular events. Interestingly, the prevalence of prothrombin mutations is higher in patients with a patent foramen ovale as compared to stroke patients without a patent foramen ovale, raising the possibility that there may be an association between the coagulopathy and the formation of intracardiac shunts. No significant association was found between the *MTHFR* genotype and strokes related to patent foramen ovale. With the introduction of devices to close patent foramen ovale percutaneously, the risks of closure has fallen. A meta-analysis of five studies though with some heterogeneity of medical treatment and nature of the patent foramen ovale, suggests that closure is superior to medical therapy for reducing stroke risk in patients with cryptogenic stroke.

CONCLUDING COMMENTS

The entire nervous system is potentially vulnerable to metastatic disease, typically occurring in the setting of a known disseminated systemic malignancy. Approximately 45 percent of patients with systemic cancer and neurologic deficits are found to have metastatic involvement of the nervous system. The most common cancer-related neurologic diagnosis is brain metastasis (16%), followed by bone metastasis (10%) and epidural metastasis (9%). The incidence of metastatic involvement of the nervous system continues to rise due to improved treatment strategies directed toward primary cancers and systemic metastases. In 2019, estimated new cancer cases in the United States exceeded 1.7 million.[1]

Metastatic involvement of the central nervous system, including its overlying structures, and the peripheral nervous system causes significant neurologic morbidity and mortality. The skeletal muscles are

Brain

EPIDEMIOLOGY

In the United States between 2010 and 2013, 217,687 out of 1.3 million patients with malignancy were diagnosed with one or more metastases. A total of 26,430 patients, 2 percent of all patients with cancer and 12.1 percent of those with metastatic disease, were found to have brain metastases at diagnosis. The estimated incidence of identified brain metastases among patients with newly diagnosed cancer is 23,598 annually. Patients with small cell and nonsmall cell lung cancer have the highest rate of brain metastasis at the time of cancer diagnosis. Among patients with metastatic disease, patients with melanoma (28.2%), lung adenocarcinoma (26.8%), nonsmall cell lung cancer not otherwise specified/other lung cancer (25.6%), small cell lung cancer (23.5%), squamous cell lung carcinoma (15.9%), bronchioloalveolar carcinoma (15.5%), and renal cancer (10.8%) have the highest incidence proportion of brain metastases.[2] Brain metastases are more common in Hispanics or Asians than other ethnic groups. The incidence of brain metastasis is increasing and this has been related to improvements in systemic therapy and to greater utilization of appropriate imaging studies.

PATHOPHYSIOLOGY

The most common mechanism of spread to the brain is hematogenous dissemination. The "anatomic or mechanical" hypothesis states that the distribution of metastases is related to the amount of blood flow to the brain. This phenomenon explains the predilection for brain metastases to involve the cerebral hemisphere in 80 percent, cerebellum in 15 percent, and brainstem in 5 percent of cases. As cancer cells travel through the arterial circulation, they become trapped in the end arteries at the gray–white matter junction (Fig. 26-1). Only about two-thirds of metastases can be explained by blood flow alone, suggesting that other factors play a role. The "seed and soil" mechanism postulates that appropriate tumor cells or "seeds" grow in site-specific hosts or "soil." Brain metastases are hypothesized to result from neurotropic factors facilitating "brain-homing" and direct interaction with neural substance. The vascular basement membrane of pre-existing blood vessels promotes nonsprouting angiogenesis and proliferation of metastatic tumor cells by means of tumor cell vascular endothelial growth factor (VEGF).

Clinical studies have detected specific genomic mutations present in brain metastases, but not in the primary tumor or in extracranial metastases. In a comprehensive genomic study of matched brain metastases, primary tumors, and normal tissues, over 50 percent of brain metastases had additional targetable mutations that were not found in the matched clinically sampled primary tumors.[3] These additional oncogenic alterations may have driven the proliferation or survival of a prometastatic subclone within the primary tumor, leading to metastases. Contiguous brain invasion from intracranial dural and skull-base metastases is another mechanism by which brain metastases occur.[4]

PATHOLOGY

Grossly, metastatic tumors in the brain are well-circumscribed and surrounded by edematous white matter; cystic degeneration, necrosis, and hemorrhage can be seen. Metastatic lesions from melanoma, choriocarcinoma, and renal cell carcinoma have a high tendency for intratumoral hemorrhage. Microscopically, brain metastases are usually well-demarcated and generally appear histologically similar to the primary tumor. Vascular proliferation within the lesions and reactive astrocytosis in the surrounding brain parenchyma may be encountered. Metastases from breast, kidney, and colon are usually solitary, whereas multiple metastases are common from melanoma and lung carcinoma. Molecular genetic analysis can provide information in determining metastatic cancers of unknown origin. Molecular studies also define oncogenic pathways such as in lung cancer (ALK, C-MET, ROS1, RET), breast cancer (Her2/Neu), and melanoma (BRAFV600E, NRAS, CKIT) that can be targeted for therapy.[4]

CLINICAL FEATURES

Neurologic manifestations in patients with brain metastases may be focal, resulting from local displacement or

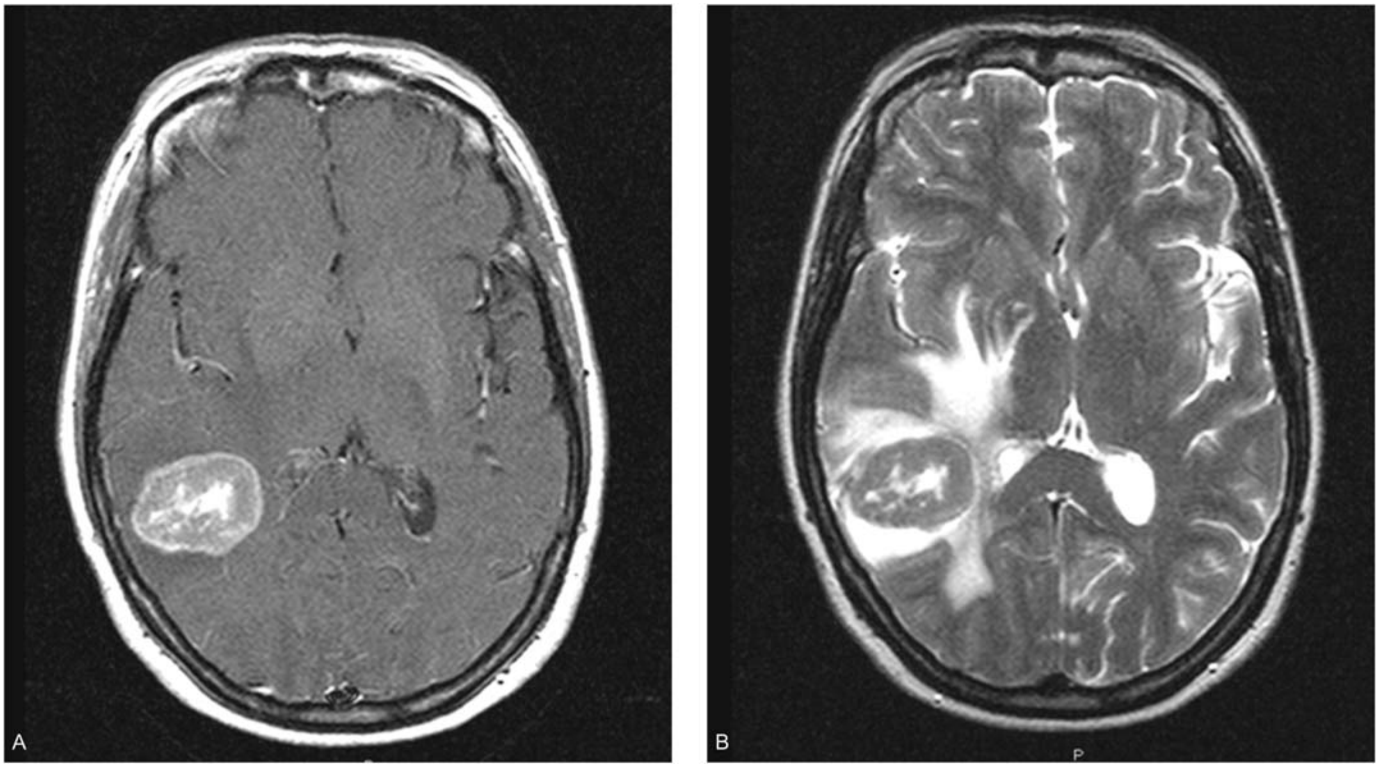

FIGURE 26-1 ■ Solitary brain metastasis in a patient with breast carcinoma. *A*, Postcontrast T1-weighted gadolinium magnetic resonance imaging (MRI) sequence demonstrating peripheral and central enhancement of a mass in the right posterior temporal lobe; *B*, T2-weighted MRI sequence demonstrates a large field of high signal with finger-like projections in the white matter extending anteriorly within the temporal lobe and posteriorly within the parietal lobe, consistent with vasogenic edema.

destruction of the surrounding parenchyma by the tumor or edema, or generalized due to increased intracranial pressure (ICP) or hydrocephalus. Patients usually present with subacute or chronic progressive neurologic signs and symptoms. Headache, typically worse in the morning, is the most common presenting symptom, affecting approximately 50 percent of patients. Focal neurologic deficits are present in 30 to 40 percent of patients, cognitive dysfunction in 30 to 35 percent, and seizures as a presenting feature in 15 to 20 percent. Another 5 to 10 percent of patients present with acute "stroke-like" symptoms due to intratumoral hemorrhage. Nearly 15 percent are asymptomatic.

Over 80 percent of patients diagnosed with brain metastases have a known systemic malignancy (metachronous presentation). In up to 30 percent of patients, brain metastases are diagnosed at the same time as the primary malignancy (synchronous presentation) and in another 5 to 10 percent the brain metastases are the presenting manifestation (precocious presentation). A majority of patients (more than 30%) have multiple metastases with more than four lesions, 20 to 30 percent have two to three lesions ("oligometastases"), and another 20 to 30 percent have a solitary metastasis.[4,5]

DIAGNOSTIC STUDIES

Magnetic resonance imaging (MRI) is the diagnostic modality of choice for the evaluation and monitoring of patients with brain metastases and is much more sensitive than computed tomography (CT) in detecting the number, size, location, and secondary effects of the lesions. Brain metastases tend to be multiple, spherical, and located at the gray–white matter junction, with surrounding vasogenic edema. These lesions appear isointense or hypointense on precontrast T1-weighted MRI sequences and enhance avidly upon contrast administration due to a disrupted blood–brain barrier. The surrounding edema is hyperintense on T2-weighted and fluid-attenuated inversion recovery sequences (Fig. 26-1). The amount of surrounding edema is often disproportionate to the size of the lesions. Intratumoral hemorrhage within the tumor, when present, is evident on precontrast T1 and gradient

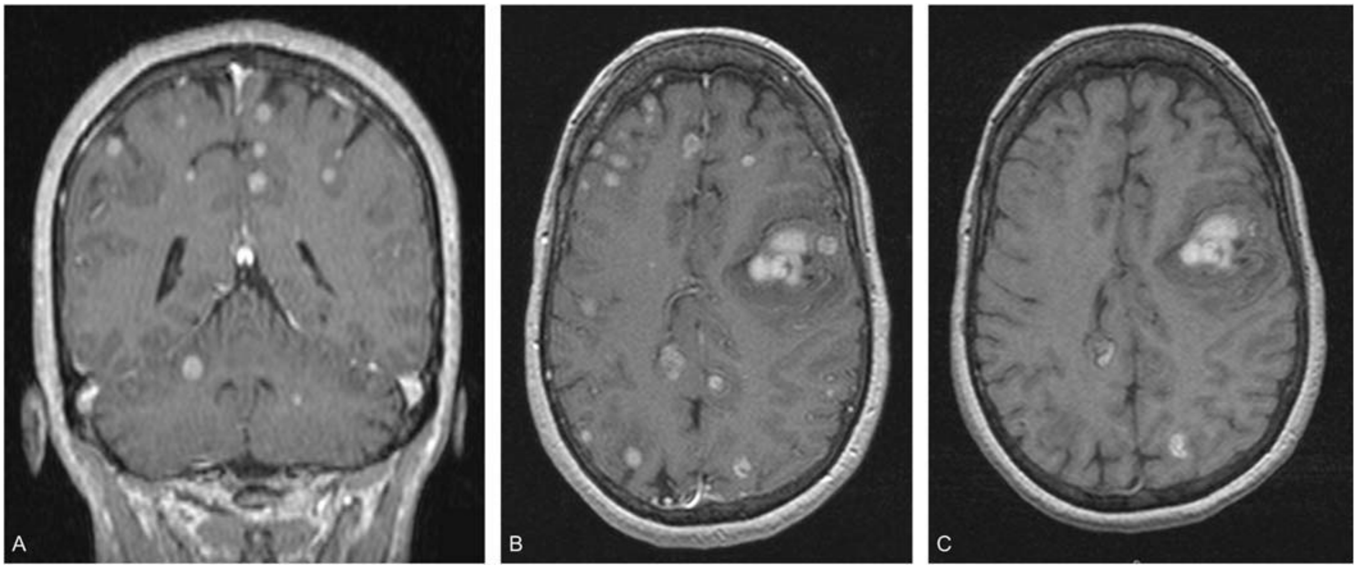

FIGURE 26-2 ■ Multiple metastases with intratumoral hemorrhage from metastatic melanoma. *A* and *B*, Numerous contrast-enhancing lesions are present on T1-weighted postcontrast MR images of the supratentorial and infratentorial brain. *C*, Several lesions are present, the largest in the left frontal lobe, and show T1 shortening consistent with the presence of blood, with surrounding edema resulting in midline shift towards the contralateral side.

recalled echo sequencing (Fig. 26-2). CT studies are generally utilized in acute settings to determine the presence of hemorrhage, herniation, or hydrocephalus. For patients previously treated with radiation, the differentiation of tumor recurrence from radiation effects with routine MRI may be challenging. Increased glucose metabolism with [^{18}F]fluorodeoxyglucose positron emission tomography (FDG-PET) studies is characteristic for brain metastases, whereas lesions composed of radiation necrosis are frequently hypometabolic. Increase in relative cerebral blood volume on MR perfusion imaging may also allow this distinction. MR spectroscopy often shows lower choline-to-creatinine ratio in brain metastases than in high-grade gliomas.[4,5]

A search for primary malignancy should be performed in patients with suspected brain metastases without a known systemic cancer. CT of the chest takes precedence over abdominal and pelvic evaluation because of the high frequency of brain metastases originating from the lungs. Whole-body FDG-PET is also helpful in investigating the primary source, although it has low specificity in differentiating malignant from benign inflammatory lesions. Biopsy of tumors discovered upon systemic evaluation is often easier than biopsy or resection of the brain lesion.[4,5]

DIFFERENTIAL DIAGNOSIS

Several conditions mimic the radiologic findings of brain metastases including high-grade glioma, lymphoma, abscess, stroke, and demyelinating disorders. Different imaging techniques and special characteristics of the lesions may help distinguish between these clinical entities. An elevated cerebral blood volume in perfusion studies reflects tumor vascularity and is diminished in edema, radiation necrosis, or infarct. MR spectroscopy detects the metabolic characteristics of these lesions, differentiating spectra of metastases, gliomas, vasogenic edema, or gliosis, and other mass lesions. Diffusion-weighted imaging (DWI) detects areas of the brain with decreased proton mobility, while the apparent diffusion coefficient (ADC) characterizes the rate of diffusional motion; unrestricted diffusion in DWI and high ADC value in the center of a ring-enhancing mass are suggestive of a necrotic mass as seen in metastasis or high-grade glioma. Restricted diffusion represents cytotoxic edema in an acute infarct, and is also seen in highly cellular lesions such as cerebral abscess, infectious encephalitis, or primary CNS lymphoma. In many cases, brain biopsy is required for definitive diagnosis.

PROGNOSTIC VARIABLES

Classifying patients with brain metastases based on prognosis helps clinicians maximize survival while avoiding unnecessary treatments. Important factors that predict outcomes are age, performance status, status of primary tumor, and extent of extracranial disease. The Radiation Therapy Oncology Group used recursive partitioning analysis (RPA) to categorize patients into three prognostic classes. Patients harboring all four favorable prognostic factors [age less than 65 years, Karnofsky performance status (KPS) of at least 70, controlled primary tumor, and no extracranial metastases] had the best prognosis, with expected median survival of 7.1 months. Patients with KPS of 70 or more but at least one other unfavorable factor have an intermediate prognosis, with expected median survival of 4.2 months. A KPS of less than 70 is a poor-prognostic factor, with median survival of 2.3 months (Table 26-1). Important prognostic factors also vary depending on tumor type. KPS, number of brain metastases, extracranial metastasis, and hemoglobin are important prognostic factors for renal cell carcinoma. The updated Disease-Specific Graded Prognostic Assessment (DS-GPA) which incorporated gene and molecular alteration data with clinical factors identified KPS, age, presence of extracranial metastases, number of brain metastases, and the presence of *EGFR* or *ALK* gene alterations for lung cancer and *BRAF* status for melanoma as significant prognostic factors, whereas in breast cancer, the hormonal status (estrogen receptor and progesterone receptor), human epidermal growth factors receptor (EGFR) 2 status, KPS, and age are important factors, but not the number of brain metastases or status of systemic disease.[4,5]

TREATMENT

Management includes supportive care for palliation of symptoms and definitive treatment directed toward the metastases, aiming to prolong survival while preserving quality of life. Most patients die from their systemic disease rather than from their metastases.

TABLE 26-1 ■ Recursive Partitioning Analysis (RPA) Categorization of Patients into Three Prognostic Classes

RPA Class	Factors	Median Survival
1	Age <65 years old KPS ≥ 70 Controlled primary tumor No extracranial metastases	7.1 months
2	All patients not in class 1 or 3	4.2 months
3	KPS <70	2.3 months

KPS, Karnofsky performance status.
Further details are provided by Gaspar LE, Scott C, Murray K, et al: Validation of the RTOG recursive partitioning analysis (RPA) classification for brain metastases. Int J Radiat Oncol Biol Phys 47:1001, 2000.

Supportive Treatment

Dexamethasone is the corticosteroid of choice in controlling vasogenic edema, as it has a long half-life, the best CNS penetration, the fewest mineralocorticoid side effects, and is the least protein bound. The recommended starting dose is 4 to 8 mg daily for symptomatic patients, and this can be increased to 16 to 32 mg daily for patients presenting with acute signs of increased ICP or with severe symptoms. Its therapeutic effects are usually evident within 24 to 72 hours in up to 75 percent of patients. Once clinical benefit occurs, dexamethasone should be titrated down to the lowest possible dose that provides relief of symptoms, in order to minimize adverse effects. Prophylactic treatment for peptic ulcers is generally not recommended, except for patients with a history of previous ulcer, those taking concurrent nonsteroidal anti-inflammatory drugs, or the elderly. Among patients with brain metastases, 20 percent experience seizures, and antiepileptic drugs (AEDs) should be given when they occur. Older AEDs such as phenytoin, phenobarbital, and carbamazepine induce cytochrome P-450 hepatic enzymes, which potentially can accelerate the metabolism of many chemotherapeutic agents. Because of these drug interactions, nonenzyme-inducing AEDs such as levetiracetam are preferable. Evidence has failed to show benefit of prophylactic AEDs in decreasing the incidence of new-onset seizures, and therefore prophylaxis is not recommended. The benefit for prophylactic AEDs in the perioperative period has not been proven; when AEDs are utilized in this manner, they should be discontinued 1 to 2 weeks postoperatively.

Surgery

Resection of brain metastases is performed to achieve local disease control, provide a histologic diagnosis, promote decompression from elevated ICP, and allow tapering of corticosteroids. Three randomized controlled trials have examined the benefit of surgery combined with whole-brain radiation therapy (WBRT) compared to WBRT alone in patients with a solitary brain metastasis; a fourth randomized trial compared both treatments to surgery alone. These studies demonstrated significant benefits in local disease control and prolongation of functional independence from combination treatment compared to resection or radiotherapy alone, when given to patients with a single metastasis who were 60 years old or less and had controlled systemic disease and good KPS (Table 26-2). For patients with more than one metastasis, surgery is generally limited to removal of the dominant, life-threatening lesion, and to obtain a histologic diagnosis.

Whole-Brain Radiotherapy

Treatment with WBRT targets both gross and microscopic metastases. Significant reduction of local and remote intracranial recurrence has been demonstrated in patients with solitary and oligometastases who received WBRT following surgical resection or stereotactic radiosurgery; however, overall survival and preservation of functional independence did not differ between those treated with or without adjuvant WBRT. An individual patient data meta-analysis of three randomized trials assessing stereotactic radiosurgery with or without WBRT demonstrated a survival advantage for stereotactic radiosurgery alone in patients with one to four brain metastases, KPS of 70 or higher, and age of 50 or younger. Furthermore, in this cohort, no apparent increased risk of new brain metastases was observed, supporting stereotactic radiosurgery alone in patients with up to four brain metastases in this age group. In older patients (>50 years old), WBRT decreased the risk of new brain metastases, but did not affect survival. A phase III trial randomizing patients with one to three brain metastases to stereotactic radiosurgery alone or followed by WBRT demonstrated a more frequent neurocognitive decline in patients who received WBRT after stereotactic radiosurgery without significant difference in survival.[6] For patients with multiple metastases not amenable to surgery or stereotactic radiosurgery, or patients with poor-prognostic factors and limited life expectancy, WBRT is used for palliation of symptoms, prolonging overall survival for up to 3 to 6 months. A phase III randomized trial (QUARTZ) demonstrated that optimal supportive care (OSC) is as effective as OSC with WBRT in patients with nonsmall cell lung cancer with brain metastases unsuitable for surgery or stereotactic radiosurgery. Because of the lack of significant benefit in overall survival and reported neurocognitive toxicity, it is recommended to withhold WBRT after local control with either surgery or stereotactic radiosurgery. The addition of memantine and hippocampal avoidance with WBRT may reduce the risk of neurocognitive decline without a significant difference in intracranial progression-free survival and overall survival.[4,5]

Stereotactic Radiosurgery

Stereotactic radiosurgery is focused radiotherapy in which high-dose, single-fraction irradiation is directed at metastases while sparing the surrounding normal brain tissues from radiation exposure. It can be delivered by linear accelerator or gamma knife. It is beneficial in treating lesions less than 3 cm in size that are located in the eloquent areas, in the deep structures of the brain, or both, when these are not amenable to surgery. Hypofractionated radiosurgery (2 to 5 fractions of smaller doses) is used for larger metastases to decrease the risk of radionecrosis. The risk of radiation-induced neurocognitive dysfunction is markedly less than with WBRT. Retrospective studies comparing surgery and stereotactic radiosurgery report similar outcome. Therefore, the choice between surgery and stereotactic

radiosurgery for local control depends on the number, location, and size of brain metastases, neurologic symptoms, and patient and physician preferences.[4,5]

For patients with unresectable solitary or oligometastases with good prognostic factors (RPA class I), stereotactic radiosurgery following WBRT confers better local control of lesions and stabilization or improvement of performance status compared to WBRT alone, but survival advantage has been demonstrated only in patients with a single metastasis. The addition of stereotactic radiosurgery to WBRT seems in fact to confer survival benefit for patients with a good prognosis regardless of whether they have one, two, or three brain metastases; however, the survival benefit does not extend to patients with a poor prognosis. Randomized controlled trials comparing stereotactic radiosurgery alone or followed by WBRT showed improved local and remote intracranial control with combined treatment, without significant difference in overall survival and performance status. Based on these randomized trials, close monitoring without WBRT following stereotactic radiosurgery is recommended for patients with one to four brain metastases and good performance status.[4,5]

Postoperative stereotactic radiosurgery is another approach to decrease the risk of local recurrence while avoiding the neurocognitive toxicity from WBRT. A phase III randomized trial concluded that stereotactic radiosurgery to the surgical cavity results in improved cognitive outcome, better preservation of quality of life and functional independence compared to postsurgery WBRT, without significant difference in overall survival.[7] Stereotactic radiosurgery should be considered one of the standards of care as a less toxic alternative to WBRT after resection of a brain metastasis.[4,5,7]

Chemotherapy

Chemotherapy is recommended as first-line treatment for chemosensitive brain metastases such as germ cell tumors and non-Hodgkin lymphoma. Response rates to cytotoxic chemotherapy are high in small cell lung cancer (30 to 80%), intermediate rates in breast cancer (30 to 50%) and nonsmall cell lung cancer (10 to 30%), and low rates in melanoma (10 to 15%); responses in the brain do not always parallel those of systemic disease. Treatment response is higher for chemotherapy-naïve tumors, but as most of these patients have already failed previous chemotherapy, radiotherapy is a more effective option in the treatment of brain metastases. Various chemotherapeutic agents in combination with two or three other agents and radiation therapy have been used (Table 26-3).[4,5]

Targeted Therapies

Molecular targeted therapies have shown promising roles in the treatment of brain metastases, including gefitinib, erlotinib, afitinib and osimertinib [epidermal growth factor receptor (EGFR) inhibitors] and crizotinib (ALK and ROS1 inhibitor) for nonsmall cell lung cancer; lapatinib (EGFR and HER2 inhibitors) for HER2-positive breast cancer; and dabrafenib and vemurafenib (BRAF inhibitor) and trametinib (MEK inhibitor) for melanoma (Table 26-3).[4,5]

Immunotherapy

Immunotherapy has shown promising results in treating brain metastases. Emerging data suggest that immune checkpoint inhibitors (ICI) can stimulate T cells peripherally, resulting in antitumor effects in the central nervous system. ICI blocking programmed cell death protein 1 (PD-1) and its ligand (PD-L1) and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) have shown efficacy in brain metastases (Table 26-3). Pembrolizumab (anti-PD1) monotherapy has shown intracranial response rates of 20 to 30 percent in patients with melanoma and nonsmall cell lung carcinoma; while combination of nivolumab (anti-PD-1) and ipilimumab (anti-CTLA-4) has demonstrated an intracranial response in 55 percent of patients with brain metastases from melanoma. Radiation therapy with immunotherapy augments antitumor immune responses at a local site as well as at distant metastatic site, known as the abscopal phenomenon.[4,5]

Prophylactic Cranial Irradiation

In malignancies with a high predilection to metastasize to the brain such as small cell lung cancer (SCLC), prophylactic cranial irradiation (PCI) may be used. Patients with limited-stage SCLC who achieve complete response to chemotherapy have a decreased incidence of brain metastases (relative risk 0.46; 95% CI 0.38 to 0.57) and absolute decrease in 3-year cumulative incidence of brain metastases (33% vs. 59%) with PCI.[8] However, while PCI can decrease the incidence of symptomatic brain metastases in extensive-stage SCLC, the impact of PCI on overall survival is uncertain due to differences in the results between

TABLE 26-3 ■ Evolving Systemic Treatment Options for Brain Metastases From Three Common Malignancies

Malignancies	Agents
	Cytotoxic Chemotherapies
NSCLC	Cisplatin or carboplatin, pemetrexed, etoposide, vinorelbine, temozolomide
Breast cancer	Cyclophosphamide, 5-FU, methotrexate, vincristine, cisplatin, etoposide, capecitabine, high-dose methotrexate
Melanoma	Fotemustine, temozolomide
	Targeted therapies
NSCLC	First-generation EGFR-TKI (gefetinib, erlotinib), second-generation EGFR-TKI (afatinib), third-generation EGFR-TKI (osimertinib), first-generation ALK inhibitor (crizotinib), second-generation ALK inhibitor (ceritinib, alectinib), third-generation ALK inhibitors (brigatinib, lorlatinib)
Breast cancer (HER2-positive)	HER-2 inhibitors (trastuzumab, pertuzumab, neratinib), ADC trastuzumab-emtansine (TDM-1), dual EGFR and HER2-TKI (lapatinib), CDK 4/6 inhibitor (abemaciclib)
Melanoma	BRAF V600E inhibitors (dabrafenib, vemurafenib), MEK inhibitor (trametinib), cKIT inhibitors (imatinib, dasatinib)
	Immunotherapies
NSCLC	Anti-PD1 (nivolumab, pembrolizumab)
Melanoma	Anti-PD1(nivolumab, pembrolizumab), Anti-CTLA4 (ipilimumab)

NSCLC, Nonsmall cell lung cancer; EGFR-TKI, epidermal growth factor receptor-tyrosine kinase inhibitor; ALK, anaplastic lymphoma kinase; CDK, cyclin-dependent kinase; ADC, antibody–drug conjugate; PD1, programmed death receptor 1; CTLA4, cytotoxic T-lymphocyte-associated protein 4; MEK, mitogen-activated protein kinase.

two phase III randomized trials. Thus, individualized discussion is recommended in patients with extensive-stage SCLC due to the risk of radiation-induced side effects and insufficient evidence on survival benefit of PCI. This prophylactic strategy has not shown the same degree of benefit in NSCLC.

Skull Base

DEFINITION AND EPIDEMIOLOGY

The base of the skull forms the floor of the cranial cavity and is composed of the ethmoid, sphenoid, occipital, paired frontal, and paired parietal bones. Metastases to the skull base may involve the cranial nerves and blood vessels that pass through foramina in these bones. Skull-base metastases occur in 4 percent of cancer patients, frequently late in the course of the disease. The most common responsible primary malignancies are prostate (38.5%), breast (20.5%), lymphoma (8%), and lung (6%).[9]

PATHOPHYSIOLOGY

The skull base may become involved directly from hematogenous spread of malignant cells or by retrograde seeding through the Batson plexus, a common route in prostate carcinoma. Osseous metastases may entrap and compress the nearby cranial nerves and vessels, producing neurologic signs and symptoms. Direct extension from head and neck malignancies may also involve the skull base.[9]

CLINICAL FEATURES

Skull-base metastases produce symptoms when they enlarge and compress surrounding structures, causing pain and neurologic deficits. The development of cranial neuropathies or craniofacial pain in patients with malignancy should raise the suspicion of skull-base metastases. Cranial neuropathies are the presenting symptom in 28 percent of patients with such metastases. The extraocular motor nerves are most commonly involved, followed by the trigeminal and hypoglossal nerves. The anatomic location involved can lead to specific clinical syndromes, including orbital syndrome in 12.5 percent, parasellar and sellar syndromes in 29 percent, middle fossa syndromes in 6 percent, jugular foramen syndromes in 3.5 percent, and occipital condyle syndrome in 16 percent of patients (Table 26-4).[9]

DIAGNOSTIC STUDIES

Advances in MRI techniques have greatly improved the identification and evaluation of the extent of skull-base metastases, including bone marrow invasion, perineural spread, and cranial nerve, leptomeningeal, and brain parenchymal involvement (Fig. 26-3). Radionuclide bone scanning can detect skull-base metastases in 30 to 50 percent of these patients, but it has a relatively poor sensitivity in detecting purely lytic lesions. CT using bone windowing is the best means of detecting lytic bone destruction. Dual-isotope single-photon emission computed tomography (SPECT) may show increased uptake in the skull base. CSF examination and biopsy, including endoscopic and minimally invasive techniques, are sometimes indicated to establish the diagnosis of skull-base metastases.

Differential Diagnosis

Primary skull tumors, such as osteoma and chondrosarcoma, and benign tumor-like lesions including fibrous dysplasia may appear radiographically similar to skull-base metastases. Patients with metastases are generally older, with a median age of 70 years, have shorter duration of symptoms (median of 2 months), and present less frequently with neurologic deficits than patients with these other lesions.[9]

Treatment

Radiation therapy is the standard treatment, providing pain relief, improvement of cranial nerve dysfunction and local control. The beneficial effects parallel the timing of irradiation—87 percent of patients who receive radiation within 1 month of symptom onset show clinical improvement compared with 25 percent of patients treated after 3 months. Stereotactic radiosurgery provides clinical improvement in 62 percent and tumor control in 67 to 95 percent of patients, and can be used as an initial treatment, especially for lesions near neural structures and for previously irradiated tumors. For chemosensitive tumors such as breast and prostate carcinomas, chemotherapy and hormonal therapy in combination with radiation therapy offer survival benefits. Surgery may be considered for radioresistant tumors such as melanoma, renal cell carcinomas, and sarcomas, as well as in patients with rapid neurologic decline, such as visual loss, with the goal of preserving neurologic status and symptom relief.[9]

Prognosis

Skull-base metastases are typically seen in disseminated malignancies, and the overall median survival is 31 months. Patients with metastases from breast carcinoma have the best survival (60 months); prostate carcinoma and lymphoma, intermediate survival; and lung and colon carcinomas the worst survival (2.5 and 2.1 months, respectively).[9]

Intracranial Dura

Definition and Epidemiology

Carcinomatous infiltration of the dura and epidural space is found at autopsy in 9 to 14 percent of

TABLE 26-4 ■ Skull-Base Syndromes, Associated Cranial Neuropathies, Accompanying Findings, and Most Common Primary Malignancies

Skull-Base Syndromes	Cranial Neuropathies	Associated Findings	Common Primary Malignancies
Orbital syndrome	CN II, III, IV, VI, and V-1	Supraorbital frontal headache, pain, diplopia, proptosis, periorbital swelling, decreased vision	Prostate cancer Lymphoma Breast cancer
Parasellar/cavernous sinus syndrome	CN III, IV, VI, V-1, and V-2	Supraorbital frontal headache, no proptosis, vision may be affected late in the course	Lymphoma
Middle fossa/Gasserian ganglion syndrome	CN V-2 and V-3 sensory and motor roots; CN III, IV, VI, and VII (less common)	Lightning-like facial pain, sparing the forehead; headache is uncommon	Breast cancer Lung cancer
Jugular foramen syndrome	CN IX, X and XI (Vernet syndrome) plus CN XII (Collet–Sicard syndrome)	Unilateral occipital and postauricular pain; dysphagia; hoarseness; Horner syndrome	Breast cancer Melanoma Ewing sarcoma Prostate cancer
Occipital condyle	CN XII	Occipital pain, stiff neck	Breast cancer Prostate cancer
Numb chin syndrome	Mental nerve	Unilateral anesthesia of chin and lower lip	Breast cancer Lymphoma Melanoma Lung cancer Prostate cancer

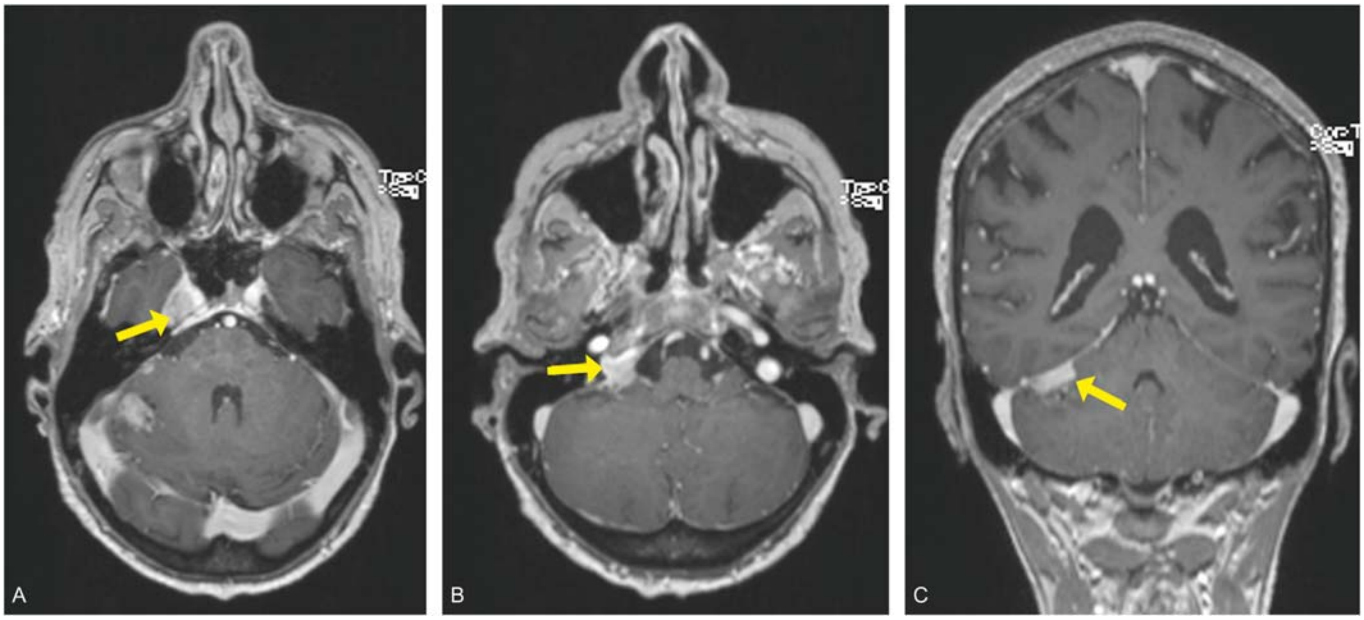

FIGURE 26-3 ■ Skull-base metastases. A 73-year-old patient with history of nonsmall cell lung carcinoma presented with right cavernous sinus syndrome. MRI demonstrates multiple avidly enhancing lesions within *A*, the right Meckel cave and *B*, the right jugular foramen. Dural-based metastases also are seen *C*, along the inferior surface of the right tentorium.

patients with primary malignancies. Common primary tumors include breast, prostate, and lung carcinomas. They are more common in women; the mean age at diagnosis is 59 years.[9]

Pathophysiology

A majority of patients develop intracranial dural metastases by direct extension from skull metastases, whereas hematogenous spread accounts for 33 to 43 percent. Nontraumatic subdural hematoma occurs in 15 to 40 percent of patients, presumably due to rupture of fragile tumor vessels and to mechanical obstruction of external dural vessels leading to dilation and rupture of dural capillaries. Chronic subdural hematoma alters the barrier properties of the dura, promoting tumor infiltration.[9]

Clinical Features

Dural metastases produce symptoms through traction of the dura, invasion of venous sinuses, elevation of ICP, and compression of the underlying brain parenchyma, cavernous sinus, and surrounding neural structures. Common presentations include headache, cranial neuropathies, visual changes, altered mentation, and seizures. The presence of new or localized headache in these patients is suggestive of subdural hematoma and should prompt imaging. Between 11 and 50 percent of patients are asymptomatic, diagnosed incidentally on imaging or at autopsy.[9]

Diagnostic Studies and Differential Diagnosis

Gadolinium-enhanced MRI is the imaging study of choice for identification of dural metastases. These lesions typically enhance homogeneously and may be single or multiple. They may appear as localized or diffuse thickening or nodular enhancement of the dura (Fig. 26-4). CT scan can detect bony involvement. The main differential diagnosis is meningioma, which also presents as an extra-axial, well-circumscribed, hyperdense, contrast-enhancing lesion with a dural tail and hyperostosis of overlying bone. High-lipid signal in MR spectroscopy, a low relative cerebral blood volume in dynamic contrast (perfusion) MRI, increased FDG-PET uptake, and accumulation of tracer in octreotide brain scintigraphy all favor metastasis over meningioma. Pachymeningeal metastases demonstrate dural enhancement localized under the inner table of the skull and do not follow the contour of the gyri in contrast to leptomeningeal involvement.[9]

Treatment

Surgical resection improves overall survival and should be considered as initial treatment for patients with controlled systemic disease and a single, symptomatic,

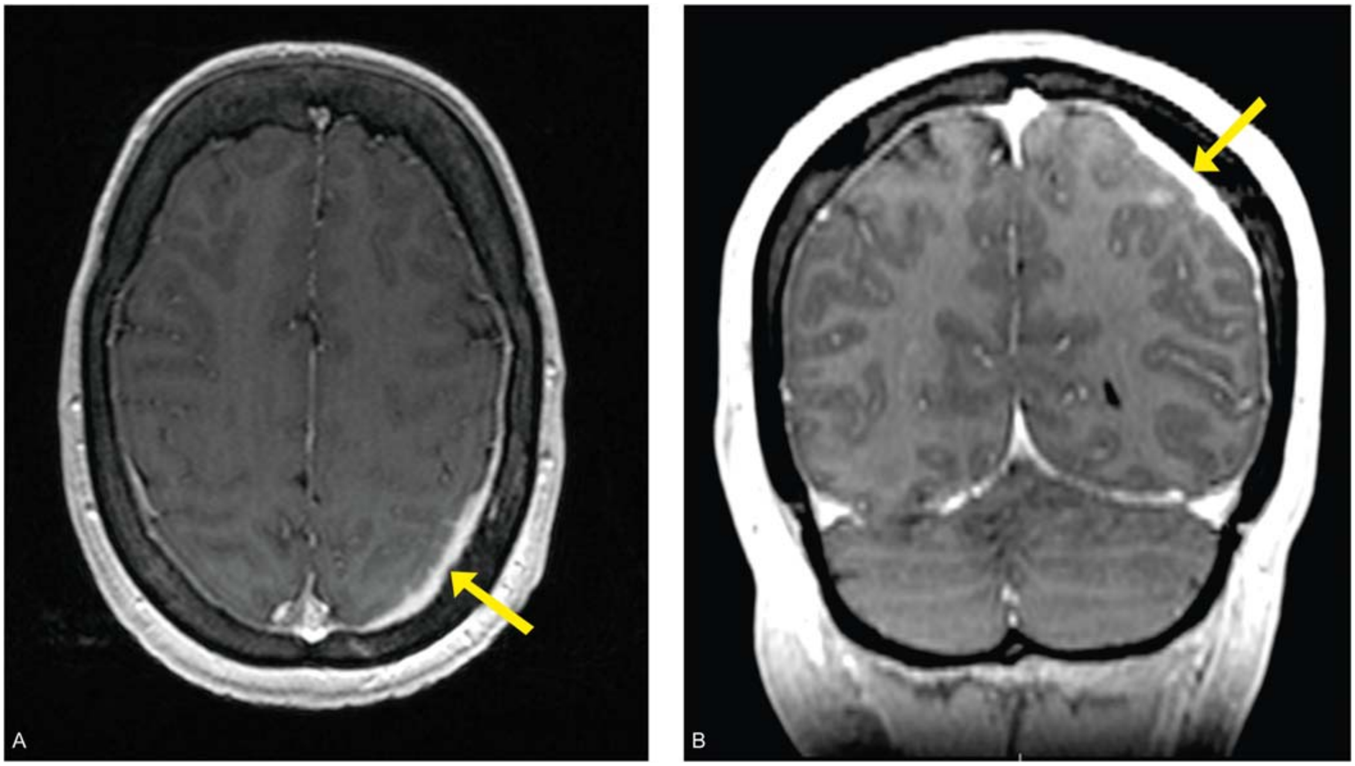

FIGURE 26-4 ■ Dural metastasis from breast cancer. Axial, *A*, and coronal, *B*, T1-weighted, contrast-enhanced brain MR images demonstrating dural thickening along the left parietal convexity.

resectable intracranial dural metastasis. Stereotactic radiosurgery also improves local control. Systemic chemotherapy prolongs progression-free survival, perhaps because dural metastases are outside the blood–brain barrier. For patients who are not candidates for surgery, have poor-performance status, and short-life expectancy, focal or whole-brain radiation can be considered.

PROGNOSIS

The overall median survival is 6 to 9.5 months and progression-free survival is 3.7 months with dural metastases. Patients with primary hematologic malignancies or breast and prostate carcinomas have relatively favorable courses compared to those with other primary cancers. Poor-performance status and lung carcinoma are adverse prognostic factors, while treatment with resection and chemotherapy is associated with improved overall and progression-free survival.[9]

Spine and Spinal Cord

EPIDEMIOLOGY

Bone is the most common site of metastases, and the axial skeleton is the most frequent site affected. Autopsy series reveal spinal metastasis in more than 70 percent of patients with disseminated cancer. The incidence is greatest for breast (73%) and prostate (68%) cancers, followed by thyroid (42%), kidney (35%), and lung (36%) cancers. Spinal metastases are 20 times more common than primary spinal tumors.[10]

CLASSIFICATION BY ANATOMIC LOCATION

Spinal tumors are classified according to anatomic location (Table 26-5). Extradural metastases account for more than 94 percent of secondary spinal tumors. Most arise from the vertebral bodies and extend to the spinal canal, eventually compressing the spinal cord or cauda equina. Intradural extramedullary metastases are rare and usually represent tertiary spread via CSF from cerebral metastases to the cauda equina, termed "drop metastasis." Intramedullary metastases account for about 3.5 percent of spinal metastases and are increasing in frequency, likely due to improvement in detection.[10]

EPIDURAL SPINAL CORD COMPRESSION

Epidemiology

The annual incidence of hospitalization related to epidural spinal cord compression among patients

TABLE 26-5 ■ Anatomic Categories of Spinal Cord Tumors

Anatomic Locations	Tumors
Extradural	Metastases Chordomas Sarcomas Lymphomas Plasmacytomas and multiple myeloma
Intradural, extramedullary	Meningioma Nerve sheath tumors
Intramedullary	Ependymomas Astrocytomas Metastases

with cancer is 3.4 percent. The most common primary sources are lung, breast, and prostate cancer, and multiple myeloma. The thoracic spine is most commonly involved (70%), followed by the lumbar (20%) and cervical (10%) spine; this distribution reflects the number and volume of vertebral bodies in each spinal segment. Multiple noncontiguous lesions are common, occurring in 10 to 40 percent of cases.[10]

Pathophysiology

Epidural spinal cord compression occurs when tumor invades the epidural space and compresses the thecal sac. This results from several mechanisms. Hematogenous spread is the most common route, occurring in 85 percent of cases. The Batson venous plexus drains the vertebrae and skull and forms anastomoses with veins draining the thoracic, abdominal, and pelvic organs and breast. This valveless venous system serves as a pathway to transmit metastatic cells to the spinal column. Tumor cells may also seed via the arterial circulation to the vertebral bodies, which have a relatively large blood flow. Metastatic cells cause vertebral bone destruction, mass expansion within the vertebral body, and eventual outgrowth into the epidural space. Less commonly, tumor cells from the paraspinal region reach the epidural space directly through the intervertebral foramen, particularly in patients with lymphoma and neuroblastoma. Direct hematogenous metastasis to the epidural space is rare.

Direct mechanical injury to the axons and myelin, along with secondary vascular compromise of the epidural venous plexus and spinal arteries, results in spinal cord edema, infarction, and subsequent dysfunction. Tumor production of VEGF is also associated with spinal cord hypoxia. In addition, tumor invasion of the bony spine can harm the spinal cord by destabilization of the spinal column.[10]

Clinical Features

Back pain is the most common presenting symptom, affecting more than 95 percent of patients with epidural spinal cord compression. The pain is initially localized over the involved vertebral bodies and is attributable to stretching of the periosteum and other adjacent pain-sensitive structures. It is typically chronic, with a median duration of 2 months, and increases in severity over time. It is frequently worse with the Valsalva maneuver and recumbency as a result of distention of the venous plexus. When nerve roots are involved, patients may complain of radicular pain or a tight band around the chest and abdomen. Acute pain raises the suspicion of pathologic compression fracture. Pain on movement suggests mechanical instability. The Spine Instability Neoplastic Score, a classification system based on six clinical and radiographic criteria, aids clinicians in predicting spine stability and assists in treatment decision-making.[11] Motor deficits are the second most common symptom (60 to 85%) followed by sensory symptoms (60%). The weakness may be upper motor neuron in type from compression of the spinal cord when the lesion is above the L1−2 vertebral bodies, or lower motor neuron in type from compression of the cauda equina when the lesion is below this level. More than half of patients with epidural spinal cord compression are nonambulatory upon diagnosis. Spinal cord compression produces a sensory level at or above the level of epidural involvement, and nerve root compression results in a dermatomal pattern of sensory deficits. Patients with compression of the posterior columns in the cervical and upper thoracic segments of the spinal cord may experience the Lhermitte phenomenon. Autonomic symptoms, including bowel and bladder dysfunction, sexual disturbance, and orthostatic hypotension, tend to occur late in the course of epidural spinal cord compression.[10,12]

Diagnostic Studies

Epidural spinal cord compression is a neuro-oncologic emergency as neurologic deficits may progress rapidly. MRI is optimal for detecting the lesion, with an overall accuracy of at least 95 percent. Because

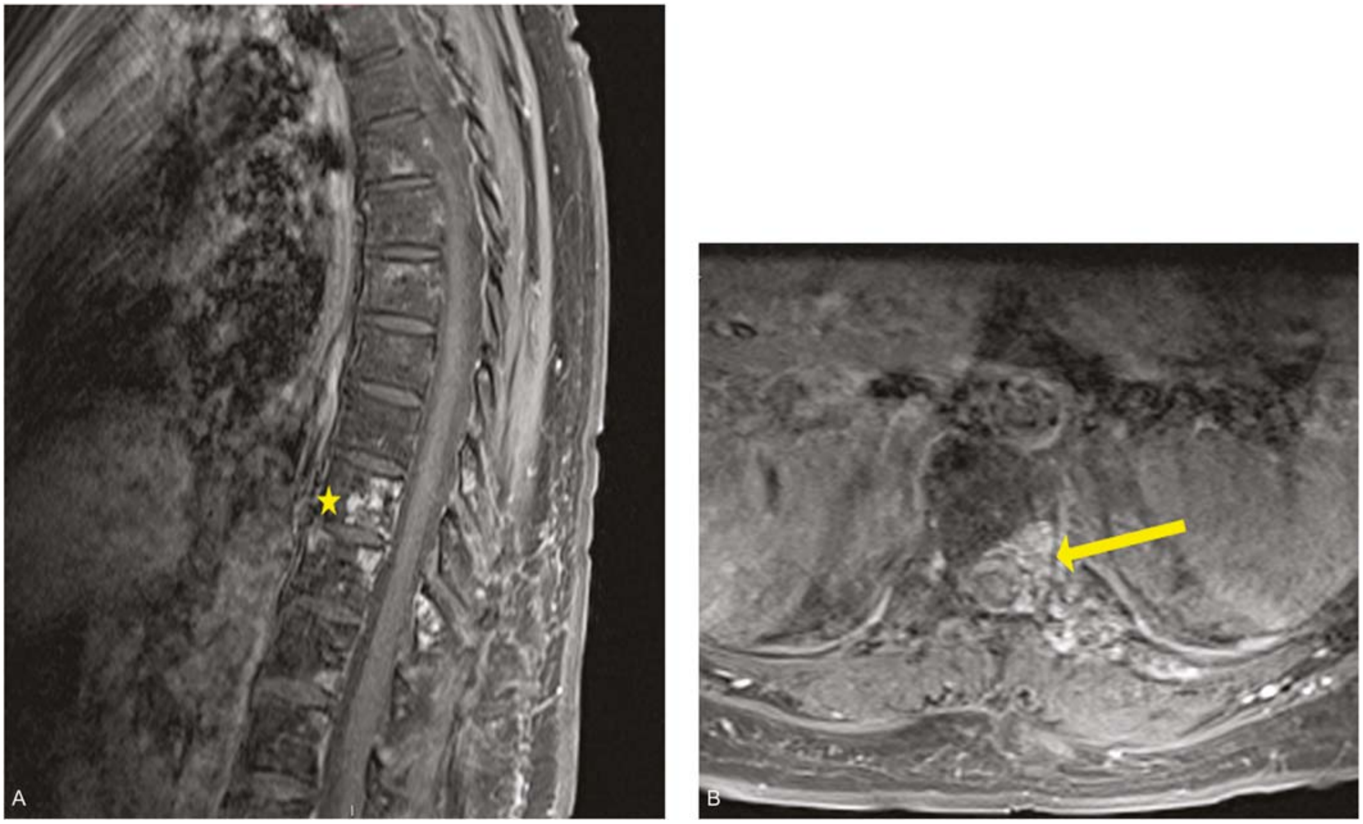

FIGURE 26-5 ■ Epidural spinal cord compression secondary to metastatic breast cancer. Postcontrast MRI demonstrates, *A*, numerous metastatic lesions involving nearly all the thoracic vertebral bodies, with greatest involvement at the T9 vertebral body (*star*). There is mild neuroforaminal encroachment by the tumor at the left T9-10 level, *B*.

multiple lesions are common, the entire spine should be imaged. Vertebral metastases appear hypointense on T1-weighted MRI sequences, hyperintense on T2-weighted sequences, and show postgadolinium enhancement (Fig. 26-5). A scale has been developed to describe the degree of spinal cord compression based on axial T2-weighted MR images and this may guide treatment decisions (Table 26-6). Increased T2 signal within the spinal cord represents venous congestion or ischemia. For patients in whom MRI is contraindicated, CT myelography is an acceptable alternative. Plain radiography, bone scans, and spinal CT do not adequately depict the tumor, spinal cord, and paraspinal region. Around 80 percent of patients with epidural spinal cord compression have a known systemic malignancy, and immediate treatment should be initiated once the diagnosis is made. For patients without prior history of cancer, biopsy of the paraspinal or vertebral lesion to make a tissue diagnosis is warranted.[10,12]

TABLE 26-6 ■ **Epidural Spinal Cord Compression (ESCC) Score**

Grades		Description
Low-grade	0	Tumor confined to the bone only
	1	Tumor with epidural extension without contact with the spinal cord or just spinal cord abutment without displacement
	1a	Epidural impingement, without thecal sac compression
	1b	Epidural tumor with thecal sac compression, without spinal cord abutment
	1c	Epidural tumor with thecal sac compression, with spinal cord abutment, without cord compression
High-grade	2	Tumor compresses the spinal cord, with CSF visible around the cord
	3	Tumor compresses the spinal cord, with no CSF visible around the cord

Derived from Bilsky MH, Laufer I, Fourney DR, et al: Reliability analysis of the epidural spinal cord compression scale. J Neurosurg Spine 13:324, 2010.

Treatment

The goals of treatment are palliative, including pain relief and preservation or recovery of neurologic function, maintenance of spinal stability, durable local tumor control, and improved quality of life. A decision framework, NOMS (neurologic, oncologic, mechanical instability, and systemic disease), has been developed to facilitate treatment decision-making in patients with metastatic spine tumors.[13] The neurologic assessment evaluates the presence of myelopathy, functional radiculopathy, and degree of epidural spinal cord compression (high-grade vs. low-grade compression). The oncologic consideration is based on the expected tumoral response and durability of response to available treatments, including surgery, radiation therapy, and systemic treatment. Mechanical instability is a separate consideration, because symptomatic pathologic fractures do not respond to radiation alone and typically require stabilization. The fourth consideration is the extent of systemic disease and presence of medical co-morbidities that affect the risk—benefit ratio of a proposed treatment and expected overall survival based on extent of disease and tumor histology.[12]

Corticosteroids, typically dexamethasone, are recommended for patients with neurologic deficits. They may temporarily stabilize neurologic dysfunction by reducing tumor and spinal cord edema, alleviate pain through antiprostaglandin effects, and have a direct cytotoxic effect on certain malignancies such as lymphoma and multiple myeloma. Patients with minimal or nonprogressive weakness may receive moderate dexamethasone doses (e.g., 8 to 10 mg loading dose, followed by 16 mg/day in divided doses). Some treat patients with rapidly progressive motor symptoms with higher doses, such as with a 100 mg loading dose followed by up to 96 mg/day. When these high doses are used, rapid taper is important to minimize the risk of complications such as steroid myopathies and peptic ulcers.[10]

The objectives of surgery include obtaining a histologic diagnosis, local tumor control, pain relief, and spinal cord decompression and removal of epidural disease to allow spinal stereotactic radiosurgery and stereotactic body radiotherapy (SBRT). Other aims are to restore neurologic status, reestablish spine stability, and correct deformity. Compared to patients treated with radiotherapy alone, patients undergoing timely surgery followed by radiation therapy are more likely to recover or maintain ambulation, achieve better pain control, have preservation of continence, and experience longer median survival. Surgical stabilization followed by decompression in patients with radioresistant tumors with high-grade compression is strongly recommended. The advent of spinal stereotactic radiosurgery as postoperative adjuvant treatment has changed the goals of surgery. The surgical goal is now to create a target for safe delivery of spinal stereotactic radiosurgery rather than maximal debulking followed by external beam radiation therapy. Separation surgery focuses on reconstitution of spinal fluid space to create a 2-mm margin between the tumor and spinal cord, but without resection of the vertebral body or paraspinal tumor, leaving the bulk of the tumor to be treated by radiation. Separation surgery followed by spinal stereotactic radiosurgery is safe and effective in durable local tumor control regardless of tumor histology-specific radiosensitivity.[12]

Conventional external beam radiation therapy improves back pain (in 60% of patients), ambulation (70%), and continence (90%). Important predictors of response to radiotherapy include performance status at the start of treatment, tumor radiosensitivity, and rapidity of onset of neurologic deficits. Radiosensitive tumors such as myeloma, lymphoma, seminoma, small cell lung cancer, prostate cancer, and breast carcinomas respond better than generally radioresistant metastases such as melanoma, osteosarcoma, gastrointestinal cancers, and renal cell carcinoma. For patients with a poor prognosis, two fractions of 8 Gy given 1 week apart are recommended, while those with a good prognosis are given higher total doses with more fractions. The most common dose and fractionation schedule being utilized in the United States is 30 Gy divided into 10 fractions.[10,12]

The effectiveness of conventional external beam radiation therapy to spinal metastases is limited due to poor-radiation tolerance of the spinal cord. For this reason, stereotactic radiosurgery has been utilized increasingly to treat spinal metastases, allowing safe delivery of high-dose radiation to metastases within or adjacent to the vertebral bodies and spinal cord, while minimizing toxicity to the surrounding structures. High-dose single stereotactic radiosurgery (16 to 24 Gy) or hypofractionated (24 to 30 Gy in two to three fractions) stereotactic body radiotherapy offers a significantly higher biologic effective dose and more precise dose delivery with shorter treatment schedule compared to external beam radiation therapy. The higher dose of stereotactic radiosurgery increases the percentage of DNA damage and obviates the histologic dependence that exists in conventional radiation therapy, with 12-month local control rates of over 85 percent, including classically radioresistant tumors. Because stereotactic radiosurgery has a steep fall-off gradient of target dose with negligible skin effects, it can be given soon after surgery without concern for wound complications. The complications of spinal stereotactic radiosurgery are generally mild and self-limited.[12]

Chemotherapy has a limited role in patients with epidural spinal cord compression because of the need to decompress the spinal cord urgently in order to preserve neurologic functions. In patients with chemosensitive tumors such as lymphoma and seminoma who have minimal or no neurologic deficits, chemotherapy may be considered. The combination of spinal stereotactic radiosurgery with immunotherapy demonstrates promising results by inducing an abscopal effect, leading to improvement of systemic disease control.[10]

Prognosis

The median survival following diagnosis of metastatic epidural spinal cord compression is historically reported at 3 to 6 months. However, with improvements in treatment, many patients survive for several years after treatment. The strongest factors affecting survival include the degree of neurologic deficit at the time of diagnosis and the primary tumor type. Patients with hematologic malignancies, breast cancer, and prostate cancer have longer survival, while those with carcinoma of the lung have the shortest. Nonambulatory patients do poorly, and those with bladder and bowel dysfunction have the worst prognosis.[10,12]

INTRAMEDULLARY SPINAL CORD METASTASES

Epidemiology and Pathophysiology

Intramedullary spinal cord metastases are rare, usually encountered in the setting of extensive metastatic disease. These metastases are typically solitary and can occur in any segment of the spinal cord. The majority of patients have concomitant brain metastases and one-quarter have leptomeningeal carcinomatosis. Almost half of intramedullary spinal cord metastases originate from lung cancer, particularly small cell lung cancer; less common primary neoplasms are melanoma, lymphoma, and breast, colorectal, and renal cell cancer. Tumor cells reach the parenchyma of the spinal cord by hematogenous dissemination, direct extension from leptomeninges, along nerve roots, or through Virchow–Robin spaces.[10]

Clinical Features

Weakness is present in 90 percent of patients at the time of diagnosis. Other common presentations are sensory loss, sphincter dysfunction, back pain, and radicular pain. Neurologic deficits develop much earlier, usually soon after the onset of spinal or radicular pain, than in patients with epidural spinal cord compression. The presence of a Brown-Séquard syndrome or asymmetric myelopathy strongly suggests intramedullary rather than epidural metastases. Intramedullary metastases may be mistaken for radiation myelopathy, but can be differentiated by the slow and relatively painless presentation of the latter.

Diagnostic Studies

MRI with gadolinium enhancement reliably identifies intramedullary metastases, which appear as well-defined lesions with avid contrast enhancement that are hypointense on T1- and hyperintense on T2-weighted sequences; prominent surrounding edema is common (Fig. 26-6). Spinal MRI may also detect concomitant leptomeningeal involvement. Brain MRI should be performed even in the absence of cerebral symptoms, as concurrent brain metastases are common.

Treatment and Prognosis

Fractionated radiotherapy is the main treatment modality for intramedullary metastases. The goals of radiotherapy are to control tumor growth, palliate symptoms, and improve neurologic deficits. With the development of new techniques including MR or CT navigation, cavitron ultrasonic surgical aspiration, and intraoperative electrophysiologic monitoring, surgical excision has been used increasingly in patients with limited systemic disease and radioresistant tumors. In general, patients with intramedullary spinal cord metastases have a limited clinical response to treatment and a very poor prognosis, with a median survival of 4 months.[10]

Leptomeninges

Definition

Leptomeningeal metastasis or neoplastic meningitis refers to the dissemination of cancer cells to the CSF, pia, and arachnoid mater. Depending on the underlying malignancy, this condition may be termed leptomeningeal carcinomatosis, lymphomatous meningitis, or leukemic meningitis.[14]

Epidemiology

Leptomeningeal carcinomatosis is diagnosed in 5 to 10 percent of patients with solid cancers and 5 to 20 percent of those with hematologic malignancies. It also occurs in 1 to 2 percent of patients with primary brain tumors. The most common solid tumor sources are breast (12 to 34%), lung (10 to 26%) carcinomas, and melanoma (17 to 25%), while the most common hematologic tumor sources are acute lymphoblastic leukemia (10%), acute myeloid leukemia (5 to 10%), primary CNS or ocular lymphoma (20%), and non-Hodgkin's lymphoma (20%). The median age of diagnosis is 56 years and median KPS is 70. More than 70 percent of patients with leptomeningeal disease have advanced and uncontrolled systemic disease. Approximately 19 percent of cancer patients with neurologic signs and symptoms have evidence of leptomeningeal metastases on autopsy studies.[14]

Pathophysiology

Leptomeningeal seeding occurs through several mechanisms, including hematogenous spread via Batson plexus or arterial dissemination, direct extension from adjacent structures, and migration from systemic tumors along perineural or perivascular spaces. Once tumor cells reach the leptomeninges, they can spread throughout the CNS via the CSF, resulting in multifocal neuraxis seeding. Tumor infiltration is most prominent in the skull base, the posterior surface of the spinal cord, and cauda equina, producing cranial nerve palsies and radiculopathies. Tumor deposits may result in obstruction of CSF flow, leading to hydrocephalus and sometimes to increased ICP. Blood vessels crossing the subarachnoid space may become occluded, leading to cerebral or spinal infarction.[14]

Clinical Features

Clinical manifestations of leptomeningeal metastases can be classified into three categories: cerebral involvement resulting in headache, altered mental status, nausea, vomiting, gait disturbance, and cerebellar signs; cranial nerve involvement presenting with diplopia, visual loss, hearing changes, and facial weakness; and spinal symptoms including weakness, paresthesias, radicular neck or back pain, and bowel or bladder dysfunction. The majority of patients present with multifocal symptoms.

Diagnostic Studies

Gadolinium-enhanced MRI of the entire neuraxis is warranted to evaluate the extent of CNS disease and plan treatment. Neuroimaging should precede lumbar puncture as intracranial hypotension from lumbar puncture may produce pachymeningeal enhancement that mimics leptomeningeal metastases.

MRI findings that are highly suggestive of leptomeningeal metastases include linear or nodular enhancement of leptomeninges, which is often visible in the cerebral sulci, cerebellar folia, basal cisterns, and cauda equina; enhancement of the subependyma, and cranial or spinal nerves; and hydrocephalus (Fig. 26-7). A high-clinical suspicion of leptomeningeal metastases coupled with consistent MRI findings is sufficient to establish the diagnosis, even in the absence of malignant cells on CSF cytology.[14]

While identifying malignant cells in the CSF is the gold standard for diagnosis, its sensitivity is low. To minimize false-negative studies, the following measures are recommended: withdrawal of at least 10.5 ml of CSF for analysis; immediate processing of the sample; obtaining CSF from a site adjacent to the affected CNS region; and repeated CSF sampling and analysis. The sensitivity of CSF cytology is 71 percent for the first sample, 86 percent after two samples, 90 percent following three samples, and up to 93 percent after more than three samples. Flow cytometry analysis improves this sensitivity for patients with hematologic malignancies. Other CSF parameters suggestive of leptomeningeal metastases are elevated opening pressure, elevated leukocyte count, increased protein content, and decreased glucose level. CSF flow block develops at various levels in 30 to 70 percent of patients with leptomeningeal metastases and can be seen with radionuclide studies. Several organ-specific biomarkers in the CSF such as CA 15-3 in breast cancer and CEA and Cyfra 21.1 in nonsmall cell lung cancer, may assist in diagnosis. Isolation and quantification of circulating tumor cells can detect malignant cells in CSF through the use of immunoflow cytometry technique with fluorescently labeled antibodies. In epithelial tumors, an antibody against epithelial cell adhesion molecule (EpCAM) is used, as this protein is expressed in various epithelial cancers such as breast, lung, and gastrointestinal cancers; high-molecular-weight melanoma-associated antigen/melanoma chondroitin sulfate proteoglycan (HMW-MAA/MCSP) is used for melanoma. Available studies on circulating tumor cells in the CSF of patients with leptomeningeal metastases have a reported sensitivity of 78 to 100 percent, compared to 44 to 67 percent with cytology at first lumbar puncture. The specificity of circulating tumor cells

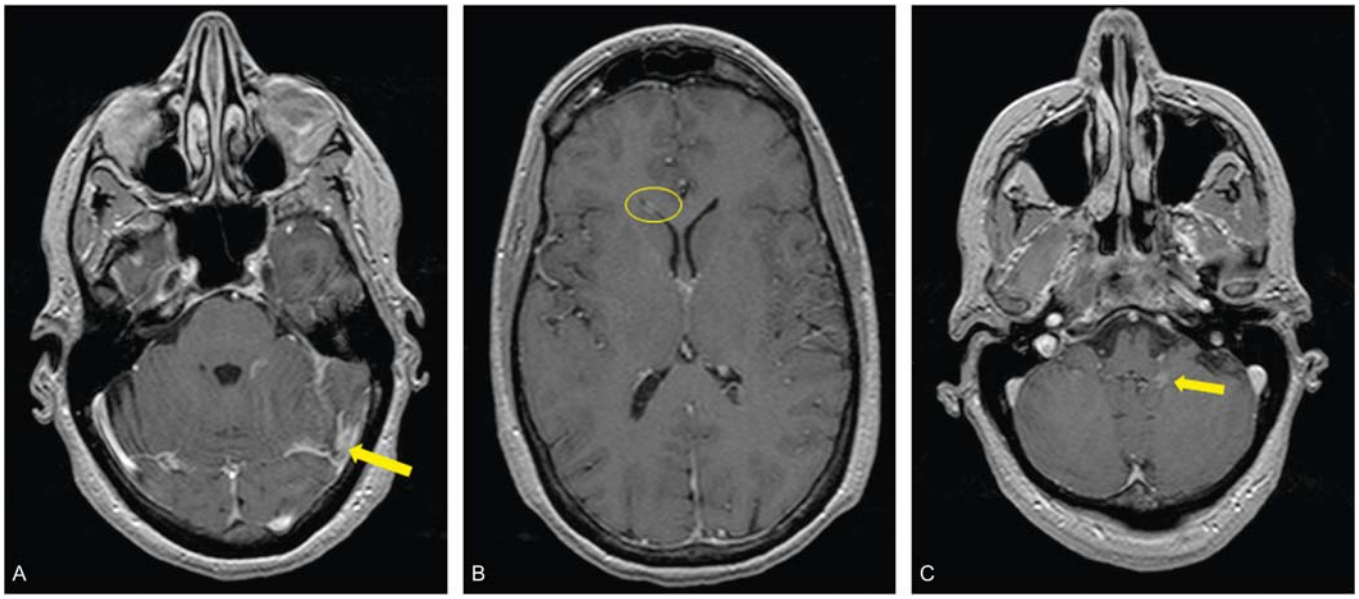

FIGURE 26-7 ▪ Leptomeningeal metastasis from breast carcinoma. Postcontrast MRI demonstrates leptomeningeal enhancement along the left superior cerebellar surface in *A*, the margin of the frontal horn of the right lateral ventricle in *B*, and the left foramen of Luschka in *C*.

ranged between 84 and 100 percent. However, prospective studies with larger samples are required to validate these findings.[14,15]

TREATMENT

Goals of treatment are to improve or stabilize neurologic function, maintain quality of life, and prolong survival. Treatment optimally should be directed toward the entire neuraxis, as tumor cells are disseminated widely throughout the CSF. However, craniospinal radiotherapy is rarely employed because of its significant adverse effects such as gastrointestinal toxicity, mucositis, and bone marrow suppression, and the lack of significant improvement in survival compared to chemotherapy. Involved-field radiotherapy to sites of symptomatic or bulky disease provides palliation of symptoms, treatment of bulky disease, and restoration of CSF flow. Whole-brain radiation therapy and/or placement of a ventriculoperitoneal shunt may be required for patients with communicating hydrocephalus. Patients with breast cancer, leukemia, and lymphoma have a higher likelihood than those with other malignancies of responding to radiotherapy.[14]

Chemotherapy can be given systemically or by the intrathecal route. Systemic chemotherapy can treat both leptomeningeal and systemic disease. Since the blood—brain barrier is intact or only partially disrupted in leptomeningeal disease, agents that are lipid soluble and can be administered safely and achieve a therapeutic level of CSF penetration at higher doses are utilized, such as methotrexate (3 to 8 g/m^2) or cytarabine (3 g/m^2). Other drugs that can cross the blood—brain barrier are capecitabine, thiotepa, and temozolomide. Tumor histology and response to prior drug exposure guide the choice of chemotherapeutic agent.

Intrathecal delivery has several advantages over systemic chemotherapy, including circumvention of the blood—brain barrier and reduction of systemic adverse effects because the drug is delivered directly into the subarachnoid space, and reduced overall dosage. This approach is not appropriate for bulky leptomeningeal diseases as drug concentration is only 1 to 2 percent of the CSF concentration at 1 to 2 mm from the surface. Agents primarily given by the intrathecal route are methotrexate and cytarabine (Ara-C). Randomized trials demonstrated no difference in survival using single-agent methotrexate or thiotepa compared to a combination of methotrexate, thiotepa, and cytarabine in patients with leptomeningeal carcinomatosis from solid tumors. Intrathecal administration of rituximab, an anti-CD20 monoclonal antibody, and trastuzumab, an antihuman epidermal growth factor receptor (HER-2) monoclonal antibody, have been investigated for lymphomatous meningitis and HER-2-positive breast leptomeningeal metastases, respectively, but are not considered standard yet. Intrathecal agents can be delivered via lumbar puncture or intraventricular (Ommaya) reservoir. Repeated lumbar punctures are inconvenient for patients, may result in inadvertent delivery of drugs outside the thecal sac, and produce a more variable drug concentration than intraventricular administration. Although ventricular reservoirs are usually well tolerated, complications such as misplacement, catheter tip occlusion, and infection may occur.[14]

Systemic administration of targeted therapies has shown clinical benefits, such as epidermal growth factors (EGFR) tyrosine kinase inhibitors (erlotinib, gefitinib, and osimertinib) in patients with nonsmall cell lung cancer, anaplastic lymphoma kinase (ALK) inhibitors (crizotinib, ceritinib and alectinib) in ALK fusion-positive nonsmall cell lung cancer patients, trastuzumab in HER2-positive breast cancer, and BRAF inhibitors (dabrafenib and vemurafenib) for melanoma. Prospective trials are needed to validate these findings. Due to limited CNS penetration at standard daily dosing, an intermittent "pulsatile" administration of high-dose tyrosine kinase inhibitors can boost CSF drug concentration. Pulsatile erlotinib is a reasonable alternative in EGFR-positive nonsmall cell lung cancer patients with new or worsening leptomeningeal or brain metastases, without evidence of systemic progression during standard erlotinib dose.[14]

Aggressive supportive treatment should be given to all patients with leptomeningeal metastases including corticosteroids for vasogenic edema and increased ICP, AEDs for seizures, opioid drugs for adequate analgesia, and antidepressants and anxiolytics as needed.

PROGNOSIS

The median survival for untreated leptomeningeal metastases is 4 to 6 weeks, and death often results from progressive neurologic dysfunction. With treatment, median survival is increased to 4 to 8 months. Patients with hematologic tumors have improved survival (median of 4.7 months) compared with solid tumors (median of 2.3 months). Tumor histology and molecular types are also important prognostic factors. The National Comprehensive Cancer Network suggests stratifying patients into either good- or poor-risk groups to guide decision-making regarding treatment. Patients with poor risk are those with low KPS, multiple, serious, or major neurologic deficits, extensive systemic disease with few treatment options, bulky CNS disease, leptomeningeal disease-related encephalopathy, and the presence of CSF block. The goal of treatment for these poor-risk patients is palliation of symptoms. For patients with better risk factors, a more aggressive treatment approach is recommended.

METASTASES TO THE PERIPHERAL NERVOUS SYSTEM

Plexuses

DEFINITION AND EPIDEMIOLOGY

Metastatic plexopathy affects 1 percent of cancer patients and may involve the cervical, brachial, or lumbosacral plexus.[16]

PATHOPHYSIOLOGY

Involvement of the plexus can occur by direct extension from contiguous tumors, from metastases to adjacent soft tissue, bony structures, or lymph nodes, or rarely by direct metastases to the nerves within the plexuses.

ANATOMIC CONSIDERATIONS AND CLINICAL FEATURES

Neurologic manifestations depend on the involved plexus. Patients typically present with new localized pain that is burning and aching in quality, progressive in nature, and increases in severity and frequency over days to weeks. Focal deficits, such as weakness, numbness, and areflexia, develop over weeks or months.

Cervical Plexus

The cervical plexus, composed of the anterior rami of C1 to C4 cervical roots, innervates most neck muscles and provides sensory innervation to the anterior and lateral neck. Cervical plexopathy commonly occurs as a result of direct invasion from contiguous neck soft tissue tumors or indirectly from regional lymph node metastases from head and neck squamous cell carcinomas, lymphoma, or lung and breast adenocarcinomas. Involvement of the cervical plexus is less common than the brachial or lumbosacral plexus.

Patients with metastases of the cervical plexus typically complain of pain within the submandibular and subglottic area, posterior or lateral neck, or around the shoulder. Coughing, neck movement, or assuming a recumbent position exacerbates the pain. Sensory loss commonly develops along the C2, C3, and C4 dermatomal distribution. This is in contrast to sensory loss from surgical neck dissection, which occurs in the distribution of the superficial branches of the greater auricular nerve or transverse cervical branches. Involvement of the distal spinal accessory nerve produces partial trapezius and sternocleidomastoid weakness. Paralysis of the hemidiaphragm, causing dyspnea when supine or upon exertion, results from phrenic nerve involvement.

Brachial Plexus

The anterior rami of the lower four cervical and first thoracic nerve roots form the brachial plexus, providing motor and sensory innervation to most of the upper limb except the trapezius muscle and area of skin near the axilla. The lower trunk (C8 and T1) is closely related to the axillary lymph nodes and is most often involved in metastatic cancer. The upper trunk (C5–6) is free of lymph nodes and is less frequently affected. However, primary head and neck squamous cell carcinoma can invade the brachial plexus from above, affecting the upper plexus preferentially. Brachial plexopathy occurs in 0.43 percent of cancer patients, with breast and lung carcinomas being the most common associated malignancies. Melanoma, non-Hodgkin lymphoma, Burkitt lymphoma, renal cell carcinoma, and testicular seminoma are other less common sources.[16]

Pain is the most common presenting symptom of metastatic brachial plexopathy, and is moderate-to-severe in intensity, beginning in the shoulder girdle and radiating to the elbow, medial side of the forearm, and the fourth and fifth fingers, often exacerbated by shoulder movement. Focal weakness, atrophy, or sensory changes in the distribution of the C7 to T1 dermatomes are common. Involvement of the inferior trunk and medial cord of the brachial plexus from a carcinoma of the lung apex results in the superior sulcus or Pancoast syndrome; patients present with pain and numbness along the ulnar border of the hand and forearm, intrinsic hand muscle weakness, and a palpable mass in the supraclavicular area or axilla. Tumors located near the T1 nerve root involving the stellate ganglion may result in ipsilateral

Horner syndrome, which occurs in 25 percent of patients with Pancoast syndrome. Lymphedema secondary to lymphatic obstruction is present in 17 percent.[16]

Lumbosacral Plexus

The lumbar plexus is formed from the anterior rami of the T12 to L4 nerves, while nerve roots from L4 to S3 merge to form the sacral plexus. These plexuses supply motor and sensory innervation to the lower extremities and parts of the pelvis. Metastatic involvement of the lumbosacral plexus occurs in 0.71 percent of cancer patients. Tumors within the abdomen and pelvis may directly infiltrate the lumbosacral plexus, and the most common responsible tumors are cervical, uterine, colorectal, bladder, and prostate carcinomas, retroperitoneal sarcomas, and lymphomas. Tumors that commonly metastasize to the lumbosacral plexus are cancers of the breast and lung and lymphoma. Perineural spread of prostate cancer to the lumbosacral plexus has been reported rarely.[16]

More than 90 percent of patients with lumbosacral plexopathy present with pain. Lumbar plexus involvement results in pain in the costovertebral angle, whereas involvement of the lower sacral plexus causes pain in the hip and buttock, or radiating pain in the ipsilateral lower extremity. Pain is worsened by Valsalva maneuver, prolonged weight bearing, ambulation, sitting, or supine positioning. Motor and sensory loss develops in 60 percent of patients. The most common clinical signs are leg weakness (86% of these patients), sensory loss (73%), areflexia (64%), and leg edema (47%). Up to 25 percent of patients suffer from incontinence or impotence, which usually signifies bilateral and sacral involvement.

DIAGNOSTIC STUDIES

MRI is the neuroimaging study of choice for neoplastic plexopathy, typically showing a mass adjacent to the plexus or evidence of metastatic infiltration with hypointensity on T1-weighted imaging, hyperintensity on T2-weighted imaging, and gadolinium enhancement. These MRI findings are nonspecific and may occur in both metastatic and radiation plexopathy. The finding of linear or nodular enhancement along the nerves favors plexus metastases, while a thin "tram track" pattern of enhancement is associated with radiation-induced plexopathy.[17] Electrophysiologic studies can demonstrate the degree, type, and distribution of plexus involvement. Electromyography is helpful in delineating metastatic from radiation plexopathy, as myokymic discharges are common in the latter. Nerve conduction studies reveal variable axonal loss in both types of plexopathy, but patients with radiation plexopathy may also show signs of focal conduction block. FDG-PET studies aid in distinguishing neoplastic disease from radiation plexopathy—in metastatic disease there is increased uptake in the involved region whereas radiation plexopathy is typically hypometabolic. Nevertheless, normal neuroimaging and electrophysiologic studies do not always exclude a metastatic plexopathy.

DIFFERENTIAL DIAGNOSIS

Radiation plexopathy is the main differential diagnosis to consider in patients with suspected metastatic plexopathy. The incidence of radiation-induced brachial plexopathy in women with breast carcinoma is 1.8 to 9 percent, with 5 percent having disabling symptoms. Typically, radiation plexopathy develops from 0.5 to 20 years after treatment when the brachial plexus is affected, and 1 to 5 years after treatment with lumbosacral involvement. The risk of radiation plexopathy increases with radiation dose; the tolerance dose for brachial plexus (5 percent risk at 5 years) is 60 Gy for conventional fractionation regimens. Mechanisms of radiation injury include direct toxic effects on axons and indirect damage from fibrosis or fibrinoid necrosis within the vasa nervorum, resulting in microinfarctions. Usual presentations of radiation plexopathy include paresthesias and hypesthesia, followed by weakness and amyotrophy. In contrast to metastatic plexopathy, pain is usually mild and follows the sensory symptoms; the lower trunk of the brachial plexus is less likely to be involved as it is protected by the clavicle during radiation therapy. Horner syndrome is similarly uncommon, whereas lymphedema is more common than in metastatic plexopathy. Bilateral lumbosacral plexopathy is most likely due to radiation injury rather than neoplastic involvement. The presence of myokymic discharges on electrophysiologic studies strongly supports the diagnosis of radiation-induced plexopathy, which is present in up to 60% of patients. MRI generally reveals hypointensity on T1- and T2-weighted sequences, reflecting fibrosis without nerve enhancement; however, fibrotic changes with substantial inflammation can demonstrate both hyperintensity on T2-weighted images and contrast enhancement.[16,17]

Other differential diagnoses include plexopathy from intra-arterial chemotherapy, diabetes, infection, and hemorrhage, as well as infectious and paraneoplastic syndromes.

TREATMENT AND PROGNOSIS

The prognosis for most patients with metastatic plexopathy is generally poor because of the presence of advanced disease, and the primary therapeutic goal is palliation of symptoms. Aggressive pain management and prevention of complications of immobility are the focus of treatment. Radiation therapy can control local tumor growth, providing pain relief in 46 percent of patients with neoplastic brachial plexopathy and 85 percent of those with lumbosacral plexopathy. Intra-arterial chemotherapy has limited use in the treatment of intractable pain due to plexopathy, and paradoxically can also cause plexopathy. A multimodal approach in treating cancer pain should utilize opiate analgesics, infusion pumps, local and regional blocks, sympathetic ganglionic blocks, and epidural anesthetics. Dysethesias and paresthesias can be managed with transcutaneous nerve stimulation, tricyclic antidepressants, gabapentin, lamotrigine, topiramate, carbamazepine, phenytoin, and valproic acid. Rhizotomy and neurotractomy may be used in selected cases of chronic pain. Physical and occupational therapy and decreasing lymphedema by using compressive devices and diuretics can also be beneficial.

Radiation-induced malignancies (e.g., sarcomas) and atypical peripheral nerve sheath tumors develop rarely in patients with metastatic plexopathy treated with radiation. These neoplasms may appear from 4 to 41 years after radiation treatment, presenting as painful masses and leading to progressive neurologic deficits. Genetic conditions such as neurofibromatosis type 1 or ataxia-telangiectasia may predispose to these tumors. Patients with radiation-induced sarcomas warrant surgical excision with adjuvant chemoradiotherapy, whereas surgical resection is the main treatment for radiation-induced peripheral nerve sheath tumors.[16]

Peripheral Nerves

DEFINITION AND EPIDEMIOLOGY

Metastases to the peripheral and cranial nerves are relatively rare. Peripheral nerve dysfunction in cancer patients is commonly due to effects of chemotherapy, as is discussed in Chapter 28.

MECHANISMS, CLINICAL FEATURES, AND DIAGNOSIS

Peripheral nerves may be involved through extension or compression from adjacent bony or soft tissue structures such as the skull base, vertebrae, pelvis, lymph nodes, muscles, connective tissue, or nearby organs. Ulnar nerves may be affected by tumors at the elbow or axilla, radial nerves from the humerus, intercostal nerves by rib metastases, sciatic nerves from the bony pelvis, and fibular (peroneal) nerves behind the fibular head. Tumor invasion or metastasis to the mediastinal lymph nodes can cause hoarseness and vocal cord paralysis from involvement of the recurrent laryngeal nerve. Breast, prostate, lung, kidney, and thyroid cancers are the most common cause of peripheral nerve involvement. The recurrent laryngeal nerve, phrenic nerve, and cervical sympathetic nerves may be affected in lung cancers. Patients commonly present with severe, lancinating pain. Focal weakness, numbness, fasciculations, cramping, muscle atrophy, and reflex loss can help localize the involved peripheral nerve. Tinel sign and local tenderness can be elicited at the site of metastasis.

Metastases from solid tumors within the peripheral nerves themselves are exceedingly rare. Intraneural metastases resembling multiple neuropathies were reported in a patient with carcinoid tumor. Increasing pain, numbness, and weakness relating to the involved nerves are the usual presenting symptoms. Hematogenous spread to the posterior root ganglia has been reported in patients with colon and lung carcinoma.[16]

Occlusion of nerve vessels from ischemia is another mechanism for nerve injury from tumors such as intravascular lymphoma, a rare, high-grade, extranodal non-Hodgkin lymphoma with a tropism for the endothelium, commonly affecting the CNS and skin. Infiltration of lymphoma cells into the peripheral nervous system is referred to as neurolymphomatosis and signifies local invasion occurring outside the arachnoid investment of the nerves. This mechanism is distinct from infiltration associated with subarachnoid seeding from perineural tumors seen in epidural lymphoma. The malignant lymphocytes in neurolymphomatosis are clustered in perivascular sites, in contrast to meningeal lymphoma where the lymphocytes are in the epineurium. Large B-cell lymphoma is the most common cause; less frequent are T-cell, natural killer cell, and Hodgkin lymphomas. The average age at diagnosis of neurolymphomatosis is 55.5 years; 60 percent of patients are male.

Four patterns of presentations have been identified in patients with neurolymphomatosis: painful involvement of nerves or roots, cranial neuropathy with or without pain, painless involvement of peripheral nerves, and painful or painless involvement of a single peripheral nerve. The lumbosacral roots and cauda equina are the most common sites of involvement in the peripheral nervous system. Neurologic dysfunction usually antedates discovery of systemic lymphoma and is responsive to corticosteroids. Clinical findings suggesting neurolymphomatosis rather than paraneoplastic or inflammatory processes include severe pain, asymmetric distribution, and rapid evolution. MRI reveals enhancement or T2-weighted hyperintensity within the peripheral nerves. PET-CT is helpful in visualizing the involved nerve, which demonstrates hypermetabolism when the lesion is sufficiently large. Electrophysiologic studies reveal areas of demyelination at the site of lymphoma cell infiltration with axonal degeneration distally. CSF examination may be normal or may show increased protein concentration or a pleocytosis; these findings may be confused with acute or chronic inflammatory demyelinating polyneuropathy. Malignant cells are identified in up to 40% of patients. Biopsy of a clinically affected nerve is the gold standard for diagnosis. Histopathologic findings show tumor cell infiltration of the endoneurium and perineurium, displaying B-cell-associated surface antigens (CD19 and CD20) with high-proliferation index. Although biopsy is sensitive, it still may be falsely negative despite widespread lymphomatous involvement of peripheral nerves. In these cases, integration of clinical information, imaging findings, morphologic data from neural and non-neural tissues, and CSF studies may be helpful in establishing the clinical diagnosis. The response to empiric treatment may also lead to the correct diagnosis.[16]

TREATMENT AND PROGNOSIS

Systemic chemotherapy addressing multiple sites of involvement together with focal radiotherapy may offer relief of symptoms. For neurolymphomatosis, treatment principles are similar to primary CNS lymphoma. Methotrexate treatment in patients with neurolymphomatosis may provide clinical improvement and at least partial radiographic improvement. Radiotherapy is indicated for drug-refractory localized lymphomatous aggregates. When treated promptly and properly, neurolymphomatosis carries a similar prognosis to primary CNS lymphoma.[16]

METASTASES TO MUSCLES

Epidemiology and Pathophysiology

Skeletal muscle metastases are a rare occurrence in patients with malignancy, despite the fact that skeletal muscle comprises 50 percent of total body mass. The prevalence of metastases to muscles in autopsy studies ranges from 0.03 to 17.5 percent, and a retrospective study demonstrated that 0.42 to 4.9 percent of oncologic patients had muscle metastases. The rarity of these metastases is due to a number of factors, including blood flow variability between resting and exercise states causing a reduction of tumor cell adherence to underlying tissues, skeletal muscles producing anticancer factors such as leukemia inhibitory factor and interleukin-6, skeletal muscle microvasculature having the biochemical ability to destroy the cancer cells, and the skeletal muscles removing lactic acid, which plays a role in neovascularization.[18]

The hypothesized mechanisms of metastases include hematogenous dissemination by arterial emboli or venous spread (especially through the Batson plexus), extension from intramuscular lymph nodes, or perineural spread. The most frequent primary tumors are genitourinary and gastrointestinal cancers and melanoma. Metastases are most commonly located in paravertebral, iliopsoas, gluteal, and intercostal muscles.[18]

Clinical Features

Most patients with skeletal muscle metastases are asymptomatic, and these metastases are found incidentally during staging. Local pain and swelling occur in 14 percent, usually in patients with large lesions with massive infiltration or destruction. Patients with psoas involvement may present with "malignant psoas syndrome" with fixed flexion of ipsilateral hip and knees. Painless palpable masses arise in 10 percent of patients.[18]

Diagnostic Studies

The advent of CT, MRI, and FDG PET has facilitated detection of skeletal muscle metastases. Different types of CT findings have been recognized, including focal intramuscular masses with homogeneous contrast enhancement, abscess-like intramuscular lesions, diffuse metastatic muscle infiltration, multifocal intramuscular calcification, and intramuscular bleeding. MRI with gadolinium is superior to CT both in diagnosis and in planning treatment. The majority of patients with skeletal muscle metastases demonstrate extensive peritumoral enhancement associated with central necrosis. The increasing use of FDG PET/CT for staging and follow-up has resulted in the detection of many unsuspected cases of skeletal muscle metastases, which show high tumor-to-background contrast resolution. Needle biopsy establishes the diagnosis definitively.[18,19]

Differential Diagnosis

Conditions that may mimic skeletal muscle metastases are muscle hemangioma, intramuscular ganglion, myxoma, ischiorectal bursitis, benign muscle calcifications such as myositis ossificans, calcific tendinitis, angiomatosis, systemic sclerosis, and calcific myonecrosis.[18]

Treatment and Prognosis

As most patients have widespread systemic disease, the prognosis is generally poor. The main goal of treatment is therefore palliation, and therapeutic options include radiotherapy or chemotherapy. Surgical excision is considered for lesions larger than 4 cm and recommended for rapidly expanding lesions or those producing neurologic deficits. Reports have shown effective control of local tumor recurrence after wide excision that includes the infiltrative borders of the tumor.[19]

CONCLUDING COMMENTS

Cancer can involve any part of the nervous system and lead to significant neurologic morbidity, at times representing a catastrophic event for patients with cancer. Knowledge of both common and rare manifestations of nervous system metastases aids clinicians in early recognition and proper localization. Distinguishing metastatic from nonmetastatic diseases such as those with infectious, inflammatory, and vascular etiologies or from complications of cancer therapy is imperative. The appropriate use of neurodiagnostic modalities such as MRI frequently assists in reaching a correct diagnosis. Clinicians should establish realistic therapeutic goals, including symptomatic treatment to maintain quality of life of these patients. A multidisciplinary approach involving neurologists, neuro-oncologists, medical oncologists, radiation oncologists, neurosurgeons, specialists in palliative care, and rehabilitation experts is necessary.

  - *Peripheral Nerve Hyperexcitability (Neuromyotonia)*
- Muscle Syndromes

The term *paraneoplastic syndrome* is often used to refer to symptoms or signs resulting from dysfunction of organs or tissues caused by a cancer, but which are not a direct effect of invasion by the neoplasm or its metastases. Perhaps most accurately, the term is used in a restricted sense to describe specific neurologic disorders that occur with increased frequency in patients with certain cancers, and are not caused by invasion, infection, systemic metabolic disorders, vascular disease, or side effects of cancer therapy. Paraneoplastic syndromes may affect virtually any organ or tissue (Table 27-1), including multiple regions within the nervous system (Table 27-2). These disorders, also termed *remote effects of cancer on the nervous system*, detailed in Table 27-3, are typically immune mediated, and encompass a clinically and pathologically more restricted group of disorders than the other nonmetastatic effects of cancer.[1,2] In addition to paraneoplastic immune-mediated disorders, this chapter addresses the increasingly recognized group of immune-mediated neurologic syndromes which have similar clinical features to the more traditionally recognized paraneoplastic syndromes but occur without an associated cancer.[3,4] These nonparaneoplastic immune-mediated syndromes are important to understand as they are often more responsive to immunotherapies than their closest counterpart paraneoplastic conditions.

GENERAL CONSIDERATIONS

Incidence

Several studies have addressed the frequency of paraneoplastic and nonparaneoplastic syndromes. Wide-ranging estimates from these studies are due to: (1) varied definitions; (2) the rigor used to exclude other causes of neurologic dysfunction; (3) the care with which the neurologic evaluation was performed; and (4) biases introduced by referral patterns. For example, the Lambert–Eaton myasthenic syndrome (LEMS) occurs in 3 percent or less of patients with small cell lung cancer (SCLC), but about 50 percent

TABLE 27-1 ■ Selected Non-Neurologic Paraneoplastic Syndromes

General Physiologic (Host-Reactive) Syndromes

Fever
Anorexia and cachexia
Fatigue and "weakness"
Dysgeusia

Hematologic and Vascular Syndromes

Anemia
Leukemoid reaction
Eosinophilia, basophilia
Thrombocytosis
Thrombocytopenia
Hypercoagulability (Trousseau syndrome)
Erythrocytosis
Hyperviscosity

Skin and Connective Tissue Syndromes

Acanthosis nigricans
Tripe palms
Erythemas
Pruritus
Vasculitis
Flushing
Sweet syndrome
Ichthyosis
Hypertrichosis
Pachydermoperiostosis
Melanosis, vitiligo

Endocrine-Metabolic Syndromes

Cushing syndrome
Hypoglycemia and hyperglycemia
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Carcinoid syndrome
Hypercalcemia and hypocalcemia
Systemic nodular panniculitis
Acromegaly
Gynecomastia
Hypernatremia

Gastrointestinal Syndromes

Protein-losing enteropathy
Malabsorption
Exudative enteropathy
Zollinger–Ellison syndrome

Collagen-Vascular Syndromes

Arthritides
Scleroderma
Lupus erythematosus
Amyloidosis
Palmar fasciitis

Renal Syndromes

Glomerulonephritis
Nephrotic syndrome
Renal failure
Hypokalemia

Bone Syndromes

Hypophosphatemic osteomalacia

Pulmonary osteoarthropathy

Clubbing
Synovitis

TABLE 27-2 ■ Nonmetastatic Complications of Cancer on the Nervous System

Disorder	Example(s)
Vascular disorders	Hemorrhage/infarction
Infections	Meningitis/abscess
Nutritional disorders	Wernicke encephalopathy
Metabolic disorders	Hypocalcemia
Side effects of therapy	
Surgery and other diagnostic or therapeutic procedures	Meningitis/CSF leak
Radiation therapy	Brain/spinal cord necrosis
Chemotherapy/small molecules	Peripheral neuropathy
Biologic therapy	PML
"Remote" or paraneoplastic syndromes	(see Table 27-3)

CSF, Cerebrospinal fluid; PML, progressive multifocal leukoencephalopathy.

of SCLC patients have either subjective or objective muscle weakness. While less than 10 percent of cancer patients had a "neuromyopathy" on physical examination, abnormalities of peripheral nerve function were found by quantitative sensory testing in nearly half. Myopathic changes are found on muscle biopsy in one-third of patients with lung cancer. These neurologic symptoms can predate the detection of cancer; in patients with peripheral sensory neuropathy of unknown cause, for instance, nearly one-third in some studies developed cancer within 6 years.

True incidence figures for paraneoplastic syndromes are rare. Population-based data are available for myasthenia gravis, LEMS, and dermatomyositis. A total of 5 percent of myasthenia gravis patients have a paraneoplastic form. In another study, the annual incidence of LEMS was rare (0.4 per million persons), but was equally divided between those with SCLC and those with nonsmall cell lung cancer (NSCLC). For dermatomyositis, the overall age- and sex-adjusted incidence is around 10 per million persons; 20 percent have cancer. Nearly one-fifth in one study suffered from the amyopathic subtype (rash but no muscle weakness).

Other studies have addressed the percentage of patients with a given tumor likely to have a paraneoplastic syndrome. Myasthenia gravis occurs in 10 to 15 percent of patients with thymoma. LEMS has been found in about 3 percent of patients with lung cancer. Paraneoplastic peripheral neuropathy occurs in

10 percent of malignant monoclonal gammopathies, and in 50 percent of patients with osteosclerotic myeloma. Most known paraneoplastic syndromes are so uncommon that exact incidence figures cannot be established, but they probably occur in less than 0.01 percent of cancer patients.

A higher yield is found when patients whose symptoms suggest the possibility of a paraneoplastic syndrome have serum and cerebrospinal fluid (CSF) sent for examination for paraneoplastic antibodies. Using this approach, one-fourth of consecutive patients examined over 2 years have well-defined antineuronal autoantibodies.

Pathogenesis

Although the exact pathogenesis of most paraneoplastic syndromes has not been established, the consensus is that most, or perhaps all, neurologic paraneoplastic syndromes are immune-mediated. Evidence for this hypothesis includes the presence of autoantibodies that recognize antigens present in both the cancer and the normal nervous system. Some of these so-called paraneoplastic or onconeural antigens are also expressed in normal testes, an organ that, like the brain, is an immunologically privileged site. If the antigen cannot be identified in a cancer with a known serum paraneoplastic antibody, it may be that either the patient does not have a paraneoplastic syndrome or that some other cancer is present and caused the disorder. Examination of the CSF of patients with paraneoplastic syndromes involving the central nervous system (e.g., limbic encephalitis) usually reveals a pleocytosis, at least early in the course of the disease, with a persistently slightly elevated protein level, an increased IgG Index, and oligoclonal bands. Some of these oligoclonal bands in the CSF have been identified as paraneoplastic antibodies themselves. The relative specific level of the paraneoplastic antibody (expressed as a concentration of antibody against total IgG) is substantially higher in CSF than in the serum. This indicates that the antibody was synthesized by B cells within the central nervous system (CNS), rather than simply diffusing across the blood–brain barrier. The tumors of patients with paraneoplastic syndromes, although identical in histologic type to tumors of patients without neurologic features, are more likely to be infiltrated with inflammatory cells including T cells, B cells, and plasma cells.[5] The nervous system is usually also infiltrated by inflammatory cells, and some paraneoplastic syndromes respond to treatment with immunosuppression.

The current concept of the pathogenesis of paraneoplastic syndromes is that the tumor ectopically expresses an antigen that is normally expressed in the nervous system. Onconeural antigens are present in the tumors of all patients with antibody-positive paraneoplastic syndromes. In some tumors, such as SCLC, onconeural antigens are present in all tumors, even in those patients who do not develop paraneoplastic antibodies or a paraneoplastic syndrome. The onconeural antigen in the tumor cell is probably recognized by the immune system when tumor cells spontaneously undergo apoptosis and the apoptotic bodies containing the antigen are phagocytized by antigen-presenting cells. Current evidence conflicts as to whether the antigens in the tumor are mutated or identical in structure to normal neural antigens. The former would provide a mechanism for loss of tolerance, leading to development of paraneoplastic antibodies. The body's immune system attacks structures expressing the paraneoplastic antigen, resulting in two effects. First, the immune attack may control the growth of the tumor and in rare instances obliterate it. Second, the immune response also attacks the nervous system itself; both B and T cells can be found in the CNS of patients with CNS paraneoplastic syndromes. The B cells generally reside in the perivascular spaces and the T cells in both perivascular spaces and in the brain parenchyma. Often the granzyme-B-expressing cytotoxic T cells are closely opposed to neurons. Further, the T cells found in the nervous system are either mono- or oligoclonal and respond only to a specific antigen. Hence, these diseases appear to be T-cell driven.

By contrast, consensus suggests that autoantibodies which target the native extracellular domains of neuronal proteins are far more likely to be directly pathogenic, as they are likely to access their target antigen in vivo.[3,6] Indeed, two paraneoplastic syndromes with antibodies that target the extracellular domains of proteins expressed at the human neuromuscular junction, LEMS and myasthenia gravis, were the first to meet formal criteria for an antibody-mediated autoimmune disease. Other paraneoplastic syndromes in which antibodies likely play a causal role include NMDA receptor antibody-associated encephalitis, CASPR2 antibody-associated Morvan syndrome, AMPAR-associated encephalitis, and autonomic neuropathy with antibodies to the ganglionic acetylcholine (ACh) receptor. In addition, a variety of syndromes with autoantibodies that target the extracellular domains of native neuroglial surface proteins have no tumor associations. These include autoantibodies against leucine-rich glioma inactivated 1 (LGI1), Iglon5, the $GABA_A$ receptor, aquaporin-4 (AQP4), and myelin oligodendrocyte glycoprotein (MOG).

Diagnosis

Recommended criteria for the diagnosis of a neurologic paraneoplastic syndrome are listed in Table 27-4.[7] Alternative causes that might explain the clinical symptoms must be excluded. "Classic" refers to those neurologic disorders characteristic of a paraneoplastic syndrome as indicated in Table 27-5. Hence, a clear clinical definition of the syndrome is required. "Onconeural" refers to antibodies that recognize antigens that are restricted to the nervous system (or testes) and to some cancers. Originally, when the antigens were unknown, two separate nomenclatures were devised to designate these antibodies. The nomenclature applied at Memorial Sloan-Kettering Cancer Center (e.g., Yo, Hu) refers to the first two letters of the last name of the index patient while the Mayo Clinic terminology (e.g., anti-PCA-1, anti-ANNA-1) refers to the staining pattern by immunohistochemistry. In Table 27-5 the latter system is identified in parentheses. Once these antigens have been identified, the antigen's name is used to designate the antibody in question (e.g., NMDAR antibody). The term "well-characterized" refers to an antibody whose antigen has been robustly identified, typically by multiple laboratories.

TABLE 27-4 ■ Diagnostic Criteria for Paraneoplastic Neurologic Syndromes (PNS)

Definite PNS

1. A classic syndrome and cancer that develops within 5 y of the diagnosis of the neurologic disorder.
2. A nonclassic syndrome that resolves or significantly improves after cancer treatment without concomitant immunotherapy provided that the syndrome is not susceptible to spontaneous remission.
3. A nonclassic syndrome with onconeural antibodies (well-characterized or not) and cancer that develops within 5 y of the diagnosis of the neurologic disorder.
4. A neurologic syndrome (classic or not) with well-characterized onconeural antibodies (e.g., anti-Hu, Yo, CV2, Ri, Ma-2, or amphiphysin), and no cancer.

Possible PNS

1. A classic syndrome, no onconeural antibodies, no cancer but at high risk to have an underlying tumor.
2. A neurologic syndrome (classic or not) with partially characterized onconeural antibodies and no cancer.
3. A nonclassic syndrome, no onconeural antibodies, and cancer present within 2 y of diagnosis.

From Graus F, Delattre JY, Antoine JC, et al: Recommended diagnostic criteria for paraneoplastic neurological syndromes. J Neurol Neurosurg Psychiatry 75:1135, 2004, with permission.

The 5-year period identified in the criteria for the development of cancer is reasonable but problematic. Although in most patients with a paraneoplastic syndrome the cancer is identified within a year or so, in an occasional patient, even when the neurologic syndrome and the antibody clearly have been

TABLE 27-5 ■ The Major Antibody-Associated Neurologic Paraneoplastic and Nonparaneoplastic Disorders

Antibody Target	Location	Antigen/Gene(s)	Extracellular or Intracellular Epitope	Usual Tumor or Site of Origin	Neurologic Disorder
Antibody Markers of Neurologic Paraneoplastic Syndromes, Requiring a Search for Tumor					
Hu (ANNA-1)	Nucleus > cytoplasm (all neurons)	HuD (Elavl4); Elavl2, 3	Intracellular	SCLC, neuroblastoma, prostate	PEM, PSN, autonomic dysfunction

recognized, more than 5 years may elapse before the cancer is found. The inability to find a cancer, even after 5 years, does not mean that the patient does not have a paraneoplastic syndrome. There are rare, but well-documented, cases of a paraneoplastic syndrome being associated with spontaneous remission of a cancer.[8] Also, there are occasional patients with high-titer, well-characterized paraneoplastic antibodies who almost certainly never have had nor will develop a cancer.

The only unequivocal method of determining whether a given patient has a paraneoplastic syndrome is by identifying an autoantibody that reacts with the portion of the nervous system suffering damage and a neoplasm whose cells express the same antigen. If the antigen is not found in the neoplasm, the patient either does not have a paraneoplastic syndrome or has another cancer—as yet unfound—that expresses the antigen, and a new search should be considered.

Several clinical features can assist in the diagnosis. Most paraneoplastic syndromes develop rapidly, progress over weeks to months, and then stabilize; syndromes that begin insidiously or are characterized by exacerbations and remissions are less likely to be paraneoplastic. Many paraneoplastic syndromes result in serious neurologic disability although those with antibodies to neuronal surface epitopes are often responsive to immunotherapies. Paraneoplastic syndromes affecting the CNS are typically associated with an inflammatory CSF, including pleocytosis, elevated levels of protein, increased CSF immunoglobulins, and unique oligoclonal bands; one of these features is present in nearly all patients with a CNS paraneoplastic syndrome. Magnetic resonance imaging (MRI) may be normal or have abnormalities consistent with the clinical findings (e.g., medial temporal lobe T2-weighted hyperintensity in patients with limbic encephalitis or cerebellar atrophy in patients with paraneoplastic cerebellar degeneration). When the MRI is normal, fluorodeoxyglucose positron emission tomography (PET) scans may reveal hypometabolism in the brain that is either diffuse or focal, although these findings are nonspecific. Several of the paraneoplastic syndromes (e.g., LEMS) are so stereotypic that the correct diagnosis can be strongly suspected even before additional diagnostic testing has excluded alternative diagnoses.

ANTIBODIES

Many paraneoplastic syndromes are characterized by serum and CSF autoantibodies which react with both the areas of the nervous system involved and the underlying cancer. Some autoantibodies (e.g., Hu, Ri, and Yo antibodies) are highly specific for the presence of an underlying cancer and strongly suggest a specific cancer that can guide workup. For example, the Yo antibody is strongly associated with breast and gynecologic tumors and requires careful mammography as well as pelvic imaging. However, some paraneoplastic syndromes can be caused by many tumors, and therefore a more widespread search including total-body computed tomography (CT) or PET scan is frequently appropriate. Table 27-5 lists many of the antibodies that can be found in the serum of patients with paraneoplastic syndromes. Other autoantibodies (e.g., ACh receptor antibodies), however, are found in patients both with and without cancer. It is usually not necessary to measure antibodies in the CSF of patients in whom serum antibodies are negative. Yet, in the case of a few autoantibodies, since serum has a high total IgG level which inherently increases the test background, it is often useful to study CSF in conjunction. This is supported by the observation that patients with CNS paraneoplastic syndromes often show a higher relative concentration of the autoantibody in CSF than serum, indicating its intrathecal synthesis.

Most paraneoplastic antibodies are usually associated with specific paraneoplastic syndromes and a limited number of implicated cancers (Table 27-5). For example, the Hu-antibody is more likely to cause encephalomyelitis and is usually associated with SCLC, whereas the CRMP5 antibody is more likely to be associated with cerebellar ataxia, chorea, optic neuritis, uveitis, and LEMS. Both of these antibodies are associated with SCLC, but only the CRMP5 antibody is associated with thymoma. Regardless of the tumor type, patients with the CRMP5 antibody survive significantly longer, a finding that does not appear to be related to a less severe neurologic disorder than those patients with the Hu antibody.

As discussed above, antigens can be divided into two groups: group 1 consists of intracellular antigens, either cytoplasmic or nuclear, and group 2 consists of antigens expressed on the surface of neurons whose extracellular domains are the autoantibody targets. This division identifies disorders that usually respond to treatment and in which antibodies are likely causal (group 2), and those that usually do not respond to treatment and where the pathogenesis is likely T-cell mediated (group 1).[6]

Group 1 antigens that usually are paraneoplastic, including Hu, Yo, and several others, may occur only occasionally in patients without cancer. In one series of Hu antibody positive patients, 3 percent with clinical follow-up of more than 3 years did not develop an identifiable cancer, and there was no clinical differences between those patients who did and did not develop cancer. One possible explanation is that a cancer was present but spontaneously regressed. Both spontaneous regression of the cancer and antineuronal antibodies are thought to be more common in infants with neuroblastoma. Group 1 also consists of intracellular antigens that are cancer-specific but not usually helpful in diagnosis, including Sox 1 and Zic. Other intracellular antigens are associated with autoimmune disorders of the nervous system that are only sometimes paraneoplastic, including glutamic acid decarboxylase (GAD). Indeed, some authors prefer to classify GAD and amphiphysin in a separate group of intracellular synaptic antigens, in recognition of the potential for these autoantibodies to access their targets upon vesicle fusion with the presynaptic membrane.

Group 2 antigens can be divided into those surface antigens associated with autoimmune CNS syndromes that are often associated with an underlying tumor, such as the AMPAR and $GABA_BR$, and those which are only sometimes paraneoplastic, including CASPR2 and the NMDAR. In addition, it is increasingly recognized that some cell surface targets have a very limited, if not absent, epidemiologic association with an underlying tumor; examples include LGI1 and Iglon5.[9]

Treatment

Overall, patients with autoantibodies to intracellular antigens respond less well to immunologic therapeutic interventions than those in group 2. Nevertheless, there are two general approaches to the treatment of paraneoplastic neurologic disorders. In many cases, effective therapy focuses on treatment of the underlying tumor. This aims to prevent progression of the disease and, in some instances, leads to improvement or, more rarely, complete amelioration of the neurologic symptoms. Effective treatment of the tumor may remove the inciting antigen and thus dampen the immune response causing the neurologic damage.

Because paraneoplastic syndromes are likely immune mediated, the second treatment approach is to suppress the immune response. Several different forms of immunosuppression, including corticosteroids, plasma exchange, intravenous immunoglobulin, cyclophosphamide, and cyclosporine or tacrolimus, have been used to treat paraneoplastic syndromes (Table 27-6). This immunosuppression does not appear to worsen the outcome of the tumor, and may sometimes associate with stabilization or improvement of the syndrome, especially if administered early.

Despite these interventions, many patients with autoantibodies against group 1 antigens show limited improvement. By contrast, patients with autoantibodies against cell surface-exposed epitopes (e.g., the NMDAR or LGI1) are highly likely to respond to immunotherapy, maybe in part since many such patients do not have an underlying cancer. Treatment outcomes in these patients can frequently be almost complete. With regard to a potential third group of autoantibodies that lie intracellularly within synapses (e.g., GAD and amphiphysin antibodies), the patients may or may not have cancer and may respond well to immunosuppression.

TABLE 27-6 ■ Treatment of Neurologic Paraneoplastic Syndromes

Syndrome	Treatment
*Syndromes That Usually Respond to Treatment**	
Lambert–Eaton myasthenic syndrome	IV immunoglobulin, plasma exchange, 2,3 diaminopyridine, immunosuppression[†]
Myasthenia gravis	IV immunoglobulin, plasma exchange, immunosuppression, anticholinesterases
Dermatomyositis	IV immunoglobulin, immunosuppression
Opsoclonus-myoclonus (pediatric)	IV immunoglobulin, corticosteroids, ACTH, rituximab
Neuropathy associated with osteosclerotic myeloma	Radiation, chemotherapy
NMDAR	First line: corticosteroids, IV immunoglobulin, plasma exchange; Second line: cyclophosphamide, rituximab
LGI1	Corticosteroids, IV immunoglobulin, plasma exchange
Encephalitis with cell surface antigens other than NMDAR and LGI1 (e.g., AMPA receptor, GABA$_{A/B}$ receptor, CASPR2)	Corticosteroids, IV immunoglobulin, plasma exchange, cyclophosphamide
*Syndromes That May Respond to Treatment**	
Stiff-person syndrome	IV immunoglobulin, rituximab, diazepam, baclofen
Neuromyotonia	IV immunoglobulin, plasma exchange, phenytoin, carbamazepine
Guillain–Barré/CIDP	IV immunoglobulin, plasma exchange
Vasculitis of nerve and muscle	Corticosteroids, cyclophosphamide
Opsoclonus-myoclonus (adults)	Corticosteroids, cyclophosphamide, protein A column, clonazepam, thiamine
MAG-antibody associated peripheral neuropathy (Waldenström macroglobulinemia)	IV immunoglobulin, plasma exchange, chlorambucil, cyclophosphamide, fludarabine, rituximab
Acute necrotizing myopathy	Immunosuppression

In all cases, treatment should also focus on identifying and treating the tumor. ACTH, adrenocorticotopic hormone; CIDP, chronic inflammatory demyelinating neuropathy; IV, intravenous.

*Syndromes that usually do not respond to treatment include encephalomyelitis, sensory neuronopathy, autonomic dysfunction, cerebellar degeneration, and cancer- and melanoma-associated retinopathy.

[†] Immunosuppression includes corticosteroids or azathioprine.

SPECIFIC SYNDROMES

Paraneoplastic syndromes that affect the nervous system are classified in Table 27-5. Only some of the more common syndromes are considered in this chapter, and more extensive reviews are available elsewhere.[1,3,5]

Limbic Encephalitis

Limbic encephalitis is characterized by the acute-to-subacute onset of short-term memory loss, seizures, and behavioral abnormalities. The disorder has been reported in association with a variety of tumors including SCLC and ovarian teratoma. A clinically identical autoimmune disorder occurs in patients without cancer, and both the paraneoplastic and nonparaneoplastic forms of limbic encephalitis are associated with a variety of different autoantibodies.

Limbic encephalitis can begin with seizures and changes in mood and personality. Accompanying features include severe impairment of recent memory with relatively preserved remote memory. Patients are often agitated and confused and can show a range of behavioral features from depression and agitation to a florid delirium. Symptoms can begin quite abruptly or the onset may be more gradual, occurring over several weeks to even a few months. When behavioral changes dominate the symptomatology, particularly when the disorder affects young women, a diagnosis of primary psychiatric disease may occur before a correct diagnosis is made.[10]

In addition to these features, patients may display other specific characteristics which can be highly suggestive, if not pathognomonic, of their underlying autoantibody. For example, patients with NMDAR-antibody encephalitis often exhibit a multifaceted psychiatric prodrome with features of both mood changes and psychosis, in addition to a complex movement disorder, dysautonomia, and coma.[10,11] By contrast, patients with LGI1 antibodies exhibit a prodrome of remarkably frequent focal seizures with semiologies including thermal sensations, piloerection, and synchronous spasms of the arm and face, termed faciobrachial dystonic seizures (FBDS).[9] The latter appear exclusive to patients with LGI1 antibodies. CASPR2 antibodies are associated with peripheral nerve hyperexcitability including Morvan syndrome, but some patients present with a pure encephalitis. CASPR2 antibodies may be associated with thymic tumors, especially in patients with peripheral nerve involvement.[12]

Laboratory Findings

The CSF is often inflammatory, at least early in the course of the disease, although this finding can be variable between autoantibodies. The MRI may be subtle or normal although abnormalities, particularly medial temporal lobe hyperintensities on the T2-weighted or fluid-attenuated inversion recovery (FLAIR) sequences (Fig. 27-1), are common. Electroencephalographic (EEG) findings include focal or generalized slowing and occasional epileptiform activity, particularly in the temporal areas. There are occasionally some more specific features: patients with LGI1 antibodies have especially frequent epileptiform discharges, often subclinical, and some of the more encephalopathic patients with NMDAR antibodies can have the EEG appearance termed "extreme delta brush." Measurement of brain metabolism with PET or single-photon emission computerized tomography (SPECT) scanning demonstrates abnormalities in the medial temporal lobes. The areas may be either hypermetabolic due to seizure activity or inflammation or may be hypometabolic late in the course, related to neuronal degeneration. Very recently, strong HLA associations have been associated with LGI1 and CASPR2 antibody encephalopathies. Given their robust nature, particularly in the era of personalized medicine, these tests are likely to be part of a clinical work up of these patients.

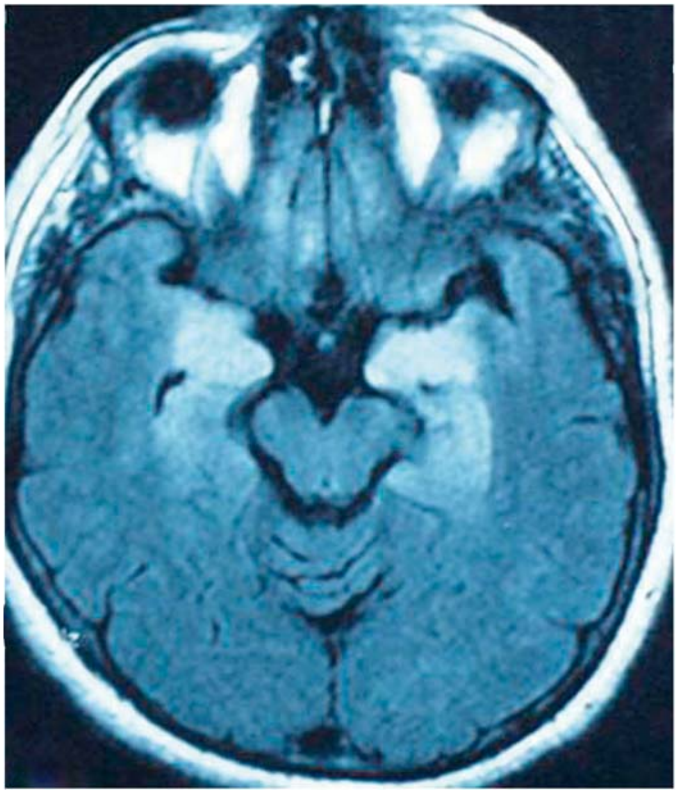

FIGURE 27-1 ■ Axial fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) of a patient with paraneoplastic limbic encephalopathy. There is marked hyperintensity in the medial temporal lobes bilaterally. In addition, there is slight dilatation of the temporal horns, suggesting atrophy.

The most important diagnostic test is measurement of autoantibodies. The commonest antibodies found in paraneoplastic limbic encephalitis are those which target Hu (SCLC), Ma2 (testicular cancer), CRMP5/CV2 (SCLC-thymoma), the NMDAR (ovarian teratoma), and the $GABA_B$ receptor (SCLC). Antibodies found in patients who frequently do not have cancer include antibodies against LGI1, CASPR2, and the $GABA_A$ receptor.

PATHOLOGY

Typical limbic encephalopathy is characterized by the destruction of hippocampal neurons along with inflammatory infiltrates both in the perivascular spaces and in the brain parenchyma. In some patients, particularly those who die many years after the disorder begins, findings are consistent with sclerosis of the hippocampus, without inflammatory infiltrates, particularly in patients with Hodgkin disease. Whether inflammation was present at onset and disappeared over time is unclear. In fact, the literature has examples of a rapid evolution from limbic encephalitis to hippocampal sclerosis; this finding may have implications for a subset of patients with adult-onset medial temporal lobe epilepsy secondary to hippocampal sclerosis.

DIAGNOSIS

Overall, not accounting for nuances of the clinical presentation, two of the most important alternate diagnoses to consider are herpes simplex encephalitis and acute primary psychiatric presentations. Other diagnostic considerations include temporal lobe tumors, systemic lupus erythematosus, Hashimoto encephalopathy, human herpes virus type 6 (especially after bone marrow transplantation), and a variety of metabolic abnormalities causing delirium.

The other important diagnostic consideration is to differentiate paraneoplastic limbic encephalitis from nonparaneoplastic autoimmune limbic encephalitis. As these two disorders are often clinically indistinguishable, almost all patients require at least an initial search for an underlying neoplasm.

TREATMENT

Aside from treatment of the tumor, immunosuppression is the mainstay of therapy, similar to that for other paraneoplastic and autoimmune disorders. The earlier treatment is started, the more likely the illness will either stabilize or improve. Yet, in some of these disorders, particularly those associated with cell surface antibody targets, even late treatment of comatose patients may lead to significant resolution of the neurologic symptoms.

Encephalomyelitis

Paraneoplastic limbic encephalopathy may also occur as part of a more widespread disorder (encephalomyelitis) that is associated with carcinoma. The clinical presentation often includes subacute sensory neuronopathy, cerebellar degeneration, myelopathy, and sometimes peripheral neuropathy or myopathy; these disorders are discussed in other sections of this chapter.

Hypothalamic Dysfunction

Isolated paraneoplastic hypothalamic dysfunction is rare. The disorder usually occurs in conjunction with a more widespread encephalitis. Hypothalamic dysfunction characteristically occurs as a part of the syndrome in patients with Ma2 (Ta) antibodies and testicular cancer, CRMP5 (CV2) encephalomyelitis associated with thymoma, and NMDA receptor antibody encephalitis, associated with ovarian teratoma in around 20 percent of cases. The disorder is sometimes responsive to immunoglobulin therapy, and also occurs in children with neuroblastoma and sometimes in children without known cancer. Symptoms of hypothalamic dysfunction include somnolence, temperature dysregulation with hyperhidrosis, endocrinopathies including diabetes insipidus and hypothyroidism, narcolepsy or somnolence, weight gain, and loss of libido.

Brain MRI may reveal evidence of inflammation in the hypothalamus including contrast enhancement. Treatment consists of discovery and treatment of the underlying tumor as well as immunosuppression. Prognosis is dependent on the underlying clinical/serologic syndrome. For example, patients with testicular cancer and Ma2 antibodies sometimes stabilize and even improve, at least partially, but patients harboring other antibodies, such as Hu antibodies, do less well.

Brainstem or Basal Ganglia Encephalitis

Paraneoplastic brainstem encephalitis, characterized by the subacute development of bulbar, midbrain, or basal ganglia signs, usually occurs as part of the more diffuse syndrome of encephalomyelitis, although it sometimes presents as a dominant or isolated clinical finding. The syndrome usually affects the lower brainstem preferentially, causing diplopia, vertigo, oscillopsia, dysarthria, dysphagia, hypoventilation, hearing loss, facial weakness, myokymia, facial numbness, or opsoclonus in various combinations. When the upper brainstem or basal ganglia are affected, movement disorders including chorea, dystonia, bradykinesia, myoclonus, and parkinsonism may occur along with daytime sleepiness. The disorder has been associated with a number of antibodies including those against Hu (usually with more widespread encephalomyelitis symptoms), Ri (typically with opsoclonus), Ma2 (featuring prominent midbrain and diencephalic dysfunction), and the NMDA receptor (with central respiratory failure and coma). In patients with adult-onset autoimmune chorea, the disorder is paraneoplastic in over one-third; CV2/CRMP5 and Hu are commonly associated antibodies. Although yet to be confirmed by several laboratories, dopamine 2 receptor (D2R) antibodies have been described in children with a basal ganglia encephalitis and also in children with Sydenham chorea.

Cerebellum

Of the paraneoplastic disorders affecting the brain, paraneoplastic cerebellar degeneration is perhaps the most easily recognized and clinically the best described. It is characterized pathologically by loss of cerebellar Purkinje cells and is associated with several different cancers and autoantibodies.

CLINICAL FINDINGS

Paraneoplastic cerebellar degeneration was first described in 1919, but the association between it and cancer was not recognized until 1938. Paraneoplastic cerebellar degeneration can be associated with any malignancy, but the most common culprits include lung cancer (particularly SCLC), ovarian or uterine cancer, and lymphoma, particularly Hodgkin disease. In most patients, neurologic symptoms prompt medical attention before the cancer itself has been identified. The cancer is usually then found within months to a year after the onset of neurologic symptoms; however, occasionally it may elude detection for several years and in some instances is found only at autopsy.

Typically, the disorder begins with dizziness or vertigo, nausea, and vomiting followed rapidly by gait ataxia evolving rapidly over days to a few months to include incoordination in the arms, legs, and trunk; dysarthria is also often present, as is nystagmus associated with oscillopsia. Within a few months, the illness usually reaches its peak and then stabilizes. By this time, most patients cannot walk and many cannot sit unsupported. Handwriting is impossible, independent eating is difficult, and speech may be difficult to understand. Oscillopsia may prevent reading or even watching television. The neurologic signs are always bilateral and usually symmetric, although at times one side may be more affected than the other. In occasional patients, this asymmetry is quite prominent. Diplopia is an early symptom in many patients, although abnormalities of ocular muscles are often not detected by the examiner. Exceptions include those with abrupt onset and patients with a milder course so that the patient can walk, write, and be understood, albeit with some difficulty.

The signs and symptoms are frequently limited to those of cerebellar or cerebellar pathway dysfunction but, in as many as 50 percent of patients, other neurologic abnormalities, usually mild, may be found on careful examination, including sensorineural hearing loss, dysphagia, hyperreflexia with or without extensor plantar responses, extrapyramidal signs, peripheral neuropathy, and cognitive abnormalities including dementia. Studies using formal neuropsychologic testing have challenged the notion of cognitive dysfunction, finding that dementia is not common when testing is controlled for impaired motor and speech production.

LABORATORY EVALUATION

Early in the course of the disease, the brain MRI is usually normal (Fig. 27-2A). However, a reduced NAA/Cr ratio on MR spectroscopy of the cerebellar vermis may occur when routine MRI is normal. If patients are followed for months to a few years, diffuse cerebellar atrophy appears (Fig. 27-2B). Occasional patients have been reported in whom hyperintensity is found in the cerebral and cerebellar white matter on T2-weighted images. Rarely, transient contrast enhancement of the cerebellar folia may suggest leptomeningeal tumor along with associated edema, which may cause hydrocephalus.

In most patients who are studied early in the course of the disease, the CSF contains an increased number

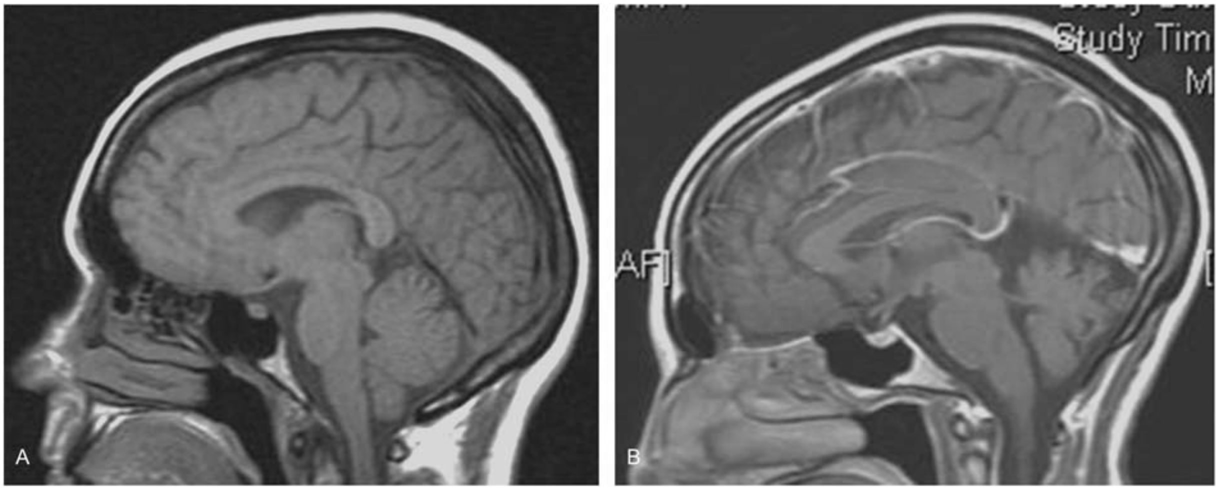

FIGURE 27-2 ■ *A*, Normal sagittal MRI of the brain. *B*, T1 contrast-enhanced sagittal MRI of the brain in a patient with paraneoplastic cerebellar degeneration. The cerebellum is atrophic, but the rest of the brain is normal.

of lymphocytes, slightly elevated protein level, and increased IgG index along with unique oligoclonal bands. The pleocytosis usually resolves with time. Some, but not all, patients with paraneoplastic cerebellar degeneration have autoantibodies in serum and CSF that react with Purkinje cells of the cerebellum and the causal tumor.

The antibody most frequently associated with pure cerebellar degeneration is against Yo (Table 27-5). This antibody recognizes a major protein antigen termed CDR2L, which is expressed in Purkinje cells of the cerebellum and in the patient's tumors. CDR2 was a previously considered antigenic target of these antibodies and may be recognized by the Yo antibodies when expressed in non-native detection systems. Yo antibodies show evidence of intrathecal synthesis from B cells that have crossed into the brain. In addition to the antibody response, cytotoxic T cells against CDR2 have also been described. Patients with breast cancer and Yo-antibody cerebellar degeneration also usually overexpress HER2.

A second autoantibody commonly found in patients with paraneoplastic cerebellar degeneration is the Tr antibody that occurs in patients with paraneoplastic cerebellar degeneration related to Hodgkin disease. The disorder often begins following the diagnosis of Hodgkin disease and sometimes when patients are in remission. The clinical presentation is generally less severe than in patients with Yo antibodies. The prognosis for successful treatment of the underlying tumor is good. Interestingly, and in alignment with this clinical improvement, the antibodies are now known to target the extracellular domain of the delta/notch-like epidermal growth factor-related receptor.

Hu antibodies usually associate with cerebellar degeneration as a part of a more widespread encephalomyelitis syndrome. In some patients, cerebellar symptoms outweigh other symptoms; in other patients, sensory neuronopathy is prominent so that it is difficult to discern the localisation or basis of the ataxia. As with the Yo antibody syndrome, symptoms may be sudden in onset and pathologic examination reveals substantial loss of Purkinje cells. Inflammatory infiltrates in Purkinje cells or the cerebellar dentate nucleus are often found in patients with the Hu antibody, perhaps because patients only survive for a short period of time.

Other less common antibodies include Ma, an antibody that recognizes both Ma1 and Ma2, which are antigens restricted to brain and testis. The paraneoplastic disorder usually is associated with encephalomyelitis, particularly brainstem and hypothalamic dysfunction, and is associated with a variety of tumors including those of breast and colon. The Ri antibody (discussed later in the section on opsoclonus) is also associated with paraneoplastic cerebellar degeneration, usually as part of the opsoclonus-myoclonus syndrome. CRMP5 (CV2) antibodies are directed against an antigen in some oligodendrocytes; the disorder has been associated with a number of neurologic problems including optic neuritis and paraneoplastic cerebellar degeneration. The most common tumor is thymoma, although some patients have SCLC and gynecologic malignancies. P/Q VGCC antibodies associated with LEMS and SCLC are also occasionally

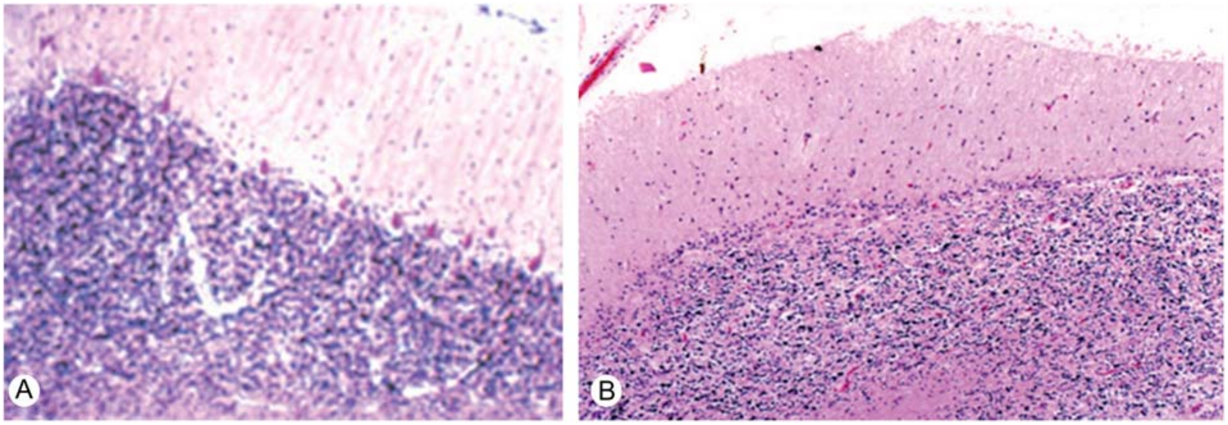

FIGURE 27-3 ■ Paraneoplastic cerebellar degeneration. *A*, Section of cerebellum of a patient who died of cancer without cerebellar symptoms. Multiple Purkinje cells are identified between the molecular *(top)* and granule cell *(bottom)* layers, both of which are normal (hematoxylin–eosin ×25). *B*, Section of cerebellum from a patient with autoantibody-positive paraneoplastic cerebellar degeneration. The molecular and granular cell layers are relatively normal, but Purkinje cells are absent, and there is a slight increase in Bergmann astroglia along with some inflammatory cells in the leptomeninges (hematoxylin–eosin ×25).

associated with paraneoplastic cerebellar degeneration. mGluR1 antibodies have been reported in patients with Hodgkin disease and paraneoplastic cerebellar degeneration. Also, patients have been reported with cerebellar ataxia as part of their CASPR2-antibody associated syndrome. A more recent description of vertigo, ataxia, and diplopia in conjunction with testicular seminomas has been associated with autoantibodies against kelch-like protein 11 (KLHL11). This, alongside CASPR2- and GAD-antibody ataxias, may be treatable forms of autoimmune ataxia. Zic4 antibodies have also been associated with cerebellar degeneration as well as encephalomyelitis in patients with SCLC, as have PCA2 and ANNA-3 antibodies. Other rarer antibodies include CARP VIII antibodies (usually with melanoma), proteasome in association with Yo antibodies (ovary and breast cancers), PKC gamma (NSCLC), Ca (no cancer yet identified), and as yet unnamed antibodies.

PATHOLOGY

In paraneoplastic forms of cerebellar ataxia, the CNS may appear grossly normal when examined at autopsy, but usually the cerebellum is atrophic, with abnormally widened sulci and small gyri. Microscopically, the hallmark of paraneoplastic cerebellar degeneration is severe, often complete, loss of the Purkinje cells of the cerebellar cortex (Fig. 27-3). Degenerating Purkinje cells may have swellings, termed torpedoes, along the course of their axons. Other pathologic features may include thinning of the molecular and granular layers of the cerebellar cortex, often without marked cell loss, and proliferation of astrocytes. The deep cerebellar nuclei are usually well preserved, although rarefied white matter may surround the nuclei, caused by the loss of Purkinje cell axons. Basket cells and tangential fibers are usually intact. Lymphocytic infiltrates, if present, are usually found in the leptomeninges around the cerebellum, in the dentate nucleus, and throughout the surrounding white matter; they are rare in the Purkinje cell layer.

In many patients, the disorder is noninflammatory, with pathologic changes restricted to the Purkinje cell layer of the cerebellum. However, pathologic changes outside the cerebellum do occur in some patients, including degeneration of the dorsal columns and pyramidal tracts of the spinal cord, degeneration of the basal ganglia (specifically the pallidum), loss of peripheral nerve fibers, and inflammatory infiltrates in the brainstem, spinal cord, and cerebral cortex.

The tumors associated with paraneoplastic cerebellar degeneration do not differ histologically from similar tumors unassociated with paraneoplastic symptoms except that the tumors are usually found to be infiltrated with lymphocytes and plasma cells. In many patients, the tumor, when identified, is still localized; metastases, if present, are usually found only in regional lymph nodes.

Diagnosis

The diagnosis depends on recognizing the characteristic clinical syndrome and excluding other cancer-associated causes of late-onset cerebellar dysfunction, such as parenchymal or leptomeningeal metastases, infections, and toxicity of therapies such as cytarabine (see Chapter 28). Causes unrelated to cancer, such as viral brainstem encephalitis or cerebellitis, demyelinating disease, Creutzfeldt–Jakob disease, infarction, hypothyroidism, and alcoholic and hereditary cerebellar degeneration, must also be excluded.

A disorder clinically identical to paraneoplastic cerebellar degeneration may occur without a cancer being identified. How often subacute cerebellar degeneration is nonparaneoplastic is uncertain, but it may be 50 percent or higher. In patients with rapidly developing cerebellar syndromes, the physician should suspect a paraneoplastic disorder, particularly when the CSF contains a lymphocytic pleocytosis. The detection of autoantibodies will identify the neurologic disorder as being paraneoplastic and suggest the likely location of the tumor, although these tumors may be very small and difficult to identify. If evaluation including total-body PET scanning fails to identify a tumor, repeated searches may be necessary. Exploratory laparotomy with salpingo-oophorectomy has been recommended in postmenopausal women with Yo antibodies and whose evaluation, including pelvic scans and mammograms, is negative. This approach has been used in several patients, and in all except one (in whom breast cancer was identified 4 months later) a tumor of the gynecologic tract was found; the tumor is sometimes apparent only microscopically.

Treatment

Reviews addressing the treatment of paraneoplastic cerebellar degeneration are available elsewhere. Overall, treatment is commonly unsuccessful, perhaps in part due to the death of Purkinje cells. The general treatment approach requires identifying and treating the causal tumor and then attempting immunosuppression. Immunosuppressive treatments have included high-dose corticosteroids. If the treatment is partially successful, consideration can be given to courses of intravenous immunoglobulin, cyclophosphamide, tacrolimus, rituximab, and mycophenolate.

Individual case reports indicate that treatment of the tumor and immunosuppression either stabilize or improve paraneoplastic cerebellar degeneration. In general, however, the Hu and Yo antibody patients rarely improve, whereas Tr or CRMP5 antibody disorders may have a better prognosis. Symptomatic improvement in the ataxia occurs in a few patients using clonazepam in daily doses varying from 0.5 to 1.5 mg. Buspirone may also give modest relief.

Opsoclonus-Myoclonus

Opsoclonus consists of involuntary, arrhythmic, multidirectional, conjugate saccades without an intersaccadic interval. Opsoclonus is often associated with diffuse or focal myoclonus as well as truncal titubation, with or without other cerebellar signs. Opsoclonus-myoclonus, also referred to as opsoclonus-myoclonus ataxia syndrome (OMAS), occurs primarily in children as a self-limited illness, probably the result of a viral infection affecting the brainstem. The disorder is paraneoplastic in about 40 percent of children. Although neuroblastoma is the common associated tumor, less than 2 percent of children with neuroblastoma have opsoclonus. However, given the known tendency of neuroblastoma to resolve spontaneously, some patients with OMAS without tumor may, in fact, have had a paraneoplastic form. These children are more likely to suffer from intrathoracic tumors with a benign pathology. Neuroblastoma prognosis is better in patients who have a paraneoplastic syndrome.

The age at peak incidence is 18 months, with more girls than boys affected. Neurologic signs precede identification of the tumor at least 50 percent of the time, making recognition of the neurologic syndrome an important clue to the presence of neuroblastoma. Ataxia, irritability, vomiting, and dementia may accompany opsoclonus-myoclonus.

A number of autoantibodies have been described in neuroblastoma-related OMAS. Affected children have a high incidence of antibodies that react with CNS antigens, but no particular antibody is pathognomonic for the syndrome. An autoantibody that binds the surface of cerebellar granule cells and is cytotoxic to neuroblastoma cell lines has been identified in pediatric patients with opsoclonus-myoclonus, with or without neuroblastoma. Some of the children had other antibodies that also reacted with cerebellar structures, including the Hu antibody. Elevated antibodies against the GluD2 receptor have been reported, as have elevated serum concentrations of Th2-chemokines.

Opsoclonus may respond to treatment with corticotropin (ACTH), plasma exchange, intravenous immunoglobulin, or rituximab and may improve after chemotherapy for the tumor. Multimodal therapy is better than corticotrophin alone. Unfortunately, many patients develop relapses and are left with significant cognitive deficits.

The disorder is less common in adults and is paraneoplastic in 15 to 20 percent of adults. Lung cancer is the most common cause, followed by ovarian teratoma. Neurologic symptoms usually precede the diagnosis of tumor and progress over several weeks, although more rapid or slower progression is observed in some instances. Opsoclonus is often associated with truncal ataxia, dysarthria, myoclonus, vertigo, and encephalopathy; some patients appear to have paraneoplastic cerebellar degeneration as well, and ophthalmoplegia has been reported. A mild CSF pleocytosis and a slightly elevated protein level are present in most patients. The results of neuroimaging are usually normal; in a few patients, an abnormality in the brainstem or cerebellum is detected by MRI. The Ri antibody is the most common associated known serology, typically occurring in women with breast cancer and other gynecologic tumors. This antibody identifies a protein called Nova, an RNA-binding protein that regulates aspects of synaptic proteins, including the glycine and $GABA_A$ receptors in the brainstem. Identifiable antibodies are usually not found in patients with opsoclonus and SCLC or ovarian teratomas.

Nonparaneoplastic causes of opsoclonus-myoclonus include viral infections, parainfectious syndromes, infection with human immunodeficiency virus, and toxic or metabolic encephalopathies. In many instances the cause is unknown. Immunosuppressive agents sometimes appear to be effective, although spontaneous remissions have also been described, making it difficult to interpret positive results. In the paraneoplastic form, the syndrome responds less well to immunotherapy unless the tumor is also treated.

Visual Loss

Paraneoplastic and nonparaneoplastic syndromes can cause visual loss by affecting either the retina or the optic nerve. They can affect photoreceptors (either rods, cones, or both) or can cause a retinal vasculitis. A paraneoplastic visual disorder can occur either as an isolated phenomenon or as part of a more widespread encephalomyelopathy or demyelinating process.

RETINOPATHY

Although all paraneoplastic visual disorders are rare, paraneoplastic retinal degeneration, also called cancer-associated retinopathy, is the most common. The two most common disorders are cancer-associated retinopathy and melanoma-associated retinopathy. The former disorder usually occurs in association with SCLC and gynecologic tumors. Typically, the visual symptoms, which include episodic visual obscurations, night blindness, light-induced glare, photosensitivity, and impaired color vision, precede the diagnosis of cancer. The symptoms progress to painless visual loss and may begin unilaterally before usually becoming bilateral. Visual testing demonstrates peripheral and ring scotomas along with loss of acuity. Fundus examination may reveal arteriolar narrowing and abnormal mottling of the retinal pigment epithelium; the electroretinogram is abnormal. The CSF is typically normal. Inflammatory cells are sometimes seen in the vitreous using slit-lamp examination. Pathologically, a loss of photoreceptors and ganglion cells with inflammatory infiltrates and macrophages is usually found. Other parts of the optic pathway are preserved, although a loss of myelin and lymphocytic infiltration of the optic nerve may occur. The melanoma-associated form is usually less severe, and generally occurs in patients already known to have melanoma; symptoms include night blindness, photopsias, and visual glare.

Several autoantibodies have been identified in patients with cancer-associated retinopathy, the most common of which is recoverin. Recoverin is a 23-kDa protein that modulates dark and light adaptation through calcium-dependent regulation of rhodopsin phosphorylation in photoreceptor cells. Several other autoantibodies may also occur in patients with paraneoplastic visual loss. Treatment of cancer-associated retinopathy is usually unsuccessful, despite immunosuppression and treatment of the cancer. A number of different antibodies have been detected in the serum of patients with melanoma-associated retinopathy and, like cancer-associated retinopathy, treatment is usually not effective.

OPTIC NEURITIS AND NEUROPATHY

Paraneoplastic optic neuropathy occurring in the absence of other neurologic symptoms is extremely uncommon. Patients with optic neuritis (some of whom also have retinitis) may harbor antibodies to collapsin response-mediator protein (CRMP5). These patients present with subacute visual loss; optic discs are swollen and visual field defects are typically present. Patients have a variety of other neurologic symptoms including cognitive changes, chorea, ataxia, sensory neuropathy, and myelopathy. The most common associated cancer is SCLC.

Far more commonly, outside of the context of multiple sclerosis, acute optic neuritis is a nonparaneoplastic phenomenon associated with antibodies against the extracellular domain of the astrocyte endfoot protein, AQP4.[13] Typically, patients with AQP4 antibodies present with severe and painful visual loss. Also, AQP4 antibodies often associate with other clinical features including a longitudinally extensive transverse myelitis (LETM) and an area postrema syndrome with hiccups and vomiting. The longitudinal and typically edematous imaging features are characteristic and are observed in both the optic nerve and the spinal cord. The natural history of these AQP4 antibody-mediated neuromyelitis optica spectrum-disorders (NMOSD) is a tendency to relapses which are the major cause of disability. The condition can affect a variety of ages, with a female preponderance. NMOSD is rarely a paraneoplastic condition.

In the acute phase, treatment with corticosteroids and plasma exchange are considered effective. For relapse prevention, there are data to support all of corticosteroids, azathioprine, mycophenolate mofetil, anti-CD20, and anti-CD19 drugs. In addition, and consistent with the complement fixing-dominant IgG1 subclass of AQP4 reactive autoantibodies, a C5 esterase inhibitor has shown efficacy in relapse reduction. Live cell-based assays, utilizing HEK cells which transiently express AQP4 are considered the gold standard for diagnosis.

Spinal Cord Syndromes

Paraneoplastic and nonparaneoplastic disorders may affect the spinal cord, either in isolation or as part of a more widespread encephalomyelitis. The below section will focus on disorders other than NMOSD.

MYELITIS

Paraneoplastic non-necrotizing myelitis occurs rarely as an isolated syndrome, and more commonly as a part of diffuse encephalomyelitis. Patients present with progressive weakness, sometimes with lower motor neuron signs including fasciculations, in association with sensory loss and autonomic dysfunction (e.g., incontinence and postural hypotension). The disorder may rarely be episodic or primarily involve posterior column function. Upper extremity findings often predominate owing to cervical cord involvement, and respiratory failure may occur. The differential diagnosis includes compressive or intrinsic spinal cord masses, other inflammatory or infectious myelopathies, and radiation injury. The CSF is typically inflammatory. Neuroimaging usually shows a normal spinal cord but, occasionally, expansion or hyperintensity of the spinal cord can be identified on T2-weighted MRI; rarely, contrast enhancement is present. No treatment is effective.

Pathologically, an intense inflammatory reaction with neuronal loss in the anterior and posterior horns is seen, with secondary nerve root degeneration and neurogenic muscle atrophy. Inflammation and degeneration of white matter tracts also can occur. A number of antibodies have been reported, including those which target CV2/CRMP5, amphiphysin, Hu, and Ri.

Subacute necrotizing myelopathy is a rare syndrome that occurs with lymphoma, leukemia, or most commonly lung cancers. Patients typically present with rapidly ascending flaccid paraplegia; back pain or radicular pain may herald the onset of neurologic dysfunction. The disease may ascend in the spinal cord, leading to respiratory failure. Inflammatory cells are usually present in the CSF. The MRI may be normal or show spinal cord swelling or contrast enhancement. The absence of an epidural mass or discrete intramedullary enhancement rules out metastatic myelopathy, which is much more common. Treatment is usually unsuccessful, although some patients respond to immunosuppression including corticosteroids. Pathologically, there is widespread necrosis involving all components of the spinal cord, but with some white matter predominance. Inflammatory infiltrates are not typical.

Motor neuron disease-like presentations may occasionally occur as a paraneoplastic syndrome. This can resemble amyotrophic lateral sclerosis with both upper and lower motor neuron dysfunction, or it may present as a progressive muscular atrophy mimic, with a pure lower motor neuron syndrome that is sometimes reversible and is associated with lymphoproliferative disorders. Subacute, nonreversible lower motor neuron syndromes have been reported in patients with Hu antibodies and SCLC. Primary lateral sclerosis, a pure upper motor neuron syndrome, is associated with solid tumors as well as with lymphoproliferative disorders. The clinical and pathologic characteristics differ little from nonparaneoplastic motor neuron disease except that the paraneoplastic disorders are often more rapid in onset and evolution, sometimes reverse spontaneously, and, at autopsy, may have more inflammatory cells than the nonparaneoplastic forms.

More recently, a group of patients with very similar optic nerve and spinal cord characteristics to NMOSD are recognized in association with antibodies to MOG. These patients are often younger than those with AQP4 antibodies, may have an associated encephalopathy, and around 50 percent have a monophasic disease course. However, relapsing disease is well recognized and necessitates individualized decisions about treatment duration. MOG antibodies are also only rarely a paraneoplastic association. In a manner akin to AQP4 antibody detection, and consistent with the concept of preferential native autoantigen targeting, MOG antibodies are most accurately detected with live cell-based assays.

STIFF-PERSON SYNDROME

Originally called the stiff-man syndrome, although it affects more women than men, this disorder is characterized by muscle stiffness and rigidity that are usually painful. The muscles involved almost always include the paraspinal and abdominal muscles and usually those of the lower extremities. In some instances, the illness is restricted to a single extremity ("stiff limb" syndrome). Sustained muscle contraction results in abnormal postures, such as an exaggerated lumbar lordosis. In addition to the chronic contractions, severe episodic muscle spasms may be precipitated by voluntary movements, unexpected environmental stimuli, and emotional upset. The arms are less commonly involved, and although stiffness of the neck and face can occur, it is rarely severe. On examination, the muscles feel hard and may be difficult to move passively. An unexpected external stimulus or a voluntary movement may precipitate an observable spasm. The electromyogram (EMG) is characterized by sustained continuous motor-unit activity that disappears during sleep and general anesthesia.

The nonparaneoplastic form of the disorder is associated with type 1 diabetes and antibodies to GAD. The paraneoplastic disorder is associated with antibodies against amphiphysin, GAD, Ri, and gephyrin. The common associated tumors include breast cancer, SCLC, Hodgkin disease, and colon cancer. More recently, the extracellular domain of the glycine α-1 subunit receptor has been shown to be a target of antibodies which associate with stiff person syndromes, especially the progressive encephalomyelitis with rigidity and myoclonus subtype.[14] Although injection of either GAD65 or amphiphysin antibodies into animals reproduces aspects of the clinical syndrome, the glycine receptor surface targeting antibodies are intuitively more likely to be causative than antibodies to the several intracellular targets.

Benzodiazepines and baclofen may relieve symptoms. Treatment of the tumor and immunosuppression with corticosteroids, intravenous immunoglobulin, or repeated plasmapheresis are sometimes effective.

Peripheral Nerve and Dorsal Root Ganglion Syndromes

Virtually any of the abnormalities that can affect the peripheral nervous system of patients without cancer can also occur as a paraneoplastic syndrome, including subacute sensory neuronopathy (dorsal root ganglionitis), sensory peripheral neuropathy, sensorimotor peripheral neuropathy (either axonal or demyelinating), autonomic neuropathy, paraproteinemic neuropathy, vasculitic neuropathy (presenting as mononeuritis multiplex), and a pure motor neuropathy or neuronopathy. The exact incidence of these disorders is not established. In tertiary centers seeing undiagnosed neuropathy patients, the incidence of paraneoplastic neuropathy is less than 10 percent.

Subacute sensory neuronopathy is the most common type of paraneoplastic peripheral neuropathy and is usually associated with SCLC. Symptoms typically begin before the cancer is identified with dysesthetic pain and numbness in the distal extremities or occasionally in the face or trunk. The symptoms may be asymmetric at onset, but progress over days to several weeks to involve all limbs, causing a severe sensory ataxia. All sensory modalities are affected, distinguishing this disorder from cisplatin neuropathy, in which pinprick and temperature sensation are typically spared. Pain is occasionally a prominent symptom. Muscle stretch reflexes are usually lost, but motor function is preserved. The CSF typically contains a mild lymphocytic pleocytosis, particularly when the sensory changes are associated with encephalomyelitis. On nerve conduction studies, sensory nerve action potentials are diminished or absent, and compound muscle action potentials are normal; EMG evidence of denervation is absent.

Pathologic changes may be limited to the dorsal root ganglia, with neuronal loss and lymphocytic inflammatory infiltrates (Fig. 27-4). Secondary changes seen on sural nerve biopsy are usually characterized by a substantial reduction in myelinated fiber density with a

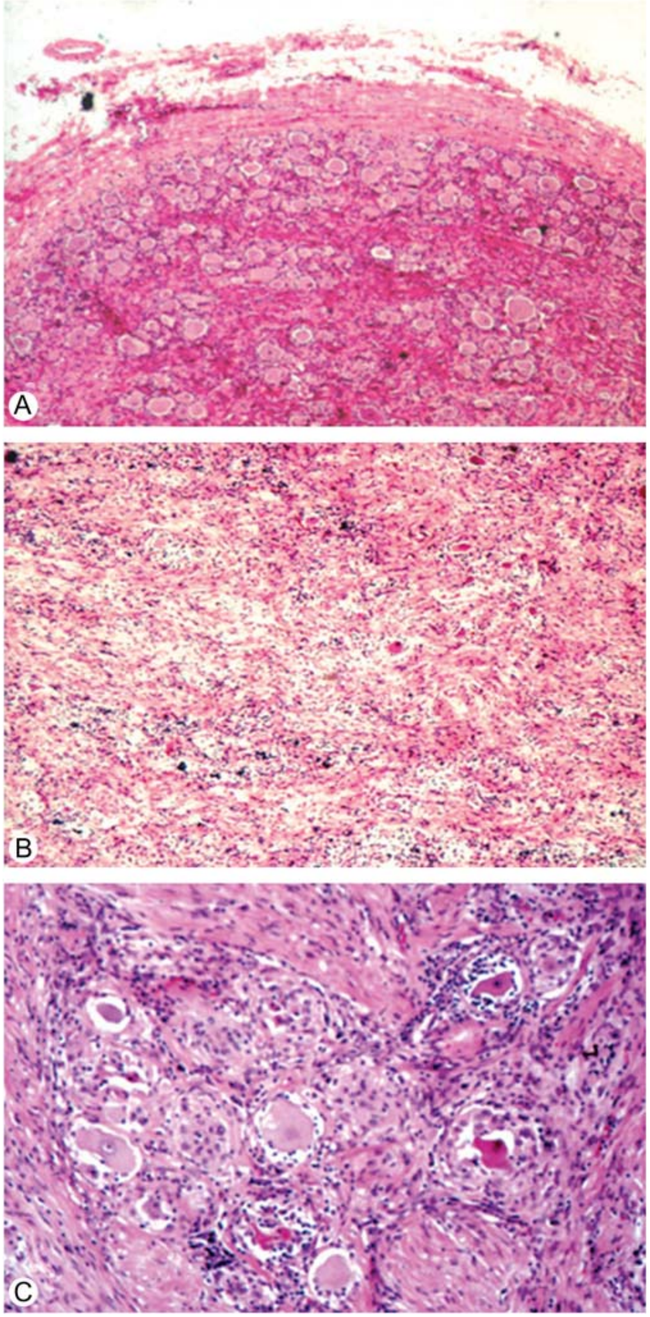

FIGURE 27-4 ■ Paraneoplastic sensory neuronopathy. *A*, Dorsal root ganglion obtained at autopsy from a patient without neurologic disease. *B*, Dorsal root ganglion obtained from a patient with paraneoplastic sensory neuronopathy and anti-Hu antibodies. Note that there are virtually no normal dorsal root ganglion neurons in the entire section. A few scattered inflammatory infiltrates are present (hematoxylin–eosin ×40). *C*, The dorsal root ganglion of another patient with Hu-antibody related subacute sensory neuronopathy. Degenerating neurons can be seen surrounded by inflammatory cells (hematoxylin–eosin ×40).

lesser reduction in small fibers; however, in those patients with severe painful neuropathy, small fibers are reduced more than myelinated fibers. In about 50 percent of patients, clinically inapparent pathologic changes are found in other regions of the nervous system. Treatment of the underlying tumor and removal of the autoantibody by plasmapheresis or immunosuppressive therapy may stabilize or sometimes improve symptoms, particularly when given early. Occasional patients have a mild and indolent sensory neuropathy.

Sensory neuronopathy can occur in previously healthy individuals or in those with a variety of underlying autoimmune conditions, including Sjögren syndrome. It can also be caused by heavy metal intoxication, including the platinum analogue chemotherapeutic agents. The disorder is paraneoplastic in only a minority of patients. At least two-thirds of patients with paraneoplastic sensory neuronopathy have SCLC as the cause. Criteria for distinguishing subacute sensory neuronopathy from other sensory neuropathies include the early development of sensory ataxia, an asymmetric distribution of sensory loss, sensory loss occurring in a nonlength-dependent manner beyond the distal lower extremities, and relatively normal motor but abnormal sensory conduction studies. Criteria for separating paraneoplastic subacute sensory neuropathy from other causes include an acute or subacute onset in four limbs, early pain, and its occurrence in men more than 60 years old. The presence of Hu antibodies is useful to confirm the paraneoplastic etiology, having a specificity of 99 percent and sensitivity of 82 percent. The more recently described antibodies against fibroblast growth factor receptor 3 may also be found in a few patients.

Subacute sensorimotor neuropathy is predominantly a distal symmetric polyneuropathy that is more marked in the lower than upper extremities and is characterized by weakness, stocking-and-glove sensory impairment to all modalities, and a loss of muscle stretch reflexes. Bulbar involvement is uncommon. Patients with mild sensory or sensorimotor neuropathy that evolve slowly over many months to years are unlikely to have carcinoma as the underlying cause. By contrast, patients with a subacute onset of a severe peripheral neuropathy leading to substantial paralysis and sensory loss are much more likely to have a paraneoplastic syndrome. A few patients with paraneoplastic sensorimotor neuropathy follow the remitting and relapsing course typical of chronic inflammatory demyelinating polyneuropathy; these patients may respond to corticosteroid therapy. Guillain–Barré syndrome, acute brachial neuritis, cauda equina syndrome, and dysfunction of individual nerves are occasionally paraneoplastic.

In most paraneoplastic sensorimotor neuropathies, the CSF is typically acellular with a normal or slightly elevated protein concentration. Nerve conduction studies are consistent with an axonal neuropathy, with low-amplitude or absent sensory nerve action potentials and normal or decreased motor nerve conduction velocities. A few patients have marked slowing of motor conduction velocities consistent with a demyelinating process. Pathologically, there is usually axonal degeneration; in a few patients, demyelination is prominent.

A relatively pure *paraneoplastic sensory neuropathy* (not neuronopathy) occurs with a variety of malignancies, but cannot be distinguished from other causes of sensory neuropathy. When no cause of a sensory neuropathy is identified, cancer is subsequently found as the etiology in approximately one-third of patients. The mean time to cancer diagnosis following the neurologic disorder is more than 2 years.

A more recent set of autoantibodies directed against molecules which are critical to the function of the paranode and node of Ranvier have been described, and termed the "nodo-paranodopathies."[15] Robustly identified antigens include neurofascin 186/155, Caspr1, and contactin-1, but their association with specific tumors is limited. Each antigen appears to associate with some recognizable, but not highly specific, clinical features. For example, patients with neurofascin 155 antibodies have a young age of onset, motor predominance, ataxia, and tremor, sometimes with additional CNS involvement. Contactin-1 antibodies are often detected in patients with an aggressive onset and/or motor predominance, and Caspr1 antibodies often are seen in patients with rapidly progressive neuropathies, sometimes with neuropathic pain. Many of these patients show a clear response to immunotherapies, and some of the autoantibodies already have demonstrated pathogenic characteristics.

Peripheral neuropathy due to microvasculitis is rare as a paraneoplastic syndrome and is found without obvious antibody involvement in patients with a variety of cancers. Vasculitic neuropathy can present either as a diffuse polyneuropathy or as mononeuritis multiplex. It can involve both peripheral and cranial nerves. The importance of making a diagnosis, which may require nerve biopsy, is that the condition may respond to corticosteroid treatment.

Peripheral neuropathy may be associated with multiple myeloma and Waldenström macroglobulinemia. With the rare osteosclerotic form of myeloma, peripheral neuropathy is present in about 50 percent of patients. Successful treatment of the myeloma often leads to amelioration of the neurologic symptoms. Amyloidosis associated with myeloma can also cause a peripheral neuropathy that responds poorly to treatment. Options for therapy include both tumor treatment and immunosuppression. Rituximab is effective in treating some neuropathies associated with IgM antibodies (Fig. 27-5).

AUTONOMIC NEUROPATHY

Paraneoplastic autonomic neuropathy is a rare syndrome that occurs alone or along with a sensory neuronopathy. Usually associated with SCLC, it may occur with other cancers and may present before or after the cancer is diagnosed. Patients present with the subacute onset of postural hypotension, pupillary abnormalities, a neurogenic bladder, or some combination of these signs. Severe constipation may be the only symptom of this paraneoplastic disorder. The syndrome is generally progressive but may stabilize or improve with treatment of the underlying tumor. When autonomic neuropathy occurs with lung cancer, it is usually part of the Hu antibody syndrome. Autonomic neuropathy also occurs with an antibody against the ganglionic acetylcholine receptor (nAChR), often without an underlying tumor. Immunization with the protein produces an autonomic neuropathy, as does passive transfer of antibodies, indicating a B cell-mediated disease. Immunosuppression including agents such as plasma exchange, rituximab, and cyclophosphamide can prove effective.

NEUROMUSCULAR JUNCTION SYNDROMES

Paraneoplastic disorders of the neuromuscular junction include LEMS and myasthenia gravis. These disorders have a common underlying mechanism in that they are caused by antibodies against ion channels and, whether paraneoplastic or not, they often respond to immunologic treatment.

LEMS is characterized by progressive proximal weakness and fatigability, but, unlike myasthenia gravis, oculobulbar symptoms are usually not severe.

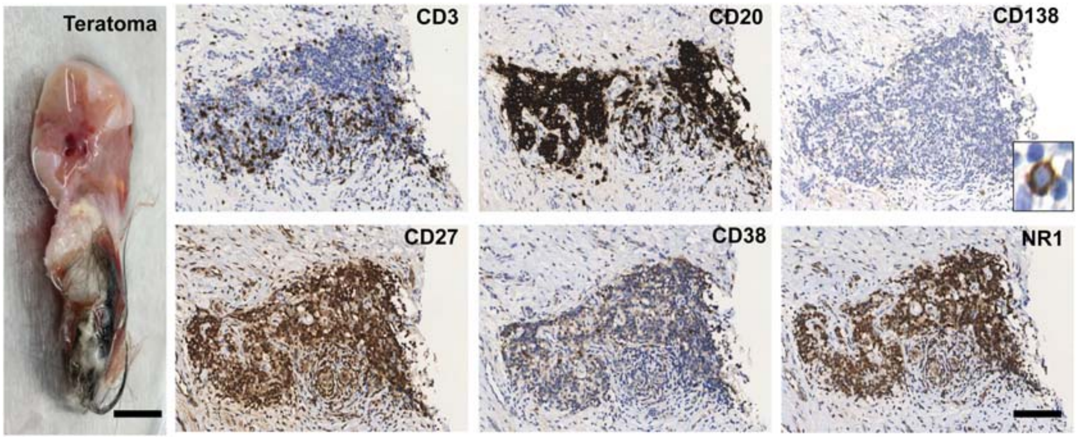

FIGURE 27-5 ■ The germinal centers in ovarian teratomas (scale bar in far left panel, 0.2 cm) of patients with NMDAR-antibodies. T cells (CD3) oppose B cells (CD20) with some plasma cells (CD138) around the rim of the lymphoid aggregates. Additional lymphocyte markers include CD27 and CD38. The dominant antigen of the patient's autoantibodies, the NR1 subunit of the *N*-methyl-D-aspartate receptor, is densely expressed in the tumor (scale bar in far right panel, 100 μm). (From Makuch M, et al: *N*-methyl-D-aspartate receptor antibody production from germinal center reactions: therapeutic implications. Ann Neurol 83:553, 2018, with permission.)

Respiratory weakness may occur. Power initially increases with effort, so that reported weakness may seem out of proportion to the examiner's findings; however, with continued effort, weakness returns. Muscle stretch reflexes, especially those in the legs, are diminished or absent but may reappear after exercise. Cholinergic dysautonomia occurs in more than 50 percent of patients, causing dry mouth and impotence. Characteristic abnormalities are found on electrophysiologic testing, including very small compound muscle action potentials that may increase to normal after brief exercise. Repetitive stimulation causes a decrement of the compound muscle action potentials at low rates of stimulation and an increment at high rates of stimulation. About 60 percent of patients with LEMS have SCLC; a few have other cancers. Some of the 40 percent who do not have cancer may have evidence of other autoimmune diseases.

The disorder results from reduced release of ACh at presynaptic nerve terminals. Antibodies that react with the P/Q-type VGCC are found in patients with or without paraneoplastic syndromes. The same P/Q-type VGCC antibodies are found in SCLC; the richest source of these channels is the cerebellum, perhaps explaining the occasional relationship of paraneoplastic cerebellar degeneration and LEMS.

LEMS is a classic autoimmune disease in that binding of circulating IgG antibodies to the VGCC reproduces the electrophysiologic abnormalities in animals; removal of IgG antibodies from humans with the disorder improves neurologic function. Accordingly, LEMS can be treated either by immunosuppression or by treatment of the underlying cancer when present. 3,4-Diaminopyridine (3,4-DAP) may improve the muscle weakness but can be difficult to obtain. Patients with SCLC-associated LEMS have a better prognosis than patients with SCLC who do not develop a paraneoplastic disorder. SOX1 antibodies are reported in 64 percent of patients with paraneoplastic LEMS but are not found in nonparaneoplastic LEMS.

Myasthenia gravis usually affects ocular, bulbar, and respiratory muscles, often sparing the extremities. In contrast to LEMS, patients grow weaker with exercise and improve with rest; repetitive stimulation decreases the compound muscle action potentials on EMG. Myasthenia gravis is usually not associated with cancer, but about 15 percent of patients have thymoma. The disorder is caused by antibodies against the ACh receptor at the neuromuscular junction. Patients with thymoma-associated myasthenia are more likely to also have other antibodies against muscle proteins such as ryanodine receptors. Myasthenia gravis usually responds to immunosuppression, acetylcholinesterase inhibitors, and thymectomy. Thymectomy is also proven to be beneficial in patients with nonthymomatous myasthenia gravis. Patients with myasthenia gravis can also have antibodies against another protein expressed at the neuromuscular junction, muscle-specific kinase (MuSK). MuSK antibody patients have some unique associated features including prominent bulbar involvement, early tongue atrophy and, importantly, a good response to rituximab.

PERIPHERAL NERVE HYPEREXCITABILITY (NEUROMYOTONIA)

Several disorders characterized by hyperexcitability at the terminal arborizations of peripheral nerves occur in patients with paraneoplastic syndromes, including neuromyotonia, the cramp-fasciculation syndrome, and Morvan syndrome.

Neuromyotonia occurs when single motor unit potentials fire spontaneously at 150 to 300 Hz, leading to chronic contraction of muscles that can be either focal or generalized. In its mildest form it is called myokymia (repetitive and recurrent firing of a motor unit potential at 2 to 60 Hz), clinically visible as undulating muscle twitching. The disorder is sometimes associated with neuropathic pain and autonomic dysfunction, especially hyperhidrosis. Patients may also demonstrate pseudomyotonia (failure of muscles to relax after contraction) and intestinal pseudo-obstruction. Some patients develop CNS symptoms of memory loss, hallucinations, insomnia, and changes in mood (Morvan syndrome). When these disorders are paraneoplastic, in around 50 percent of Morvan cases and 10 to 20 percent of isolated neuromyotonia cases, thymoma is the most common cause, but SCLC and Hodgkin disease have also been reported. There are several other underlying causes, including nerve damage associated with radiation therapy, snake bites, ion channel mutations, and inherited neuropathies. However, the disorder is often autoimmune and associated with antibodies against CASPR2, and, sometimes, against LGI1 or contactin-2.

The serum creatine kinase level is elevated in about one-half of patients. The diagnosis can be made electrophysiologically when needle EMG reveals spontaneous firing of single or multiple motor units at a rate of 150 to 300 Hz. These units fire at irregular intervals and may persist during sleep, general anesthesia, and even when peripheral nerves are blocked at proximal sites. Symptoms are relieved by blocking the neuromuscular junction, suggesting that the action potentials arise from terminal arborizations of the motor nerve.

CASPR2 and LGI1/contactin-2 antibodies have been shown to bind to neurons in areas of brain likely to cause the CNS symptoms. The definitive treatment is immunosuppression with corticosteroids, plasma exchange, or intravenous immunoglobulin. Many patients with mild forms of neuromyotonia respond to sodium channel blockers such as lamotrigine and phenytoin.

Muscle Syndromes

Polymyositis and dermatomyositis are common inflammatory autoimmune muscle diseases. Only a minority of patients suffering from these disorders have an underlying malignancy as the cause, particularly in older patients. Dermatomyositis with typical cutaneous changes is more likely than polymyositis to be paraneoplastic. Females and males are affected in approximately equal numbers. Symptoms of muscle weakness generally precede identification of the cancer, which may be at any site; breast, lung, ovarian, and gastric malignancies are the most common. Hodgkin disease and prostate and colon cancer have also been reported.

The clinical and laboratory findings in dermatomyositis and polymyositis associated with malignancy resemble those in the idiopathic disease, although cancer patients often have more striking abnormalities on muscle biopsy specimens. Patients characteristically present with proximal muscle weakness, elevated levels of serum creatine kinase, and EMG evidence suggesting a myopathic process. A muscle biopsy specimen showing an inflammatory myopathy confirms the diagnosis. Although laboratory findings do not distinguish paraneoplastic from nonparaneoplastic forms, the presence of the p155 antibody is more common in patients with cancer, whereas antisynthetase antibodies suggest an etiology not related to cancer. In fact, a range of autoantibodies has been described in various forms of myositis, perhaps most notably against HMG CoA reductase, the target of statin medications. Normal serum creatine kinase levels are occasionally found even in patients with profound muscle weakness, with or without malignancy; abnormal levels indicate a poor prognosis for the muscle disease. Weakness of respiratory and pharyngeal muscles may be life-threatening. The prognosis is not as good for the paraneoplastic disorder as it is for nonparaneoplastic forms. Corticosteroids, cyclosporine, and other immunosuppressants have been used successfully. High-dose intravenous immunoglobulin therapy is sometimes helpful in patients unresponsive to other forms of immunosuppression.

A necrotizing myopathy, with or without marked inflammation, has also been reported in patients with cancer, as has inclusion-body myositis. The necrotizing myopathy has been reported to respond to intravenous immunoglobulin, sometimes in spite of tumor progression. Corticosteroids, cyclosporine, and other immunosuppressants have also been used successfully.

    Vascular Abnormalities

Chemotherapy and radiation therapy (RT) are two of the major modalities used to treat cancer. Their goal is to kill or inactivate enough cancer cells that the body's own defenses can control the disease without unacceptable damage to normal tissue. Unfortunately, both RT and chemotherapy are relatively nonspecific and depend on their ability to do more damage to rapidly dividing cancer cells. The therapeutic/toxic ratio is often low; even in highly sensitive tumors such as acute lymphoblastic leukemia, Hodgkin disease, and germ cell tumors, for which the cure rate is high, many patients suffer serious side effects of therapy, either immediately or months to years later.

The nervous system may be expected to be relatively insensitive to the side effects of cancer therapy. It is protected from exposure to many chemotherapeutic agents by the blood–brain, blood–cerebrospinal fluid (CSF), and blood–nerve barriers. Furthermore, most neurons do not reproduce, and glia reproduce only slowly, thus affording protection against agents that are directed against dividing cells. Nevertheless, nervous system toxicity is common, second only to myelosuppression as a reason for limiting the dose of chemotherapy, and often is dose limiting for RT as well. Some newer therapies, especially targeted therapies (i.e., *ALK* inhibitors) are specifically designed to penetrate the central nervous system (CNS) to treat brain metastases; these agents could carry a greater risk of causing neurotoxicity. The purpose of this chapter is to describe the side effects of these therapeutic modalities on the central and peripheral nervous systems (PNS). The emphasis is on chemotherapeutic agents and radiotherapeutic approaches that are used widely in clinical practice, with particular attention to newer agents and especially the novel immunotherapies that have rapidly transformed the oncology landscape.

CHEMOTHERAPY

Table 28-1 classifies the major chemotherapeutic agents that have been reported to cause central nervous system (CNS) or PNS toxicity. Table 28-2 lists the neurotoxic signs caused by agents commonly used in cancer patients.[1]

TABLE 28-2 ■ Neurotoxic Signs Caused by Agents Commonly Used in Cancer Patients

Acute Encephalopathy (Delirium)	5-Azacytidine, 5-fluorouracil, asparaginase, bevacizumab, capecitabine, CAR T cells, carmustine, checkpoint inhibitors, cisplatin, cladribine, corticosteroids, cyclophosphamide, cyclosporin A, cytarabine, dacarbazine, docetaxel, etoposide (HD), fludarabine, gemcitabine, hydroxyurea, ifosfamide, imatinib, interferons, interleukins 1 and 2, methotrexate (HD, IV, IT), nelarabine, nitrosoureas (HD or arterial), paclitaxel, pentostatin, procarbazine, tacrolimus, tamoxifen, thalidomide, thiotepa (HD), tipifarnib, vincristine
Seizures	5-Fluorouracil, amifostine, asparaginase, bevacizumab, busulfan (HD), CAR T -cells, carmustine, cisplatin, corticosteroids, cyclophosphamide (HD), cyclosporin A, cytarabine, dacarbazine, docetaxel, erythropoietin, etanercept, etoposide (HD), fludarabine (HD), gemcitabine, hydroxyurea, ifosfamide, interferon, interleukin-2, letrozole, leuprolide, methotrexate, nelarabine, octreotide, paclitaxel, pentostatin (HD), temozolomide, teniposide, thalidomide, topotecan (IT), vincristine
Headaches Without Meningitis	5-Fluorouracil, anastrozole, asparaginase, CAR T cells, carmustine, capecitabine, cetuximab, cisplatin, cladribine, corticosteroids, cytarabine, erlotinib, estramustine, etoposide, fludarabine, gefitinib, gemtuzamab, hydroxyurea, ibritumomab, imatinib, interferons, interleukins, isotretinoin, ixabepilone, letrozole, leuprolide, methotrexate, nelarabine, panitumumab, procarbazine, retinoic acid, rituximab (IV and IT), sorafenib, sunitinib, tamoxifen, temozolomide, thalidomide, thiotepa, topotecan, traztusumab, vemurafenib, vincristine
Visual Loss	5-Fluorouracil, bevacizumab, carboplatin, carmustine, cisplatin, cytarabine, etanercept, etoposide, fludarabine, interferon, interleukin, ipilimumab, isotretinoin, methotrexate, nitrosoureas (IA), oxaliplatin, paclitaxel, pentostatin, tamoxifen, vincristine
Chronic Encephalopathy (Dementia)	5-Fluorouracil, carmofur, carmustine, cisplatin, cytarabine, dacarbazine, fludarabine, ifosfamide, interferon-alpha, methotrexate, rituximab (IT), topotecan (IT)
Peripheral Neuropathy	5-Azacitidine, 5-fluorouracil, bortezomib, cabazitaxel, capecitabine, carboplatin, carfilzomib, checkpoint inhibitors, cisplatin, cladribine, cytarabine, docetaxel, etoposide, fludarabine, gemcitabine, ifosfamide, interferon, ipilimumab, ixabepilone, lenalidomide, nab-paclitaxel, nelarabine, oxaliplatin, paclitaxel, pemetrexed, pentostatin, procarbazine, sorafenib, sunitinib, teniposide, thalidomide, tipifarnib, vinca alkaloids
Cerebellar Dysfunction (Ataxia)	5-Fluorouracil, cyclosporin A, cytarabine, nelarabine, procarbazine, vinblastine, vincristine
Myelopathy (Intrathecal Drugs)	Cytarabine, methotrexate, thiotepa
Aseptic Meningitis	Checkpoint inhibitors, cytarabine (IT), IVIg, methotrexate (IT), monoclonal antibodies, rituximab (IT), thiotepa (IT), topotecan (IT)

Ara-C, Cytosine arabinoside or cytarabine; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; HD, high-dose; IT, intrathecal; IV, intravenous; IVIg, intravenous γ-globulin; NSAIDs, nonsteroidal anti-inflammatory drugs; OKT-3, orthoclone; TNF, tumor necrosis factor.

Antimetabolites

FLUDARABINE

Fludarabine (2-fluoroadenosine arabinoside) is active against a variety of lymphoproliferative neoplasms. It is highly immunosuppressive and has been associated with the development of progressive multifocal leukoencephalopathy (PML) in some patients. In addition, fludarabine can cause delayed neurotoxicity leading to a severe encephalopathy and occasionally cortical blindness. Older patients and those receiving higher doses of the drug are at greater risk.

METHOTREXATE

Methotrexate causes both acute and delayed neurotoxicity. The side effects associated with intrathecal administration are listed in the section on Intrathecal Chemotherapy.

A stroke-like syndrome affecting adults or children occasionally follows systemic high-dose methotrexate infusion. The disorder usually follows the second or third treatment by 5 or 6 days and is characterized by alternating hemiparesis associated with aphasia and sometimes encephalopathy or coma. Unequivocal seizure activity is rare, and the electroencephalogram

(EEG) typically is slow. Magnetic resonance imaging (MRI) displays foci of hyperintensity on fluid-attenuated inversion recovery (FLAIR) sequences and diffusion-weighted imaging displays well-delineated hyperintense areas affecting the deep white matter but not conforming to a vascular territory. Apparent diffusion coefficient (ADC) maps demonstrate decreased signal intensity in a corresponding distribution, suggesting restricted diffusion, similar to an acute vascular event. Patients generally recover spontaneously in 48 to 72 hours with complete or partial resolution of the imaging abnormalities. Recurrences are rare with subsequent treatments. The pathogenesis is unknown.

Leukoencephalopathy may appear months to years following therapy, beginning insidiously or abruptly with personality changes and learning disability. The disorder generally follows repeated doses of intravenous high-dose methotrexate or intrathecal methotrexate, but it may occur after standard doses as well. Although the syndrome can be caused by methotrexate alone, it is enhanced by brain RT and the combination of systemic and intrathecal drug. The sequence of modalities is probably also important. When methotrexate is administered concurrently with or follows cranial RT, the synergy is particularly toxic. The clinical course varies. Patients may recover slowly over weeks or months, their symptoms may stabilize with a mild to moderate dementia, or relentless progression may occur, with spastic hemiparesis or quadriparesis, severe dementia, and coma, ending in death. Seizures can occur, usually late in the course. The MRI reveals cerebral atrophy, bilateral and diffuse periventricular white matter hyperintensity on T2-weighted or FLAIR sequences (Fig. 28-1), ventricular dilatation, and, sometimes, cortical calcifications. Similar findings may occasionally be seen in asymptomatic patients who have received methotrexate. Focal enhancement may be present in the early stages, but does not persist. Neurologic signs are usually preceded by radiographic white matter changes on MRI, and identical radiographic findings may be seen in patients years after prophylactic treatment with intrathecal or intravenous methotrexate, even in the absence of RT. No effective treatment exists.

Cytarabine (Cytosine Arabinoside)

Intravenous high-dose cytarabine (ara-C; 3 g/m^2 per 12 hours for 8 to 12 doses) may cause central or peripheral neurologic disorders. Cerebellar dysfunction occurs most frequently in older patients and in those with pre-existing renal dysfunction, usually at a cumulative dose ≥ 36 g/m^2; however, it has been reported after a single dose of 3 g/m^2. Patients develop dysarthria, nystagmus, and appendicular and gait ataxia. Confusion, lethargy, and somnolence may also occur. With cessation of the drug, complete resolution of symptoms and signs generally occurs within 2 weeks, but some have persistent deficits.

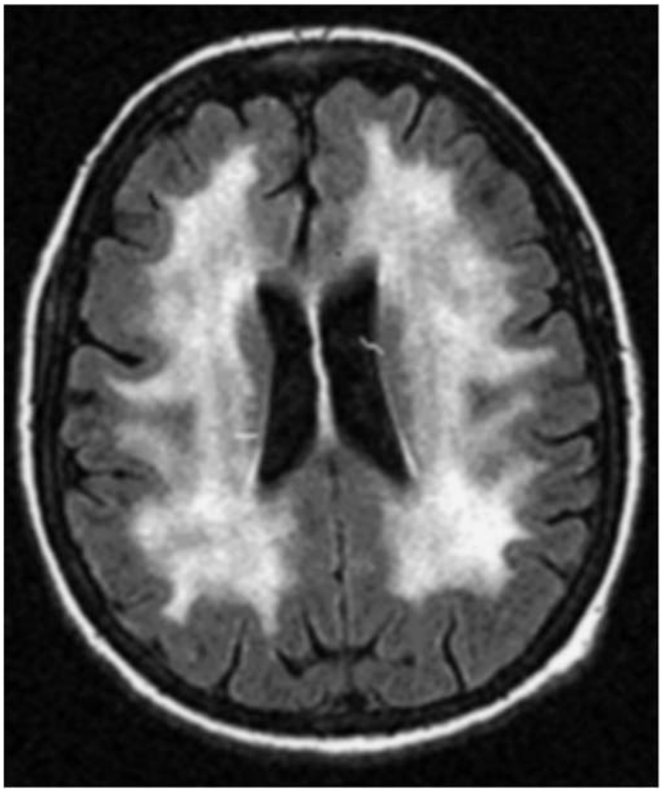

FIGURE 28-1 ■ Treatment-induced leukoencephalopathy. Fluid-attenuated inversion recovery magnetic resonance imaging of the brain demonstrates diffuse periventricular white matter hyperintensity following treatment with methotrexate and whole-brain radiotherapy.

Peripheral neuropathy, axonal or demyelinating or both, is a rare complication of ara-C. Other reported toxicities include seizures, intracranial hypertension, reversible ocular toxicity (blurred vision, photophobia, burning eye pain, and blindness), bulbar and pseudobulbar palsy, Horner syndrome, the "painful legs, moving toes" syndrome, brachial plexopathy, reversible bilateral lateral rectus palsies, and acute aseptic meningitis (after intravenous injection). There is no treatment for any of the neurotoxic effects of ara-C but many patients recover spontaneously.

NELARABINE

Nelarabine is a purine analogue that is used in the treatment of T-cell acute lymphoblastic leukemia. Motor and/or sensory peripheral neuropathy occurs in approximately 20 percent of patients. Central neurotoxicity most frequently includes somnolence and fatigue around 1 week after drug administration. Other symptoms include headache, seizures, ataxia, tremor, amnesia, and paraplegia has also been reported. The deficits may not be reversible and so drug discontinuation is recommended.

GEMCITABINE

Gemcitabine is a deoxycytidine analogue. Sensory neuropathy occurs in approximately 10 percent of patients, and autonomic neuropathy has also been reported. Gemcitabine can also cause an acute myositis, which may be multifocal. Patients may present with painful symmetric weakness of the proximal muscles, with elevation of muscle enzymes in the blood. Symptoms resolve rapidly with discontinuation of the drug and with corticosteroids, and patients often do well with rechallenge. Gemcitabine can also cause a focal myositis hours to days after administration, in a field previously irradiated months or even years earlier, known as radiation recall. Many other agents have also been associated with radiation recall, including capecitabine and docetaxel.

Mictrotubule Agents

IXABEPILONE

Ixabepilone is an epothilone that stabilizes microtubules and induces apoptosis. Neuropathy is the most common neurotoxicity, occurring in more than 60 percent. It is predominantly sensory, but a mild motor neuropathy may occur infrequently. The sensory neuropathy is generally mild to moderate and improves with drug discontinuation, typically within 1 to 2 months. Alternatively, dose reduction can be employed if the severity is no worse than grade 2 by National Cancer Institute common toxicity criteria (NCI CTC), and stopped if it reaches grade 3. Less common neurologic side effects include headache and dizziness.

TAXANES

Paclitaxel and Docetaxel

Approximately 60 percent of patients receiving paclitaxel (Taxol) at $\leq 250\,\text{mg/m}^2$ dose develop paresthesias of the hands and feet that do not usually progress and may resolve despite continued therapy. The neuropathy is predominantly sensory and affects all modalities. Paclitaxel causes axonal damage, with secondary demyelination, probably reflecting damage to the cell body. A few patients also develop proximal muscle weakness that resolves; it is usually associated with peripheral neuropathy. Acute arthralgia and myalgia of the legs that curtail activity (and are sometimes mistaken for neuropathy) may occur 2 to 3 days after a course of paclitaxel. Encephalopathy and seizures may occur, but are rare. Docetaxel causes the same type of sensory neuropathy as paclitaxel but is less neurotoxic. Paclitaxel or docetaxel neuropathy is enhanced by prior or subsequent neurotoxic chemotherapy, particularly cisplatin or vinorelbine. To date there are insufficient human data to support any neuroprotective agents against taxane-induced (or any chemotherapy-induced) peripheral neuropathy.

Nab-paclitaxel

Nab-paclitaxel, an albumin-bound formulation of paclitaxel, has a higher incidence of grade 3 sensory neuropathy compared to standard paclitaxel. Patients may improve with discontinuation, and the drug may be rechallenged at a reduced dose.

Cabazitaxel

Cabazitaxel is a semisynthetic taxane that can be effective in docetaxel- and paclitaxel-resistant tumors. Peripheral neuropathy can occur but is rarely severe.

VINCRISTINE

Vincristine affects primarily the peripheral nerves but can also be toxic to the CNS, cranial nerves, and autonomic nervous system (Table 28-3). Vinorelbine and vinblastine are much less neurotoxic. A dose-limiting sensorimotor neuropathy appears in virtually all patients. The earliest complaint is tingling and paresthesias of the fingertips and later of the toes. Fine movements of the fingers and toes are often

TABLE 28-3 ■ The Spectrum of Vincristine Neurotoxicity

Toxic Effect	Subacute (1 day–2 weeks)	Intermediate (1–4 weeks)	Chronic (>3 weeks)
Peripheral neuropathy	Depressed Achilles reflex (universal)	Other tendon reflexes depressed, paresthesias	Sensory loss, weakness, "foot drop" gait
Myopathy?	Muscle pain, tenderness, (especially quadriceps); jaw pain	–	–
Autonomic neuropathy	Ileus with cramping abdominal pain	Constipation, urinary hesitancy, impotence, orthostatic hypotension	–
Cranial neuropathy (uncommon)	–	–	Optic atrophy; ptosis; sixth, seventh, and eighth cranial nerve dysfunction; hoarseness; dysphagia
"Central" toxicity	–	Seizure, SIADH	–

Modified from DeAngelis LM, Posner JB: Neurologic Complications of Cancer. 2nd Ed, Oxford University Press, New York, 2009.
SIADH, syndrome of inappropriate antidiuretic hormone secretion.

impaired. Muscle cramps, usually diurnal, affect arms and legs and may be the first symptom of neurotoxicity. Weakness, especially of the extensors of the feet and hands, is frequent. Foot drop is either unilateral or bilateral; unilateral foot drop is more common in patients who have lost weight and habitually sit with crossed legs, causing peroneal nerve compression. The weakness is usually tolerable, but rarely patients may become bedbound or quadriparetic, particularly if there is a pre-existing neuropathy. The sensory symptoms, weakness, and lost reflexes are reversible, but may require months to improve after the medication is stopped. Neurophysiologic studies show an axonal neuropathy.

Vincristine occasionally causes *focal neuropathies* of peripheral or cranial nerves.[1] The most common is oculomotor nerve involvement with ptosis. Less frequent is ophthalmoplegia with diplopia. The recurrent laryngeal nerve, facial nerve, acoustic nerve, and optic nerve are also affected occasionally. These various neuropathies may be bilateral or unilateral. Night blindness due to retinal damage has also been reported.

Autonomic neuropathy, characterized by colicky abdominal pain and constipation, occurs in almost all patients. Rarely, paralytic ileus develops and may be fatal. Prevention of constipation is essential, and all patients should receive a prophylactic bowel regimen. Other manifestations of autonomic dysfunction include bladder atony, impotence, and postural hypotension.

CNS toxicity may result from hyponatremia due to inappropriate secretion of antidiuretic hormone (SIADH). Encephalopathy and focal or generalized seizures not associated with SIADH have also been reported. Cortical blindness and other CNS signs, including athetosis, ataxia, and parkinsonian-like symptoms, usually reverse after treatment is discontinued.

DNA-Damaging Drugs

ALKYLATING AGENTS

Ifosfamide

High-dose ifosfamide has been associated with a reversible encephalopathy of varying severity, which is a dose-limiting adverse effect. The most common manifestations include confusion, stupor, and mutism, rarely evolving into coma; less common features include seizures, hallucinations, personality changes, blurred vision, extrapyramidal symptoms, cerebellar symptoms, and urinary incontinence. EEG abnormalities are found in 65 percent of patients, and nonconvulsive status epilepticus has been reported. Although death or permanent disability can occur, the encephalopathy is usually reversible and can be treated with methylene blue.[2]

Temozolomide

Temozolomide is standard chemotherapy for high-grade gliomas, and common side effects include nausea, fatigue, myelosuppression, and constipation. It rarely produces significant neurologic toxicity, though headaches may occur in up to 40 percent of patients.[3]

TABLE 28-4 ■ Neurotoxicity of Cisplatin

Common	
	Peripheral neuropathy (large fiber, sensory)
	Lhermitte sign
	Hearing loss (high frequency)
	Tinnitus
Uncommon	
	Encephalopathy
	Visual loss (retinal, optic nerve, cortical)
	Seizures
	Herniation (hydration-related)
	Electrolyte imbalance (Ca^{2+}, Mg^{2+}, Na^{+}, SIADH)
	Vestibular toxicity
	Autonomic neuropathy

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

PLATINUMS

The platinums (cisplatin, oxaliplatin, carboplatin) contain a heavy-metal moiety, and they therefore cause a peripheral neuropathy (Table 28-4).

Cisplatin

The peripheral neuropathy associated with cisplatin is dose dependent and usually follows cumulative doses exceeding 400 mg/m^2. It is characterized by numbness and tingling in the extremities, occasionally painful. The first symptoms usually appear during treatment, but typically they progress for several months after therapy is completed. The disorder affects predominantly the large sensory fibers; the deep tendon reflexes disappear and proprioception is lost, often resulting in ataxia. Pain and temperature sensation are spared, and power may be normal. The disorder may be confused with paraneoplastic sensory neuronopathy, which usually affects all sensory modalities equally. Nerve conduction studies reveal a sensory axonopathy. With discontinuation of the drug, the neuropathy may improve and the patient's condition may even return to normal after many months; however, many are left with permanent disability. Because maximal injury is not observed until months after discontinuation of the drug, dose adjustment is not possible to accommodate ongoing neural damage. There is no known treatment and there are insufficient data to support preventative pretreatment with acetylcysteine, acetyl-L-carnitine, amifostine, calcium and magnesium, growth factors, glutathione, Org 2766, oxcarbazepine, or vitamin E.[4]

Lhermitte sign appearing during or shortly after treatment with cisplatin suggests a transient demyelinating lesion in the posterior columns of the spinal cord. In some instances, patients may experience paresthesias down the arms when the upper limbs are abducted, suggesting that the brachial plexus may be demyelinated as well. Lhermitte sign resolves completely and is not associated with any permanent damage.

Muscle cramps not related to electrolyte imbalance (see later) are also common but, like Lhermitte sign, they usually resolve spontaneously.

Ototoxicity is caused by cisplatin. Hearing loss results from hair cell damage. The hearing loss is often subclinical and affects primarily the high-frequency range ($>$4,000 Hz). Tinnitus may precede hearing loss; rarely, high-dose cisplatin causes acute deafness. Animal studies suggest that prophylactic vitamin E or sodium thiosulfate may reduce this toxicity. Human data on amifostine are insufficient to support its use as an otoprotective agent.[4] Radiotherapy that encompasses the VIII nerve complex and hearing apparatus can enhance the ototoxicity of cisplatin regardless of the sequence of the two modalities. Vestibular toxicity is much less common than hearing loss.

Encephalopathy is rare following intravenous infusion, and is characterized by seizures and focal brain dysfunction, particularly cortical blindness, but the symptoms are usually reversible. Encephalopathy due to the drug must be differentiated from the electrolyte disorders that result from its administration. Vigorous hydration precedes cisplatin use and can lead to water intoxication and cerebral herniation. SIADH with hyponatremia and seizures may also occur.

Cisplatin has been implicated in late vascular toxicity, such as Raynaud phenomenon and the cardiac and cerebral infarction that sometimes follows multiagent chemotherapy. Vascular toxicity can also be subacute and occur within days to weeks of cisplatin administration. Other rare complications of cisplatin include irreversible myelopathy, taste disturbances, and a myasthenic syndrome.

Oxaliplatin

Oxaliplatin produces two types of peripheral neuropathy. The first occurs during or shortly after infusion and consists of paresthesias and dysesthesias of the hands, feet, and perioral region with jaw tightness. These symptoms are usually transient, may be triggered by cold, and may increase in both duration and severity with repeated drug administration. A pharyngolaryngeal dysesthesia syndrome accompanied by a sensation of shortness of breath without any objective evidence of respiratory distress has been described. Second, oxaliplatin can induce a peripheral sensory neuropathy similar to that seen with cisplatin. This neurotoxicity generally follows a cumulative dose greater than 540 mg/m^2 and is characterized by sensory ataxia, jaw pain, eye pain, ptosis, leg cramps, visual changes, and voice changes. Although reversible, these clinical findings may persist for months and require discontinuation of treatment. Less common neurologic complications include Lhermitte phenomenon and urinary retention; ototoxicity is rare.

Carboplatin

Carboplatin is less neurotoxic than cisplatin or oxaliplatin. Rare cases of peripheral neuropathy can occur but usually after high doses of carboplatin in patients treated with combinations of other cytotoxic agents.

Monoclonal Antibodies

BEVACIZUMAB

Bevacizumab is a monoclonal antibody that binds to and inhibits soluble vascular endothelial growth factor (VEGF), a mediator of tumor angiogenesis.[5] Patients treated with bevacizumab have an increased incidence of systemic hemorrhages as well as venous thromboembolism. Arterial thromboembolism is also seen, albeit uncommonly, including stroke and transient ischemic attacks (TIAs). The risk of CNS hemorrhage in patients with glioblastoma is under 4 percent, and comparable to the risk associated with the disease itself. Bevacizumab's most common side effect is hypertension, which rarely may lead to posterior reversible encephalopathy syndrome (PRES) in some patients. Symptoms include headache, lethargy, visual disturbances including blindness, and seizures. Symptoms usually resolve with discontinuation of the drug and with blood pressure control, though permanent deficits can occur. Rarely, bevacizumab may cause visual loss due to optic neuropathy.

RITUXIMAB

Rituximab is a monoclonal antibody directed against the CD20 antigen found on the surface of malignant and normal B lymphocytes. It is used to treat non-Hodgkin lymphoma as well as other disorders in which B lymphocytes are implicated in disease pathogenesis. Neurologic side effects are uncommon but can include myalgias, dizziness, and headache. Rituximab has also rarely been associated with PML.

Small-Molecule Inhibitors

BORTEZOMIB AND CARFILZOMIB

Bortezomib is a proteosome inhibitor that is primarily effective against multiple myeloma. It causes a cumulative dose-dependent painful peripheral neuropathy that is predominantly sensory, but is also associated with enhanced vulnerability to pressure-point neuropathies, such as peroneal nerve compression.[4] Symptoms usually improve, even without stopping treatment, but some patients are left with fixed deficits. Carfilzomib is a second-generation proteasome inhibitor; it causes a peripheral neuropathy that tends to be less severe than bortezomib.

SELUMETINIB

Selumetinib is a small-molecule inhibitor of MEK, a mitogen-activated protein kinase, used in clinical trials against solid tumors and melanoma. It can cause dropped head syndrome, a focal noninflammatory myopathy characterized by neck pain, neck extensor weakness, and elevated serum creatine kinase levels. ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) scan may show abnormal uptake in the affected muscles. Corticosteroids do not improve the condition, but discontinuation of the drug leads to recovery.

Retinoids

The retinoids are a group of compounds consisting of vitamin A and related derivatives. They are used to treat acute promyelocytic leukemia (APL) as well as other malignancies. Headaches may occur, sometimes in association with intracranial hypertension, but headaches may occur independently as well. There may be an increased risk of suicide and depression in patients treated with retinoids, although this is currently unclear.

Immunotherapy

The term *cancer immunotherapy* encompasses a variety of different treatment strategies designed to harness the power of the body's own immune system and alter it to target cancer cells more effectively for therapeutic purposes. While immunotherapy has revolutionized cancer care for many patients, these therapies have been associated with several different and novel neurotoxicities. As the number of available agents grows and the number of approved indications grows as well, vigilance is necessary for the detection of neurotoxicity, as early detection and management often mitigate toxicity severity and duration. Although different immunotherapy strategies exist, the two main treatments discussed here are with the checkpoint inhibitors (CPIs) and chimeric antigen receptor (CAR) T cells.

CHECKPOINT INHIBITORS

Treatment with CPIs has improved the outcome of patients with a variety of cancers. They work by targeting normal checkpoints in the immune system that would typically suppress an immune response. Cancers often find ways to exploit these immunosuppressive mechanisms, and CPIs aim to block these inhibitory pathways, thereby "unleashing" the immune system to attack the cancer. Approved therapies include those that target the checkpoints cytotoxic T-lymphocyte-associated-4 (CTLA-4; ipilimumab and atezolizumab), programmed cell death protein 1 (PD-1; nivolumab and pembrolizumab), and its ligand on cancer cells (PD-L1; durvalumab, avelumab, and cemiplimab).

Neurologic toxicities with these drugs are similar across the entire class and are discussed in aggregate. Neurologic toxicities are uncommon, occurring in 1 to 5 percent of patients treated with CPIs, but may be severe. Because of the mechanism of action of these drugs, their side effects are unlike those seen with other chemotherapies. Toxicities result from activation of the immune system having a secondary effect on the nervous system, and can include myasthenia gravis, Guillain–Barré syndrome, peripheral neuropathy, autonomic neuropathy, aseptic meningitis, encephalitis, transverse myelitis, vasculitis, myositis, and PRES.[6,7] Vigilance, early detection, and intervention with corticosteroids are key to treatment and possible reversibility of toxicity. It is often necessary to discontinue CPI treatment.

CHIMERIC ANTIGEN RECEPTOR T-CELL THERAPIES

CAR T-cell therapy has similarly transformed the care of many patients with hematologic malignancies and is under development for the treatment of solid tumors as well. CAR T cells utilize a technology whereby a patient's own T cells are removed, modified to recognize a specific cancer cell target, expanded, and then infused back into the patient. CAR T cells offer a unique therapeutic approach for patients, but also may cause unique toxicities, including the cytokine release syndrome (CRS) and a specific form of neurologic toxicity, described here.

CRS is the result of an overly robust immune activation due to supraphysiologic elevation of cytokines.[8] Encephalopathy may accompany the systemic manifestations of CRS, such as fever, hypotension, nausea, and chills, which typically occur a few hours to a week after CAR infusion. Separately from CRS, patients may develop a specific CAR T-cell–related neurotoxicity which may be severe, occurs either during or after CRS, and is the second major adverse event seen with CAR T-cell therapy. Although much of the toxicity is self-limited and reversible, it can be severe and, rarely, fatal. As the number of cellular therapeutic products has increased (e.g., bispecific antibodies), the neurotoxicity associated with these immune modulators is now referred to as immune effector cell-associated neurologic syndrome (ICANS).

The most common neurologic symptoms include encephalopathy, aphasia, delirium, tremor, seizures, and, in rare cases, a potentially fatal, rapidly progressive cerebral edema.[9] The syndrome may also include headache, lethargy, difficulty concentrating, anxiety, sleep disorder, dizziness, ataxia, and motor dysfunction. As with CPI neurotoxicity, vigilance and early detection are key to successful treatment. Certified CAR T-cell centers have a clear algorithm to manage such toxicity including with corticosteroids, reversing agents, and "suicide switch" activating compounds.

Intrathecal Chemotherapy

Chemotherapy is sometimes given directly into the subarachnoid space as part of treatment for or prophylaxis against leptomeningeal metastases. It can either be injected into the lumbar thecal sac via lumbar puncture or into the lateral ventricle through an Ommaya reservoir. Intrathecal chemotherapy is contraindicated in patients who have elevated intracranial pressure (ICP). Increased ICP may cause plateau waves, which consist of waves of elevated ICP associated with transient neurologic symptoms such as visual changes, leg buckling, vertigo, or loss of consciousness in the setting of positional change or Valsalva maneuver. In patients with elevated ICP, intrathecally administered chemotherapy will not circulate properly through the CSF and may accumulate in the ventricle, causing toxicity when administered through an Ommaya reservoir.
